About the pagination of this eBook

This eBook contains a multi-volume set.

To navigate this eBook by page number, you will need to use the volume number and the page number, separated by a hyphen.

For example, to go to page 5 of volume 1, type “1-5” in the Go box at the bottom of the screen and click "Go."

To go to page 5 of volume 2, type “2-5”… and so forth.

Quantitative Methods

Study Session 1 **Quantitative Methods (1)** 3

Reading 1 **The Time Value of Money** 5

Introduction 5
Interest Rates 6
Future Value of a Single Cash Flow (Lump Sum) 8
Non-Annual Compounding (Future Value) 13
Continuous Compounding, Stated and Effective Rates 15
  Stated and Effective Rates 16
Future Value of a Series of Cash Flows, Future Value Annuities 17
  Equal Cash Flows—Ordinary Annuity 17
  Unequal Cash Flows 19
Present Value of a Single Cash Flow (Lump Sum) 20
Non-Annual Compounding (Present Value) 22
Present Value of a Series of Equal Cash Flows (Annuities) and Unequal Cash Flows 23
  The Present Value of a Series of Equal Cash Flows 24
  The Present Value of a Series of Unequal Cash Flows 28
Present Value of a Perpetuity and Present Values Indexed at Times other than t=0 29
  Present Values Indexed at Times Other than $t = 0$ 30
Solving for Interest Rates, Growth Rates, and Number of Periods 32
  Solving for Interest Rates and Growth Rates 32
  Solving for the Number of Periods 35
Solving for Size of Annuity Payments (Combining Future Value and Present Value Annuities) 36
Present Value and Future Value Equivalence, Additivity Principle 39
  The Cash Flow Additivity Principle 41
Summary 42
Practice Problems 44
Solutions 49

O indicates an optional segment

Reading 2 **Organizing, Visualizing, and Describing Data** 63
Introduction 64
Data Types 64
  Numerical versus Categorical Data 65
  Cross-Sectional versus Time-Series versus Panel Data 67
  Structured versus Unstructured Data 68
  Data Summarization 72
Organizing Data for Quantitative Analysis 72
Summarizing Data Using Frequency Distributions 75
Summarizing Data Using a Contingency Table 81
Data Visualization 86
  Histogram and Frequency Polygon 86
  Bar Chart 88
  Tree-Map 91
  Word Cloud 92
  Line Chart 93
  Scatter Plot 95
  Heat Map 99
  Guide to Selecting among Visualization Types 100
Measures of Central Tendency 103
  The Arithmetic Mean 103
  The Median 107
  The Mode 109
  Other Concepts of Mean 110
Quantiles 120
  Quartiles, Quintiles, Deciles, and Percentiles 120
  Quantiles in Investment Practice 126
Measures of Dispersion 126
  The Range 126
  The Mean Absolute Deviation 127
  Sample Variance and Sample Standard Deviation 128
Downside Deviation and Coefficient of Variation 131
  Coefficient of Variation 135
The Shape of the Distributions 136
  The Shape of the Distributions: Kurtosis 139
Correlation between Two Variables 142
  Properties of Correlation 143
  Limitations of Correlation Analysis 146
Summary 149
Practice Problems 154
Solutions 166

Reading 3 **Probability Concepts** 175
Introduction, Probability Concepts, and Odds Ratios 176
  Probability, Expected Value, and Variance 176

Conditional and Joint Probability 181
Expected Value (Mean), Variance, and Conditional Measures of Expected Value and Variance 192
Expected Value, Variance, Standard Deviation, Covariances, and Correlations of Portfolio Returns 199
Covariance Given a Joint Probability Function 205
Bayes' Formula 208
    Bayes' Formula 208
Principles of Counting 214
Summary 220
Practice Problems 224
Solutions 230

Study Session 2 **Quantitative Methods (2)** 237

Reading 4 **Common Probability Distributions** 239
Introduction and Discrete Random Variables 240
    Discrete Random Variables 241
Discrete and Continuous Uniform Distribution 244
    Continuous Uniform Distribution 246
Binomial Distribution 250
Normal Distribution 257
    The Normal Distribution 257
    Probabilities Using the Normal Distribution 261
    Standardizing a Random Variable 263
    Probabilities Using the Standard Normal Distribution 263
Applications of the Normal Distribution 265
Lognormal Distribution and Continuous Compounding 269
    The Lognormal Distribution 269
    Continuously Compounded Rates of Return 272
Student's *t*-, Chi-Square, and *F*-Distributions 275
    Student's *t*-Distribution 275
    Chi-Square and *F*-Distribution 277
Monte Carlo Simulation 282
Summary 288
Practice Problems 292
Solutions 299

Reading 5 **Sampling and Estimation** 305
Introduction 306
Sampling Methods 306
    Simple Random Sampling 307
    Stratified Random Sampling 308
    Cluster Sampling 309
    Non-Probability Sampling 310
    Sampling from Different Distributions 315
Distribution of the Sample Mean and the Central Limit Theorem 316
    The Central Limit Theorem 317
    Standard Error of the Sample Mean 319

Point Estimates of the Population Mean 322
    Point Estimators 322
Confidence Intervals for the Population Mean and Selection of Sample Size 326
    Selection of Sample Size 332
Resampling 334
Data Snooping Bias, Sample Selection Bias, Look-Ahead Bias, and Time-Period Bias 338
    Data Snooping Bias 338
    Sample Selection Bias 340
    Look-Ahead Bias 342
    Time-Period Bias 342
Summary 344
Practice Problems 347
Solutions 351

Reading 6 **Hypothesis Testing** 357
Introduction 358
    Why Hypothesis Testing? 358
    Implications from a Sampling Distribution 359
The Process of Hypothesis Testing 360
    Stating the Hypotheses 361
    Two-Sided vs. One-Sided Hypotheses 361
    Selecting the Appropriate Hypotheses 362
Identify the Appropriate Test Statistic 363
    Test Statistics 363
    Identifying the Distribution of the Test Statistic 364
Specify the Level of Significance 364
State the Decision Rule 366
    Determining Critical Values 367
    Decision Rules and Confidence Intervals 368
    Collect the Data and Calculate the Test Statistic 369
Make a Decision 370
    Make a Statistical Decision 370
    Make an Economic Decision 370
    Statistically Significant but Not Economically Significant? 370
The Role of *p*-Values 371
Multiple Tests and Interpreting Significance 374
Tests Concerning a Single Mean 377
Test Concerning Differences between Means with Independent Samples 381
Test Concerning Differences between Means with Dependent Samples 384
Testing Concerning Tests of Variances (Chi-Square Test) 388
    Tests of a Single Variance 388
    Test Concerning the Equality of Two Variances (*F*-Test) 391
Parametric vs. Nonparametric Tests 396
    Uses of Nonparametric Tests 397
    Nonparametric Inference: Summary 397
Tests Concerning Correlation 398
    Parametric Test of a Correlation 399

    Tests Concerning Correlation: The Spearman Rank Correlation Coefficient 401
Test of Independence Using Contingency Table Data 404
Summary 409
Practice Problems 412
Solutions 422

Reading 7 **Introduction to Linear Regression** 431
Simple Linear Regression 431
Estimating the Parameters of a Simple Linear Regression 434
    The Basics of Simple Linear Regression 434
    Estimating the Regression Line 435
    Interpreting the Regression Coefficients 438
    Cross-Sectional vs. Time-Series Regressions 440
Assumptions of the Simple Linear Regression Model 443
    Assumption 1: Linearity 443
    Assumption 2: Homoskedasticity 445
    Assumption 3: Independence 447
    Assumption 4: Normality 448
Analysis of Variance 450
    Breaking down the Sum of Squares Total into Its Components 450
    Measures of Goodness of Fit 451
    ANOVA and Standard Error of Estimate in Simple Linear Regression 453
Hypothesis Testing of Linear Regression Coefficients 455
    Hypothesis Tests of the Slope Coefficient 455
    Hypothesis Tests of the Intercept 459
    Hypothesis Tests of Slope When Independent Variable Is an Indicator Variable 459
    Test of Hypotheses: Level of Significance and *p*-Values 461
Prediction Using Simple Linear Regression and Prediction Intervals 463
Functional Forms for Simple Linear Regression 467
    The Log-Lin Model 468
    The Lin-Log Model 469
    The Log-Log Model 470
    Selecting the Correct Functional Form 472
Summary 474
Practice Problems 477
Solutions 490

How to Use the CFA Program Curriculum

Congratulations on your decision to enter the Chartered Financial Analyst (CFA®) Program. This exciting and rewarding program of study reflects your desire to become a serious investment professional. You are embarking on a program noted for its high ethical standards and the breadth of knowledge, skills, and abilities (competencies) it develops. Your commitment should be educationally and professionally rewarding.

The credential you seek is respected around the world as a mark of accomplishment and dedication. Each level of the program represents a distinct achievement in professional development. Successful completion of the program is rewarded with membership in a prestigious global community of investment professionals. CFA charterholders are dedicated to life-long learning and maintaining currency with the ever-changing dynamics of a challenging profession. CFA Program enrollment represents the first step toward a career-long commitment to professional education.

The CFA exam measures your mastery of the core knowledge, skills, and abilities required to succeed as an investment professional. These core competencies are the basis for the Candidate Body of Knowledge (CBOK™). The CBOK consists of four components:

- A broad outline that lists the major CFA Program topic areas (www.cfainstitute.org/programs/cfa/curriculum/cbok);
- Topic area weights that indicate the relative exam weightings of the top-level topic areas (www.cfainstitute.org/programs/cfa/curriculum);
- Learning outcome statements (LOS) that advise candidates about the specific knowledge, skills, and abilities they should acquire from readings covering a topic area (LOS are provided in candidate study sessions and at the beginning of each reading); and
- CFA Program curriculum that candidates receive upon exam registration.

Therefore, the key to your success on the CFA exams is studying and understanding the CBOK. The following sections provide background on the CBOK, the organization of the curriculum, features of the curriculum, and tips for designing an effective personal study program.

BACKGROUND ON THE CBOK

CFA Program is grounded in the practice of the investment profession. CFA Institute performs a continuous practice analysis with investment professionals around the world to determine the competencies that are relevant to the profession, beginning with the Global Body of Investment Knowledge (GBIK®). Regional expert panels and targeted surveys are conducted annually to verify and reinforce the continuous feedback about the GBIK. The practice analysis process ultimately defines the CBOK. The CBOK reflects the competencies that are generally accepted and applied by investment professionals. These competencies are used in practice in a generalist context and are expected to be demonstrated by a recently qualified CFA charterholder.

© 2021 CFA Institute. All rights reserved.

The CFA Institute staff—in conjunction with the Education Advisory Committee and Curriculum Level Advisors, who consist of practicing CFA charterholders—designs the CFA Program curriculum in order to deliver the CBOK to candidates. The exams, also written by CFA charterholders, are designed to allow you to demonstrate your mastery of the CBOK as set forth in the CFA Program curriculum. As you structure your personal study program, you should emphasize mastery of the CBOK and the practical application of that knowledge. For more information on the practice analysis, CBOK, and development of the CFA Program curriculum, please visit www.cfainstitute.org.

ORGANIZATION OF THE CURRICULUM

The Level I CFA Program curriculum is organized into 10 topic areas. Each topic area begins with a brief statement of the material and the depth of knowledge expected. It is then divided into one or more study sessions. These study sessions should form the basic structure of your reading and preparation. Each study session includes a statement of its structure and objective and is further divided into assigned readings. An outline illustrating the organization of these study sessions can be found at the front of each volume of the curriculum.

The readings are commissioned by CFA Institute and written by content experts, including investment professionals and university professors. Each reading includes LOS and the core material to be studied, often a combination of text, exhibits, and in-text examples and questions. End of Reading Questions (EORQs) followed by solutions help you understand and master the material. The LOS indicate what you should be able to accomplish after studying the material. The LOS, the core material, and the EORQs are dependent on each other, with the core material and EORQs providing context for understanding the scope of the LOS and enabling you to apply a principle or concept in a variety of scenarios.

The entire readings, including the EORQs, are the basis for all exam questions and are selected or developed specifically to teach the knowledge, skills, and abilities reflected in the CBOK.

You should use the LOS to guide and focus your study because each exam question is based on one or more LOS and the core material and practice problems associated with the LOS. As a candidate, you are responsible for the entirety of the required material in a study session.

We encourage you to review the information about the LOS on our website (www.cfainstitute.org/programs/cfa/curriculum/study-sessions), including the descriptions of LOS "command words" on the candidate resources page at www.cfainstitute.org.

FEATURES OF THE CURRICULUM

End of Reading Questions/Solutions *All End of Reading Questions (EORQs) as well as their solutions are part of the curriculum and are required material for the exam.* In addition to the in-text examples and questions, these EORQs help demonstrate practical applications and reinforce your understanding of the concepts presented. Some of these EORQs are adapted from past CFA exams and/or may serve as a basis for exam questions.

Glossary For your convenience, each volume includes a comprehensive Glossary. Throughout the curriculum, a **bolded** word in a reading denotes a term defined in the Glossary.

Note that the digital curriculum that is included in your exam registration fee is searchable for key words, including Glossary terms.

LOS Self-Check We have inserted checkboxes next to each LOS that you can use to track your progress in mastering the concepts in each reading.

Source Material The CFA Institute curriculum cites textbooks, journal articles, and other publications that provide additional context or information about topics covered in the readings. As a candidate, you are not responsible for familiarity with the original source materials cited in the curriculum.

Note that some readings may contain a web address or URL. The referenced sites were live at the time the reading was written or updated but may have been deactivated since then.

Some readings in the curriculum cite articles published in the *Financial Analysts Journal®*, which is the flagship publication of CFA Institute. Since its launch in 1945, the *Financial Analysts Journal* has established itself as the leading practitioner-oriented journal in the investment management community. Over the years, it has advanced the knowledge and understanding of the practice of investment management through the publication of peer-reviewed practitioner-relevant research from leading academics and practitioners. It has also featured thought-provoking opinion pieces that advance the common level of discourse within the investment management profession. Some of the most influential research in the area of investment management has appeared in the pages of the *Financial Analysts Journal*, and several Nobel laureates have contributed articles.

Candidates are not responsible for familiarity with *Financial Analysts Journal* articles that are cited in the curriculum. But, as your time and studies allow, we strongly encourage you to begin supplementing your understanding of key investment management issues by reading this, and other, CFA Institute practice-oriented publications through the Research & Analysis webpage (www.cfainstitute.org/en/research).

Errata The curriculum development process is rigorous and includes multiple rounds of reviews by content experts. Despite our efforts to produce a curriculum that is free of errors, there are times when we must make corrections. Curriculum errata are periodically updated and posted by exam level and test date online (www.cfainstitute.org/en/programs/submit-errata). If you believe you have found an error in the curriculum, you can submit your concerns through our curriculum errata reporting process found at the bottom of the Curriculum Errata webpage.

DESIGNING YOUR PERSONAL STUDY PROGRAM

Create a Schedule An orderly, systematic approach to exam preparation is critical. You should dedicate a consistent block of time every week to reading and studying. Complete all assigned readings and the associated problems and solutions in each study session. Review the LOS both before and after you study each reading to ensure that

you have mastered the applicable content and can demonstrate the knowledge, skills, and abilities described by the LOS and the assigned reading. Use the LOS self-check to track your progress and highlight areas of weakness for later review.

Successful candidates report an average of more than 300 hours preparing for each exam. Your preparation time will vary based on your prior education and experience, and you will probably spend more time on some study sessions than on others.

You should allow ample time for both in-depth study of all topic areas and additional concentration on those topic areas for which you feel the least prepared.

CFA INSTITUTE LEARNING ECOSYSTEM (LES)

As you prepare for your exam, we will email you important exam updates, testing policies, and study tips. Be sure to read these carefully.

Your exam registration fee includes access to the CFA Program Learning Ecosystem (LES). This digital learning platform provides access, even offline, to all of the readings and End of Reading Questions found in the print curriculum organized as a series of shorter online lessons with associated EORQs. This tool is your one-stop location for all study materials, including practice questions and mock exams.

The LES provides the following supplemental study tools:

Structured and Adaptive Study Plans The LES offers two ways to plan your study through the curriculum. The first is a structured plan that allows you to move through the material in the way that you feel best suits your learning. The second is an adaptive study plan based on the results of an assessment test that uses actual practice questions.

Regardless of your chosen study path, the LES tracks your level of proficiency in each topic area and presents you with a dashboard of where you stand in terms of proficiency so that you can allocate your study time efficiently.

Flashcards and Game Center The LES offers all the Glossary terms as Flashcards and tracks correct and incorrect answers. Flashcards can be filtered both by curriculum topic area and by action taken—for example, answered correctly, unanswered, and so on. These Flashcards provide a flexible way to study Glossary item definitions.

The Game Center provides several engaging ways to interact with the Flashcards in a game context. Each game tests your knowledge of the Glossary terms a in different way. Your results are scored and presented, along with a summary of candidates with high scores on the game, on your Dashboard.

Discussion Board The Discussion Board within the LES provides a way for you to interact with other candidates as you pursue your study plan. Discussions can happen at the level of individual lessons to raise questions about material in those lessons that you or other candidates can clarify or comment on. Discussions can also be posted at the level of topics or in the initial Welcome section to connect with other candidates in your area.

Practice Question Bank The LES offers access to a question bank of hundreds of practice questions that are in addition to the End of Reading Questions. These practice questions, only available on the LES, are intended to help you assess your mastery of individual topic areas as you progress through your studies. After each practice question, you will receive immediate feedback noting the correct response and indicating the relevant assigned reading so you can identify areas of weakness for further study.

Mock Exams The LES also includes access to three-hour Mock Exams that simulate the morning and afternoon sessions of the actual CFA exam. These Mock Exams are intended to be taken after you complete your study of the full curriculum and take practice questions so you can test your understanding of the curriculum and your readiness for the exam. If you take these Mock Exams within the LES, you will receive feedback afterward that notes the correct responses and indicates the relevant assigned readings so you can assess areas of weakness for further study. We recommend that you take Mock Exams during the final stages of your preparation for the actual CFA exam. For more information on the Mock Exams, please visit www.cfainstitute.org.

PREP PROVIDERS

You may choose to seek study support outside CFA Institute in the form of exam prep providers. After your CFA Program enrollment, you may receive numerous solicitations for exam prep courses and review materials. When considering a prep course, make sure the provider is committed to following the CFA Institute guidelines and high standards in its offerings.

Remember, however, that there are no shortcuts to success on the CFA exams; reading and studying the CFA Program curriculum *is* the key to success on the exam. The CFA Program exams reference only the CFA Institute assigned curriculum; no prep course or review course materials are consulted or referenced.

SUMMARY

Every question on the CFA exam is based on the content contained in the required readings and on one or more LOS. Frequently, an exam question is based on a specific example highlighted within a reading or on a specific practice problem and its solution. To make effective use of the CFA Program curriculum, please remember these key points:

1. All pages of the curriculum are required reading for the exam.
2. All questions, problems, and their solutions are part of the curriculum and are required study material for the exam. These questions are found at the end of the readings in the print versions of the curriculum. In the LES, these questions appear directly after the lesson with which they are associated. The LES provides immediate feedback on your answers and tracks your performance on these questions throughout your study.
3. We strongly encourage you to use the CFA Program Learning Ecosystem. In addition to providing access to all the curriculum material, including EORQs, in the form of shorter, focused lessons, the LES offers structured and adaptive study planning, a Discussion Board to communicate with other candidates, Flashcards, a Game Center for study activities, a test bank of practice questions, and online Mock Exams. Other supplemental study tools, such as eBook and PDF versions of the print curriculum, and additional candidate resources are available at www.cfainstitute.org.
4. Using the study planner, create a schedule and commit sufficient study time to cover the study sessions. You should also plan to review the materials, answer practice questions, and take Mock Exams.
5. Some of the concepts in the study sessions may be superseded by updated rulings and/or pronouncements issued after a reading was published. Candidates are expected to be familiar with the overall analytical framework contained in the assigned readings. Candidates are not responsible for changes that occur after the material was written.

FEEDBACK

At CFA Institute, we are committed to delivering a comprehensive and rigorous curriculum for the development of competent, ethically grounded investment professionals. We rely on candidate and investment professional comments and feedback as we work to improve the curriculum, supplemental study tools, and candidate resources.

Please send any comments or feedback to info@cfainstitute.org. You can be assured that we will review your suggestions carefully. Ongoing improvements in the curriculum will help you prepare for success on the upcoming exams and for a lifetime of learning as a serious investment professional.

Quantitative Methods

STUDY SESSIONS

Study Session 1	Quantitative Methods (1)
Study Session 2	Quantitative Methods (2)

TOPIC LEVEL LEARNING OUTCOME

The candidate should be able to explain and demonstrate the use of time value of money, data collection and analysis, elementary statistics, probability theory, probability distribution theory, sampling and estimation, hypothesis testing, and simple linear regression in financial decision-making.

The quantitative concepts and applications that follow are fundamental to financial analysis and are used throughout the CFA Program curriculum. Quantitative methods are used widely in securities and risk analysis and in corporate finance to value capital projects and select investments. Descriptive statistics provide the tools to characterize and assess risk and return and other important financial or economic variables. Probability theory, sampling and estimation, and hypothesis testing support investment and risk decision making in the presence of uncertainty. Simple linear regression helps to understand the relationship between two variables and how to make predictions.

QUANTITATIVE METHODS

STUDY SESSION

1

Quantitative Methods (1)

This study session introduces quantitative concepts and techniques used in financial analysis and investment decision making. The time value of money and discounted cash flow analysis form the basis for cash flow and security valuation. Methods for organizing and visualizing data are presented; these key skills are required for effectively performing financial analysis. Descriptive statistics used for conveying important data attributes such as central tendency, location, and dispersion are also presented. Characteristics of return distributions such as symmetry, skewness, and kurtosis are also introduced. Finally, all investment forecasts and decisions involve uncertainty: Therefore, probability theory and its application quantifying risk in investment decision making is considered.

READING ASSIGNMENTS

Reading 1	The Time Value of Money by Richard A. DeFusco, PhD, CFA, Dennis W. McLeavey, DBA, CFA, Jerald E. Pinto, PhD, CFA, and David E. Runkle, PhD, CFA
Reading 2	Organizing, Visualizing, and Describing Data by Pamela Peterson Drake, PhD, CFA, and Jian Wu, PhD
Reading 3	Probability Concepts by Richard A. DeFusco, PhD, CFA, Dennis W. McLeavey, DBA, CFA, Jerald E. Pinto, PhD, CFA, and David E. Runkle, PhD, CFA

© 2021 CFA Institute. All rights reserved.

READING

1

The Time Value of Money

by Richard A. DeFusco, PhD, CFA, Dennis W. McLeavey, DBA, CFA, Jerald E. Pinto, PhD, CFA, and David E. Runkle, PhD, CFA

Richard A. DeFusco, PhD, CFA, is at the University of Nebraska-Lincoln (USA). Dennis W. McLeavey, DBA, CFA, is at the University of Rhode Island (USA). Jerald E. Pinto, PhD, CFA, is at CFA Institute (USA). David E. Runkle, PhD, CFA, is at Jacobs Levy Equity Management (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** interpret interest rates as required rates of return, discount rates, or opportunity costs;
☐	**b.** explain an interest rate as the sum of a real risk-free rate and premiums that compensate investors for bearing distinct types of risk;
☐	**c.** calculate and interpret the effective annual rate, given the stated annual interest rate and the frequency of compounding;
☐	**d.** calculate the solution for time value of money problems with different frequencies of compounding;
☐	**e.** calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;
☐	**f.** demonstrate the use of a time line in modeling and solving time value of money problems.

INTRODUCTION

1

As individuals, we often face decisions that involve saving money for a future use, or borrowing money for current consumption. We then need to determine the amount we need to invest, if we are saving, or the cost of borrowing, if we are shopping for a loan. As investment analysts, much of our work also involves evaluating transactions with present and future cash flows. When we place a value on any security, for example, we are attempting to determine the worth of a stream of future cash flows. To carry out all the above tasks accurately, we must understand the mathematics of time value of money problems. Money has time value in that individuals value a given

© 2019 CFA Institute. All rights reserved.

amount of money more highly the earlier it is received. Therefore, a smaller amount of money now may be equivalent in value to a larger amount received at a future date. The **time value of money** as a topic in investment mathematics deals with equivalence relationships between cash flows with different dates. Mastery of time value of money concepts and techniques is essential for investment analysts.

The reading[1] is organized as follows: Section 2 introduces some terminology used throughout the reading and supplies some economic intuition for the variables we will discuss. Sections 3–5 tackle the problem of determining the worth at a future point in time of an amount invested today. Section 6 addresses the future worth of a series of cash flows. These two sections provide the tools for calculating the equivalent value at a future date of a single cash flow or series of cash flows. Sections 7–10 discuss the equivalent value today of a single future cash flow and a series of future cash flows, respectively. In Sections 11–13, we explore how to determine other quantities of interest in time value of money problems.

2

INTEREST RATES

a interpret interest rates as required rates of return, discount rates, or opportunity costs;

b explain an interest rate as the sum of a real risk-free rate and premiums that compensate investors for bearing distinct types of risk;

In this reading, we will continually refer to interest rates. In some cases, we assume a particular value for the interest rate; in other cases, the interest rate will be the unknown quantity we seek to determine. Before turning to the mechanics of time value of money problems, we must illustrate the underlying economic concepts. In this section, we briefly explain the meaning and interpretation of interest rates.

Time value of money concerns equivalence relationships between cash flows occurring on different dates. The idea of equivalence relationships is relatively simple. Consider the following exchange: You pay \$10,000 today and in return receive \$9,500 today. Would you accept this arrangement? Not likely. But what if you received the \$9,500 today and paid the \$10,000 one year from now? Can these amounts be considered equivalent? Possibly, because a payment of \$10,000 a year from now would probably be worth less to you than a payment of \$10,000 today. It would be fair, therefore, to **discount** the \$10,000 received in one year; that is, to cut its value based on how much time passes before the money is paid. An **interest rate**, denoted r, is a rate of return that reflects the relationship between differently dated cash flows. If \$9,500 today and \$10,000 in one year are equivalent in value, then \$10,000 – \$9,500 = \$500 is the required compensation for receiving \$10,000 in one year rather than now. The interest rate—the required compensation stated as a rate of return—is \$500/\$9,500 = 0.0526 or 5.26 percent.

Interest rates can be thought of in three ways. First, they can be considered required rates of return—that is, the minimum rate of return an investor must receive in order to accept the investment. Second, interest rates can be considered discount rates. In the example above, 5.26 percent is that rate at which we discounted the \$10,000 future amount to find its value today. Thus, we use the terms "interest rate" and "discount rate" almost interchangeably. Third, interest rates can be considered opportunity costs. An **opportunity cost** is the value that investors forgo by choosing a particular course of action. In the example, if the party who supplied $9,500 had instead decided to spend it today, he would have forgone earning 5.26 percent on the money. So we can view 5.26 percent as the opportunity cost of current consumption.

---

[1] Examples in this reading and other readings in quantitative methods at Level I were updated in 2018 by Professor Sanjiv Sabherwal of the University of Texas, Arlington.

Economics tells us that interest rates are set in the marketplace by the forces of supply and demand, where investors are suppliers of funds and borrowers are demanders of funds. Taking the perspective of investors in analyzing market-determined interest rates, we can view an interest rate r as being composed of a real risk-free interest rate plus a set of four premiums that are required returns or compensation for bearing distinct types of risk:

$$r = \text{Real risk-free interest rate} + \text{Inflation premium} + \text{Default risk premium} + \text{Liquidity premium} + \text{Maturity premium}$$

- The **real risk-free interest rate** is the single-period interest rate for a completely risk-free security if no inflation were expected. In economic theory, the real risk-free rate reflects the time preferences of individuals for current versus future real consumption.
- The **inflation premium** compensates investors for expected inflation and reflects the average inflation rate expected over the maturity of the debt. Inflation reduces the purchasing power of a unit of currency—the amount of goods and services one can buy with it. The sum of the real risk-free interest rate and the inflation premium is the **nominal risk-free interest rate**.[2] Many countries have governmental short-term debt whose interest rate can be considered to represent the nominal risk-free interest rate in that country. The interest rate on a 90-day US Treasury bill (T-bill), for example, represents the nominal risk-free interest rate over that time horizon.[3] US T-bills can be bought and sold in large quantities with minimal transaction costs and are backed by the full faith and credit of the US government.
- The **default risk premium** compensates investors for the possibility that the borrower will fail to make a promised payment at the contracted time and in the contracted amount.
- The **liquidity premium** compensates investors for the risk of loss relative to an investment's fair value if the investment needs to be converted to cash quickly. US T-bills, for example, do not bear a liquidity premium because large amounts can be bought and sold without affecting their market price. Many bonds of small issuers, by contrast, trade infrequently after they are issued; the interest rate on such bonds includes a liquidity premium reflecting the relatively high costs (including the impact on price) of selling a position.
- The **maturity premium** compensates investors for the increased sensitivity of the market value of debt to a change in market interest rates as maturity is extended, in general (holding all else equal). The difference between the interest

---

[2] Technically, 1 plus the nominal rate equals the product of 1 plus the real rate and 1 plus the inflation rate. As a quick approximation, however, the nominal rate is equal to the real rate plus an inflation premium. In this discussion we focus on approximate additive relationships to highlight the underlying concepts.

[3] Other developed countries issue securities similar to US Treasury bills. The French government issues BTFs or negotiable fixed-rate discount Treasury bills (*Bons du Trésor à taux fixe et à intérêts précomptés*) with maturities of up to one year. The Japanese government issues a short-term Treasury bill with maturities of 6 and 12 months. The German government issues at discount both Treasury financing paper (*Finanzierungsschätze des Bundes* or, for short, *Schätze*) and Treasury discount paper (*Bubills*) with maturities up to 24 months. In the United Kingdom, the British government issues gilt-edged Treasury bills with maturities ranging from 1 to 364 days. The Canadian government bond market is closely related to the US market; Canadian Treasury bills have maturities of 3, 6, and 12 months.

rate on longer-maturity, liquid Treasury debt and that on short-term Treasury debt reflects a positive maturity premium for the longer-term debt (and possibly different inflation premiums as well).

Using this insight into the economic meaning of interest rates, we now turn to a discussion of solving time value of money problems, starting with the future value of a single cash flow.

3

FUTURE VALUE OF A SINGLE CASH FLOW (LUMP SUM)

e calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;

f demonstrate the use of a time line in modeling and solving time value of money problems.

In this section, we introduce time value associated with a single cash flow or lump-sum investment. We describe the relationship between an initial investment or **present value (PV)**, which earns a rate of return (the interest rate per period) denoted as r, and its **future value (FV)**, which will be received N years or periods from today.

The following example illustrates this concept. Suppose you invest \$100 (PV = \$100) in an interest-bearing bank account paying 5 percent annually. At the end of the first year, you will have the \$100 plus the interest earned, 0.05 × \$100 = \$5, for a total of \$105. To formalize this one-period example, we define the following terms:

PV = present value of the investment
FV_N = future value of the investment N periods from today
r = rate of interest per period

For $N = 1$, the expression for the future value of amount PV is

$$FV_1 = PV(1 + r) \quad (1)$$

For this example, we calculate the future value one year from today as $FV_1 = \$100(1.05) = \$105$.

Now suppose you decide to invest the initial \$100 for two years with interest earned and credited to your account annually (annual compounding). At the end of the first year (the beginning of the second year), your account will have \$105, which you will leave in the bank for another year. Thus, with a beginning amount of \$105 (PV = \$105), the amount at the end of the second year will be \$105(1.05) = \$110.25. Note that the \$5.25 interest earned during the second year is 5 percent of the amount invested at the beginning of Year 2.

Another way to understand this example is to note that the amount invested at the beginning of Year 2 is composed of the original \$100 that you invested plus the \$5 interest earned during the first year. During the second year, the original principal again earns interest, as does the interest that was earned during Year 1. You can see how the original investment grows:

Original investment	\$100.00
Interest for the first year (\$100 × 0.05)	5.00
Interest for the second year based on original investment (\$100 × 0.05)	5.00
Interest for the second year based on interest earned in the first year (0.05 × \$5.00 interest on interest)	0.25
Total	\$110.25

The \$5 interest that you earned each period on the \$100 original investment is known as **simple interest** (the interest rate times the principal). **Principal** is the amount of funds originally invested. During the two-year period, you earn \$10 of simple interest. The extra \$0.25 that you have at the end of Year 2 is the interest you earned on the Year 1 interest of \$5 that you reinvested.

The interest earned on interest provides the first glimpse of the phenomenon known as **compounding**. Although the interest earned on the initial investment is important, for a given interest rate it is fixed in size from period to period. The compounded interest earned on reinvested interest is a far more powerful force because, for a given interest rate, it grows in size each period. The importance of compounding increases with the magnitude of the interest rate. For example, \$100 invested today would be worth about \$13,150 after 100 years if compounded annually at 5 percent, but worth more than \$20 million if compounded annually over the same time period at a rate of 13 percent.

To verify the \$20 million figure, we need a general formula to handle compounding for any number of periods. The following general formula relates the present value of an initial investment to its future value after N periods:

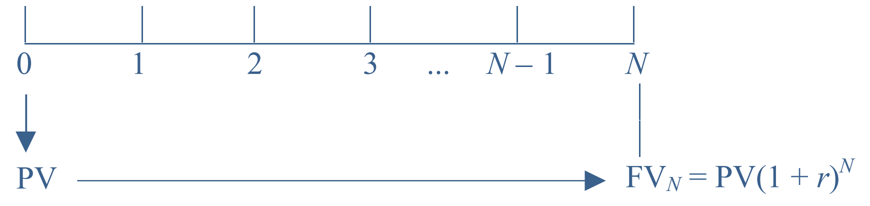
$$FV_N = PV(1 + r)^N \tag{2}$$

where r is the stated interest rate per period and N is the number of compounding periods. In the bank example, $FV_2 = \$100(1 + 0.05)^2 = \$110.25$. In the 13 percent investment example, $FV_{100} = \$100(1.13)^{100} = \$20{,}316{,}287.42$.

The most important point to remember about using the future value equation is that the stated interest rate, r, and the number of compounding periods, N, must be compatible. Both variables must be defined in the same time units. For example, if N is stated in months, then r should be the one-month interest rate, unannualized.

A time line helps us to keep track of the compatibility of time units and the interest rate per time period. In the time line, we use the time index t to represent a point in time a stated number of periods from today. Thus the present value is the amount available for investment today, indexed as $t = 0$. We can now refer to a time N periods from today as $t = N$. The time line in Figure 1 shows this relationship.

Figure 1 The Relationship between an Initial Investment, PV, and Its Future Value, FV



In Figure 1, we have positioned the initial investment, PV, at $t = 0$. Using Equation 2, we move the present value, PV, forward to $t = N$ by the factor $(1 + r)^N$. This factor is called a future value factor. We denote the future value on the time line as FV and position it at $t = N$. Suppose the future value is to be received exactly 10 periods from today's date ($N = 10$). The present value, PV, and the future value, FV, are separated in time through the factor $(1 + r)^{10}$.

The fact that the present value and the future value are separated in time has important consequences:

- We can add amounts of money only if they are indexed at the same point in time.
- For a given interest rate, the future value increases with the number of periods.
- For a given number of periods, the future value increases with the interest rate.

To better understand these concepts, consider three examples that illustrate how to apply the future value formula.

EXAMPLE 1

The Future Value of a Lump Sum with Interim Cash Reinvested at the Same Rate

You are the lucky winner of your state's lottery of \$5 million after taxes. You invest your winnings in a five-year certificate of deposit (CD) at a local financial institution. The CD promises to pay 7 percent per year compounded annually. This institution also lets you reinvest the interest at that rate for the duration of the CD. How much will you have at the end of five years if your money remains invested at 7 percent for five years with no withdrawals?

Solution:

To solve this problem, compute the future value of the \$5 million investment using the following values in Equation 2:

$$\begin{aligned} \text{PV} &= \$5{,}000{,}000 \\ r &= 7\% = 0.07 \\ N &= 5 \\ \text{FV}_N &= \text{PV}(1 + r)^N \\ &= \$5{,}000{,}000(1.07)^5 \\ &= \$5{,}000{,}000(1.402552) \\ &= \$7{,}012{,}758.65 \end{aligned}$$

At the end of five years, you will have \$7,012,758.65 if your money remains invested at 7 percent with no withdrawals.

In this and most examples in this reading, note that the factors are reported at six decimal places but the calculations may actually reflect greater precision. For example, the reported 1.402552 has been rounded up from 1.40255173 (the calculation is actually carried out with more than eight decimal places of precision by the calculator or spreadsheet). Our final result reflects the higher number of decimal places carried by the calculator or spreadsheet.[4]

---

[4] We could also solve time value of money problems using tables of interest rate factors. Solutions using tabled values of interest rate factors are generally less accurate than solutions obtained using calculators or spreadsheets, so practitioners prefer calculators or spreadsheets.

EXAMPLE 2

The Future Value of a Lump Sum with No Interim Cash

An institution offers you the following terms for a contract: For an investment of ¥2,500,000, the institution promises to pay you a lump sum six years from now at an 8 percent annual interest rate. What future amount can you expect?

Solution:

Use the following data in Equation 2 to find the future value:

$$\begin{aligned}
\text{PV} &= ¥2{,}500{,}000\\
r &= 8\% = 0.08\\
N &= 6\\
\text{FV}_N &= \text{PV}(1+r)^N\\
&= ¥2{,}500{,}000(1.08)^6\\
&= ¥2{,}500{,}000(1.586874)\\
&= ¥3{,}967{,}186
\end{aligned}$$

You can expect to receive ¥3,967,186 six years from now.

Our third example is a more complicated future value problem that illustrates the importance of keeping track of actual calendar time.

EXAMPLE 3

The Future Value of a Lump Sum

A pension fund manager estimates that his corporate sponsor will make a \$10 million contribution five years from now. The rate of return on plan assets has been estimated at 9 percent per year. The pension fund manager wants to calculate the future value of this contribution 15 years from now, which is the date at which the funds will be distributed to retirees. What is that future value?

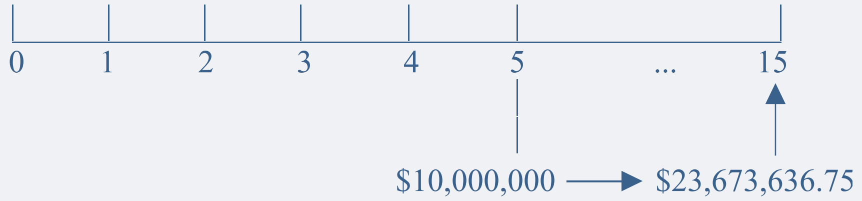
Solution:

By positioning the initial investment, PV, at $t = 5$, we can calculate the future value of the contribution using the following data in Equation 2:

$$\begin{aligned}
\text{PV} &= \$10 \text{ million}\\
r &= 9\% = 0.09\\
N &= 10\\
\text{FV}_N &= \text{PV}(1+r)^N\\
&= \$10{,}000{,}000(1.09)^{10}\\
&= \$10{,}000{,}000(2.367364)\\
&= \$23{,}673{,}636.75
\end{aligned}$$

This problem looks much like the previous two, but it differs in one important respect: its timing. From the standpoint of today ($t = 0$), the future amount of \$23,673,636.75 is 15 years into the future. Although the future value is 10 years from its present value, the present value of \$10 million will not be received for another five years.

Figure 2 The Future Value of a Lump Sum, Initial Investment Not at *t* = 0



As Figure 2 shows, we have followed the convention of indexing today as $t = 0$ and indexing subsequent times by adding 1 for each period. The additional contribution of \$10 million is to be received in five years, so it is indexed as $t = 5$ and appears as such in the figure. The future value of the investment in 10 years is then indexed at $t = 15$; that is, 10 years following the receipt of the \$10 million contribution at $t = 5$. Time lines like this one can be extremely useful when dealing with more-complicated problems, especially those involving more than one cash flow.

In a later section of this reading, we will discuss how to calculate the value today of the \$10 million to be received five years from now. For the moment, we can use Equation 2. Suppose the pension fund manager in Example 3 above were to receive \$6,499,313.86 today from the corporate sponsor. How much will that sum be worth at the end of five years? How much will it be worth at the end of 15 years?

$$\begin{aligned} \text{PV} &= \$6{,}499{,}313.86 \\ r &= 9\% = 0.09 \\ N &= 5 \\ \text{FV}_N &= \text{PV}(1+r)^N \\ &= \$6{,}499{,}313.86(1.09)^5 \\ &= \$6{,}499{,}313.86(1.538624) \\ &= \$10{,}000{,}000 \text{ at the five-year mark} \end{aligned}$$

and

$$\begin{aligned} \text{PV} &= \$6{,}499{,}313.86 \\ r &= 9\% = 0.09 \\ N &= 15 \\ \text{FV}_N &= \text{PV}(1+r)^N \\ &= \$6{,}499{,}313.86(1.09)^{15} \\ &= \$6{,}499{,}313.86(3.642482) \\ &= \$23{,}673{,}636.74 \text{ at the 15-year mark} \end{aligned}$$

These results show that today's present value of about \$6.5 million becomes \$10 million after five years and \$23.67 million after 15 years.

NON-ANNUAL COMPOUNDING (FUTURE VALUE)

4

d calculate the solution for time value of money problems with different frequencies of compounding;

In this section, we examine investments paying interest more than once a year. For instance, many banks offer a monthly interest rate that compounds 12 times a year. In such an arrangement, they pay interest on interest every month. Rather than quote the periodic monthly interest rate, financial institutions often quote an annual interest rate that we refer to as the **stated annual interest rate** or **quoted interest rate**. We denote the stated annual interest rate by r_s. For instance, your bank might state that a particular CD pays 8 percent compounded monthly. The stated annual interest rate equals the monthly interest rate multiplied by 12. In this example, the monthly interest rate is 0.08/12 = 0.0067 or 0.67 percent.[5] This rate is strictly a quoting convention because $(1 + 0.0067)^{12} = 1.083$, not 1.08; the term $(1 + r_s)$ is not meant to be a future value factor when compounding is more frequent than annual.

With more than one compounding period per year, the future value formula can be expressed as

$$\mathrm{FV}_N = \mathrm{PV}\left(1 + \frac{r_s}{m}\right)^{mN} \qquad (3)$$

where r_s is the stated annual interest rate, m is the number of compounding periods per year, and N now stands for the number of years. Note the compatibility here between the interest rate used, r_s/m, and the number of compounding periods, mN. The periodic rate, r_s/m, is the stated annual interest rate divided by the number of compounding periods per year. The number of compounding periods, mN, is the number of compounding periods in one year multiplied by the number of years. The periodic rate, r_s/m, and the number of compounding periods, mN, must be compatible.

EXAMPLE 4

The Future Value of a Lump Sum with Quarterly Compounding

Continuing with the CD example, suppose your bank offers you a CD with a two-year maturity, a stated annual interest rate of 8 percent compounded quarterly, and a feature allowing reinvestment of the interest at the same interest rate. You decide to invest $10,000. What will the CD be worth at maturity?

---

[5] To avoid rounding errors when using a financial calculator, divide 8 by 12 and then press the %*i* key, rather than simply entering 0.67 for %*i*, so we have $(1 + 0.08/12)^{12} = 1.083000$.

Solution:

Compute the future value with Equation 3 as follows:

$$\begin{aligned}
\text{PV} &= \$10{,}000\\
r_s &= 8\% = 0.08\\
m &= 4\\
r_s/m &= 0.08/4 = 0.02\\
N &= 2\\
mN &= 4(2) = 8 \text{ interest periods}\\
\text{FV}_N &= \text{PV}\left(1+\frac{r_s}{m}\right)^{mN}\\
&= \$10{,}000(1.02)^8\\
&= \$10{,}000(1.171659)\\
&= \$11{,}716.59
\end{aligned}$$

At maturity, the CD will be worth \$11,716.59.

The future value formula in Equation 3 does not differ from the one in Equation 2. Simply keep in mind that the interest rate to use is the rate per period and the exponent is the number of interest, or compounding, periods.

EXAMPLE 5

The Future Value of a Lump Sum with Monthly Compounding

An Australian bank offers to pay you 6 percent compounded monthly. You decide to invest A\$1 million for one year. What is the future value of your investment if interest payments are reinvested at 6 percent?

Solution:

Use Equation 3 to find the future value of the one-year investment as follows:

$$\begin{aligned}
\text{PV} &= \text{A}\$1{,}000{,}000\\
r_s &= 6\% = 0.06\\
m &= 12\\
r_s/m &= 0.06/12 = 0.0050\\
N &= 1\\
mN &= 12(1) = 12 \text{ interest periods}\\
\text{FV}_N &= \text{PV}\left(1+\frac{r_s}{m}\right)^{mN}\\
&= \text{A}\$1{,}000{,}000(1.005)^{12}\\
&= \text{A}\$1{,}000{,}000(1.061678)\\
&= \text{A}\$1{,}061{,}677.81
\end{aligned}$$

If you had been paid 6 percent with annual compounding, the future amount would be only A\$1,000,000(1.06) = A\$1,060,000 instead of A\$1,061,677.81 with monthly compounding.

CONTINUOUS COMPOUNDING, STATED AND EFFECTIVE RATES

5

c calculate and interpret the effective annual rate, given the stated annual interest rate and the frequency of compounding;

d calculate the solution for time value of money problems with different frequencies of compounding;

The preceding discussion on compounding periods illustrates discrete compounding, which credits interest after a discrete amount of time has elapsed. If the number of compounding periods per year becomes infinite, then interest is said to compound continuously. If we want to use the future value formula with continuous compounding, we need to find the limiting value of the future value factor for $m \rightarrow \infty$ (infinitely many compounding periods per year) in Equation 3. The expression for the future value of a sum in N years with continuous compounding is

$$\mathrm{FV}_N = \mathrm{PV}e^{r_s N} \tag{4}$$

The term $e^{r_s N}$ is the transcendental number $e \approx 2.7182818$ raised to the power $r_s N$. Most financial calculators have the function e^x.

EXAMPLE 6

The Future Value of a Lump Sum with Continuous Compounding

Suppose a \$10,000 investment will earn 8 percent compounded continuously for two years. We can compute the future value with Equation 4 as follows:

$$\begin{aligned}
\mathrm{PV} &= \$10{,}000 \\
r_s &= 8\% = 0.08 \\
N &= 2 \\
\mathrm{FV}_N &= \mathrm{PV}e^{r_s N} \\
&= \$10{,}000e^{0.08(2)} \\
&= \$10{,}000(1.173511) \\
&= \$11{,}735.11
\end{aligned}$$

With the same interest rate but using continuous compounding, the \$10,000 investment will grow to \$11,735.11 in two years, compared with \$11,716.59 using quarterly compounding as shown in Example 4.

Table 1 shows how a stated annual interest rate of 8 percent generates different ending dollar amounts with annual, semiannual, quarterly, monthly, daily, and continuous compounding for an initial investment of \$1 (carried out to six decimal places).

As Table 1 shows, all six cases have the same stated annual interest rate of 8 percent; they have different ending dollar amounts, however, because of differences in the frequency of compounding. With annual compounding, the ending amount is \$1.08. More frequent compounding results in larger ending amounts. The ending dollar amount with continuous compounding is the maximum amount that can be earned with a stated annual rate of 8 percent.

Table 1 The Effect of Compounding Frequency on Future Value

Frequency	r_s/m	mN	Future Value of $1		
Annual	8%/1 = 8%	1 × 1 = 1	$\$1.00(1.08)$	=	$1.08
Semiannual	8%/2 = 4%	2 × 1 = 2	$\$1.00(1.04)^2$	=	$1.081600
Quarterly	8%/4 = 2%	4 × 1 = 4	$\$1.00(1.02)^4$	=	$1.082432
Monthly	8%/12 = 0.6667%	12 × 1 = 12	$\$1.00(1.006667)^{12}$	=	$1.083000
Daily	8%/365 = 0.0219%	365 × 1 = 365	$\$1.00(1.000219)^{365}$	=	$1.083278
Continuous			$\$1.00e^{0.08(1)}$	=	$1.083287

Table 1 also shows that a $1 investment earning 8.16 percent compounded annually grows to the same future value at the end of one year as a $1 investment earning 8 percent compounded semiannually. This result leads us to a distinction between the stated annual interest rate and the **effective annual rate** (EAR).[6] For an 8 percent stated annual interest rate with semiannual compounding, the EAR is 8.16 percent.

5.1 Stated and Effective Rates

The stated annual interest rate does not give a future value directly, so we need a formula for the EAR. With an annual interest rate of 8 percent compounded semiannually, we receive a periodic rate of 4 percent. During the course of a year, an investment of $1 would grow to $\$1(1.04)^2 = \$1.0816$, as illustrated in Table 1. The interest earned on the $1 investment is $0.0816 and represents an effective annual rate of interest of 8.16 percent. The effective annual rate is calculated as follows:

$$\text{EAR} = (1 + \text{Periodic interest rate})^m - 1 \tag{5}$$

The periodic interest rate is the stated annual interest rate divided by m, where m is the number of compounding periods in one year. Using our previous example, we can solve for EAR as follows: $(1.04)^2 - 1 = 8.16$ percent.

The concept of EAR extends to continuous compounding. Suppose we have a rate of 8 percent compounded continuously. We can find the EAR in the same way as above by finding the appropriate future value factor. In this case, a $1 investment would grow to $\$1e^{0.08(1.0)} = \$1.0833$. The interest earned for one year represents an effective annual rate of 8.33 percent and is larger than the 8.16 percent EAR with semiannual compounding because interest is compounded more frequently. With continuous compounding, we can solve for the effective annual rate as follows:

$$\text{EAR} = e^{r_s} - 1 \tag{6}$$

---

[6] Among the terms used for the effective annual return on interest-bearing bank deposits are annual percentage yield (APY) in the United States and equivalent annual rate (EAR) in the United Kingdom. By contrast, the **annual percentage rate** (APR) measures the cost of borrowing expressed as a yearly rate. In the United States, the APR is calculated as a periodic rate times the number of payment periods per year and, as a result, some writers use APR as a general synonym for the stated annual interest rate. Nevertheless, APR is a term with legal connotations; its calculation follows regulatory standards that vary internationally. Therefore, “stated annual interest rate” is the preferred general term for an annual interest rate that does not account for compounding within the year.

We can reverse the formulas for EAR with discrete and continuous compounding to find a periodic rate that corresponds to a particular effective annual rate. Suppose we want to find the appropriate periodic rate for a given effective annual rate of 8.16 percent with semiannual compounding. We can use Equation 5 to find the periodic rate:

$$\begin{aligned} 0.0816 &= (1 + \text{Periodic rate})^2 - 1 \\ 1.0816 &= (1 + \text{Periodic rate})^2 \\ (1.0816)^{1/2} - 1 &= \text{Periodic rate} \\ (1.04) - 1 &= \text{Periodic rate} \\ 4\% &= \text{Periodic rate} \end{aligned}$$

To calculate the continuously compounded rate (the stated annual interest rate with continuous compounding) corresponding to an effective annual rate of 8.33 percent, we find the interest rate that satisfies Equation 6:

$$\begin{aligned} 0.0833 &= e^{r_s} - 1 \\ 1.0833 &= e^{r_s} \end{aligned}$$

To solve this equation, we take the natural logarithm of both sides. (Recall that the natural log of e^{r_s} is $\ln e^{r_s} = r_s$.) Therefore, $\ln 1.0833 = r_s$, resulting in $r_s = 8$ percent. We see that a stated annual rate of 8 percent with continuous compounding is equivalent to an EAR of 8.33 percent.

FUTURE VALUE OF A SERIES OF CASH FLOWS, FUTURE VALUE ANNUITIES

6

e calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;

f demonstrate the use of a time line in modeling and solving time value of money problems.

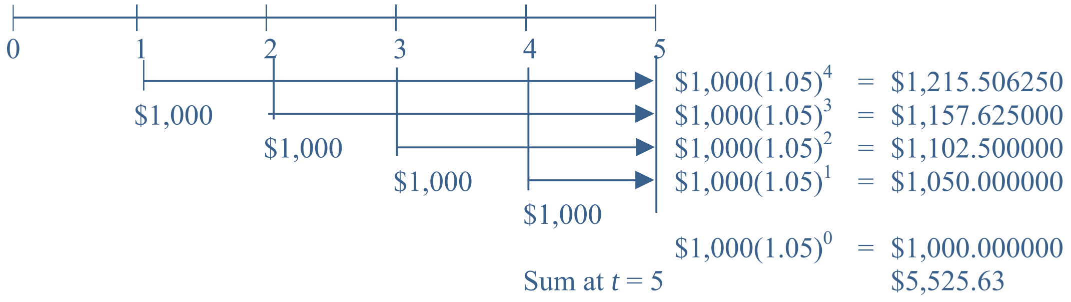
In this section, we consider series of cash flows, both even and uneven. We begin with a list of terms commonly used when valuing cash flows that are distributed over many time periods.

- An **annuity** is a finite set of level sequential cash flows.
- An **ordinary annuity** has a first cash flow that occurs one period from now (indexed at $t = 1$).
- An **annuity due** has a first cash flow that occurs immediately (indexed at $t = 0$).
- A **perpetuity** is a perpetual annuity, or a set of level never-ending sequential cash flows, with the first cash flow occurring one period from now.

6.1 Equal Cash Flows—Ordinary Annuity

Consider an ordinary annuity paying 5 percent annually. Suppose we have five separate deposits of $1,000 occurring at equally spaced intervals of one year, with the first payment occurring at $t = 1$. Our goal is to find the future value of this ordinary annuity after the last deposit at $t = 5$. The increment in the time counter is one year, so the last payment occurs five years from now. As the time line in Figure 3 shows, we find the future value of each \$1,000 deposit as of $t = 5$ with Equation 2, $\mathrm{FV}_N = \mathrm{PV}(1 + r)^N$. The arrows in Figure 3 extend from the payment date to $t = 5$. For instance, the first \$1,000 deposit made at $t = 1$ will compound over four periods. Using Equation 2, we find that the future value of the first deposit at $t = 5$ is $\$1{,}000(1.05)^4 = \$1{,}215.51$. We calculate the future value of all other payments in a similar fashion. (Note that we are finding the future value at $t = 5$, so the last payment does not earn any interest.) With all values now at $t = 5$, we can add the future values to arrive at the future value of the annuity. This amount is \$5,525.63.

Figure 3 The Future Value of a Five-Year Ordinary Annuity



We can arrive at a general annuity formula if we define the annuity amount as A, the number of time periods as N, and the interest rate per period as r. We can then define the future value as

$$\mathrm{FV}_N = A\left[(1 + r)^{N-1} + (1 + r)^{N-2} + (1 + r)^{N-3} + \ldots + (1 + r)^1 + (1 + r)^0\right]$$

which simplifies to

$$\mathrm{FV}_N = A\left[\frac{(1 + r)^N - 1}{r}\right] \tag{7}$$

The term in brackets is the future value annuity factor. This factor gives the future value of an ordinary annuity of \$1 per period. Multiplying the future value annuity factor by the annuity amount gives the future value of an ordinary annuity. For the ordinary annuity in Figure 3, we find the future value annuity factor from Equation 7 as

$$\left[\frac{(1.05)^5 - 1}{0.05}\right] = 5.525631$$

With an annuity amount $A = \$1{,}000$, the future value of the annuity is $\$1{,}000(5.525631) = \$5{,}525.63$, an amount that agrees with our earlier work.

The next example illustrates how to find the future value of an ordinary annuity using the formula in Equation 7.

EXAMPLE 7

The Future Value of an Annuity

Suppose your company's defined contribution retirement plan allows you to invest up to €20,000 per year. You plan to invest €20,000 per year in a stock index fund for the next 30 years. Historically, this fund has earned 9 percent per year on average. Assuming that you actually earn 9 percent a year, how much money will you have available for retirement after making the last payment?

Solution:

Use Equation 7 to find the future amount:

$$A = €20{,}000$$
$$r = 9\% = 0.09$$
$$N = 30$$
$$\text{FV annuity factor} = \frac{(1+r)^N - 1}{r} = \frac{(1.09)^{30} - 1}{0.09} = 136.307539$$
$$\begin{aligned} \text{FV}_N &= €20{,}000(136.307539) \\ &= €2{,}726{,}150.77 \end{aligned}$$

Assuming the fund continues to earn an average of 9 percent per year, you will have €2,726,150.77 available at retirement.

6.2 Unequal Cash Flows

In many cases, cash flow streams are unequal, precluding the simple use of the future value annuity factor. For instance, an individual investor might have a savings plan that involves unequal cash payments depending on the month of the year or lower savings during a planned vacation. One can always find the future value of a series of unequal cash flows by compounding the cash flows one at a time. Suppose you have the five cash flows described in Table 2, indexed relative to the present ($t = 0$).

Table 2 A Series of Unequal Cash Flows and Their Future Values at 5 Percent

Time	Cash Flow ($)	Future Value at Year 5		
$t = 1$	1,000	$\$1{,}000(1.05)^4$	=	$1,215.51
$t = 2$	2,000	$\$2{,}000(1.05)^3$	=	$2,315.25
$t = 3$	4,000	$\$4{,}000(1.05)^2$	=	$4,410.00
$t = 4$	5,000	$\$5{,}000(1.05)^1$	=	$5,250.00
$t = 5$	6,000	$\$6{,}000(1.05)^0$	=	$6,000.00
		Sum	=	$19,190.76

All of the payments shown in Table 2 are different. Therefore, the most direct approach to finding the future value at $t = 5$ is to compute the future value of each payment as of $t = 5$ and then sum the individual future values. The total future value at Year 5 equals $19,190.76, as shown in the third column. Later in this reading, you will learn shortcuts to take when the cash flows are close to even; these shortcuts will allow you to combine annuity and single-period calculations.

7 PRESENT VALUE OF A SINGLE CASH FLOW (LUMP SUM)

e calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;

f demonstrate the use of a time line in modeling and solving time value of money problems.

Just as the future value factor links today's present value with tomorrow's future value, the present value factor allows us to discount future value to present value. For example, with a 5 percent interest rate generating a future payoff of $105 in one year, what current amount invested at 5 percent for one year will grow to $105? The answer is $100; therefore, $100 is the present value of $105 to be received in one year at a discount rate of 5 percent.

Given a future cash flow that is to be received in N periods and an interest rate per period of r, we can use the formula for future value to solve directly for the present value as follows:

$$\mathrm{FV}_N = \mathrm{PV}(1+r)^N$$

$$\mathrm{PV} = \mathrm{FV}_N\left[\frac{1}{(1+r)^N}\right] \qquad (8)$$

$$\mathrm{PV} = \mathrm{FV}_N(1+r)^{-N}$$

We see from Equation 8 that the present value factor, $(1 + r)^{-N}$, is the reciprocal of the future value factor, $(1 + r)^N$.

EXAMPLE 8

The Present Value of a Lump Sum

An insurance company has issued a Guaranteed Investment Contract (GIC) that promises to pay $100,000 in six years with an 8 percent return rate. What amount of money must the insurer invest today at 8 percent for six years to make the promised payment?

Solution:

We can use Equation 8 to find the present value using the following data:

$$\mathrm{FV}_N = \$100{,}000$$

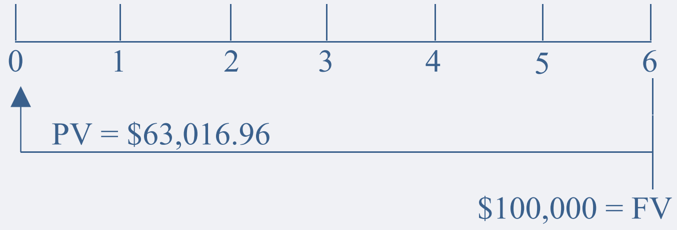
$$r = 8\% = 0.08$$

$$N = 6$$

$$\begin{aligned}\mathrm{PV} &= \mathrm{FV}_N(1+r)^{-N}\\ &= \$100{,}000\left[\frac{1}{(1.08)^6}\right]\\ &= \$100{,}000(0.6301696)\\ &= \$63{,}016.96\end{aligned}$$

We can say that \$63,016.96 today, with an interest rate of 8 percent, is equivalent to \$100,000 to be received in six years. Discounting the \$100,000 makes a future \$100,000 equivalent to \$63,016.96 when allowance is made for the time value of money. As the time line in Figure 4 shows, the \$100,000 has been discounted six full periods.

Figure 4 The Present Value of a Lump Sum to Be Received at Time $t = 6$



EXAMPLE 9

The Projected Present Value of a More Distant Future Lump Sum

Suppose you own a liquid financial asset that will pay you \$100,000 in 10 years from today. Your daughter plans to attend college four years from today, and you want to know what the asset's present value will be at that time. Given an 8 percent discount rate, what will the asset be worth four years from today?

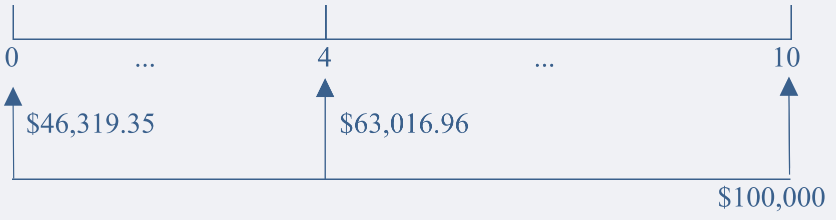
Solution:

The value of the asset is the present value of the asset's promised payment. At $t = 4$, the cash payment will be received six years later. With this information, you can solve for the value four years from today using Equation 8:

$$\begin{aligned} \mathrm{FV}_N &= \$100{,}000 \\ r &= 8\% = 0.08 \\ N &= 6 \end{aligned}$$

$$\begin{aligned} \mathrm{PV} &= \mathrm{FV}_N (1 + r)^{-N} \\ &= \$100{,}000 \frac{1}{(1.08)^6} \\ &= \$100{,}000(0.6301696) \\ &= \$63{,}016.96 \end{aligned}$$

Figure 5 The Relationship between Present Value and Future Value



The time line in Figure 5 shows the future payment of $100,000 that is to be received at $t = 10$. The time line also shows the values at $t = 4$ and at $t = 0$. Relative to the payment at $t = 10$, the amount at $t = 4$ is a projected present value, while the amount at $t = 0$ is the present value (as of today).

Present value problems require an evaluation of the present value factor, $(1 + r)^{-N}$. Present values relate to the discount rate and the number of periods in the following ways:

- For a given discount rate, the farther in the future the amount to be received, the smaller that amount's present value.
- Holding time constant, the larger the discount rate, the smaller the present value of a future amount.

8 NON-ANNUAL COMPOUNDING (PRESENT VALUE)

d calculate the solution for time value of money problems with different frequencies of compounding;

Recall that interest may be paid semiannually, quarterly, monthly, or even daily. To handle interest payments made more than once a year, we can modify the present value formula (Equation 8) as follows. Recall that r_s is the quoted interest rate and equals the periodic interest rate multiplied by the number of compounding periods in each year. In general, with more than one compounding period in a year, we can express the formula for present value as

$$PV = FV_N\left(1 + \frac{r_s}{m}\right)^{-mN} \tag{9}$$

where

m = number of compounding periods per year
r_s = quoted annual interest rate
N = number of years

The formula in Equation 9 is quite similar to that in Equation 8. As we have already noted, present value and future value factors are reciprocals. Changing the frequency of compounding does not alter this result. The only difference is the use of the periodic interest rate and the corresponding number of compounding periods.

The following example illustrates Equation 9.

EXAMPLE 10

The Present Value of a Lump Sum with Monthly Compounding

The manager of a Canadian pension fund knows that the fund must make a lump-sum payment of C$5 million 10 years from now. She wants to invest an amount today in a GIC so that it will grow to the required amount. The current interest rate on GICs is 6 percent a year, compounded monthly. How much should she invest today in the GIC?

Solution:

Use Equation 9 to find the required present value:

$$\begin{aligned}
\text{FV}_N &= \text{C\$}5{,}000{,}000 \\
r_s &= 6\% = 0.06 \\
m &= 12 \\
r_s/m &= 0.06/12 = 0.005 \\
N &= 10 \\
mN &= 12(10) = 120 \\
\text{PV} &= \text{FV}_N\left(1 + \frac{r_s}{m}\right)^{-mN} \\
&= \text{C\$}5{,}000{,}000(1.005)^{-120} \\
&= \text{C\$}5{,}000{,}000(0.549633) \\
&= \text{C\$}2{,}748{,}163.67
\end{aligned}$$

In applying Equation 9, we use the periodic rate (in this case, the monthly rate) and the appropriate number of periods with monthly compounding (in this case, 10 years of monthly compounding, or 120 periods).

PRESENT VALUE OF A SERIES OF EQUAL CASH FLOWS (ANNUITIES) AND UNEQUAL CASH FLOWS

9

- **e** calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;
- **f** demonstrate the use of a time line in modeling and solving time value of money problems.

Many applications in investment management involve assets that offer a series of cash flows over time. The cash flows may be highly uneven, relatively even, or equal. They may occur over relatively short periods of time, longer periods of time, or even stretch on indefinitely. In this section, we discuss how to find the present value of a series of cash flows.

9.1 The Present Value of a Series of Equal Cash Flows

We begin with an ordinary annuity. Recall that an ordinary annuity has equal annuity payments, with the first payment starting one period into the future. In total, the annuity makes N payments, with the first payment at $t = 1$ and the last at $t = N$. We can express the present value of an ordinary annuity as the sum of the present values of each individual annuity payment, as follows:

$$\text{PV} = \frac{A}{(1+r)} + \frac{A}{(1+r)^2} + \frac{A}{(1+r)^3} + \ldots + \frac{A}{(1+r)^{N-1}} + \frac{A}{(1+r)^N} \tag{10}$$

where

A = the annuity amount
r = the interest rate per period corresponding to the frequency of annuity payments (for example, annual, quarterly, or monthly)
N = the number of annuity payments

Because the annuity payment (A) is a constant in this equation, it can be factored out as a common term. Thus the sum of the interest factors has a shortcut expression:

$$\text{PV} = A\left[\frac{1 - \frac{1}{(1+r)^N}}{r}\right] \tag{11}$$

In much the same way that we computed the future value of an ordinary annuity, we find the present value by multiplying the annuity amount by a present value annuity factor (the term in brackets in Equation 11).

EXAMPLE 11

The Present Value of an Ordinary Annuity

Suppose you are considering purchasing a financial asset that promises to pay €1,000 per year for five years, with the first payment one year from now. The required rate of return is 12 percent per year. How much should you pay for this asset?

Solution:

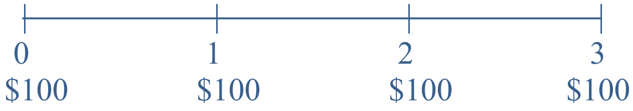
To find the value of the financial asset, use the formula for the present value of an ordinary annuity given in Equation 11 with the following data:

$$A = €1{,}000$$
$$r = 12\% = 0.12$$
$$N = 5$$
$$\text{PV} = A\left[\frac{1 - \dfrac{1}{(1+r)^N}}{r}\right]$$
$$= €1{,}000\left[\frac{1 - \dfrac{1}{(1.12)^5}}{0.12}\right]$$
$$= €1{,}000(3.604776)$$
$$= €3{,}604.78$$

The series of cash flows of €1,000 per year for five years is currently worth €3,604.78 when discounted at 12 percent.

Keeping track of the actual calendar time brings us to a specific type of annuity with level payments: the annuity due. An annuity due has its first payment occurring today ($t = 0$). In total, the annuity due will make N payments. Figure 6 presents the time line for an annuity due that makes four payments of $100.

Figure 6 An Annuity Due of $100 per Period



As Figure 6 shows, we can view the four-period annuity due as the sum of two parts: a $100 lump sum today and an ordinary annuity of $100 per period for three periods. At a 12 percent discount rate, the four $100 cash flows in this annuity due example will be worth $340.18.[7]

Expressing the value of the future series of cash flows in today's dollars gives us a convenient way of comparing annuities. The next example illustrates this approach.

---

[7] There is an alternative way to calculate the present value of an annuity due. Compared to an ordinary annuity, the payments in an annuity due are each discounted one less period. Therefore, we can modify Equation 11 to handle annuities due by multiplying the right-hand side of the equation by $(1 + r)$:

$$\text{PV}(\text{Annuity due}) = A\left\{\left[1 - (1+r)^{-N}\right]/r\right\}(1+r)$$

EXAMPLE 12

An Annuity Due as the Present Value of an Immediate Cash Flow Plus an Ordinary Annuity

You are retiring today and must choose to take your retirement benefits either as a lump sum or as an annuity. Your company's benefits officer presents you with two alternatives: an immediate lump sum of $2 million or an annuity with 20 payments of $200,000 a year with the first payment starting today. The interest rate at your bank is 7 percent per year compounded annually. Which option has the greater present value? (Ignore any tax differences between the two options.)

Solution:

To compare the two options, find the present value of each at time $t = 0$ and choose the one with the larger value. The first option's present value is $2 million, already expressed in today's dollars. The second option is an annuity due. Because the first payment occurs at $t = 0$, you can separate the annuity benefits into two pieces: an immediate $200,000 to be paid today ($t = 0$) and an ordinary annuity of $200,000 per year for 19 years. To value this option, you need to find the present value of the ordinary annuity using Equation 11 and then add $200,000 to it.

$$A = \$200{,}000$$

$$N = 19$$

$$r = 7\% = 0.07$$

$$\begin{aligned} \text{PV} &= A\left[\frac{1 - \dfrac{1}{(1+r)^N}}{r}\right] \\ &= \$200{,}000\left[\frac{1 - \dfrac{1}{(1.07)^{19}}}{0.07}\right] \\ &= \$200{,}000(10.335595) \\ &= \$2{,}067{,}119.05 \end{aligned}$$

The 19 payments of $200,000 have a present value of $2,067,119.05. Adding the initial payment of $200,000 to $2,067,119.05, we find that the total value of the annuity option is $2,267,119.05. The present value of the annuity is greater than the lump sum alternative of $2 million.

We now look at another example reiterating the equivalence of present and future values.

EXAMPLE 13

The Projected Present Value of an Ordinary Annuity

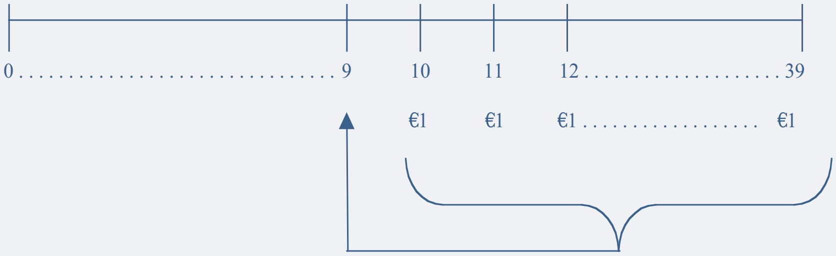
A German pension fund manager anticipates that benefits of €1 million per year must be paid to retirees. Retirements will not occur until 10 years from now at time $t = 10$. Once benefits begin to be paid, they will extend until $t = 39$ for a total of 30 payments. What is the present value of the pension liability if the appropriate annual discount rate for plan liabilities is 5 percent compounded annually?

Solution:

This problem involves an annuity with the first payment at $t = 10$. From the perspective of $t = 9$, we have an ordinary annuity with 30 payments. We can compute the present value of this annuity with Equation 11 and then look at it on a time line.

$$A = €1{,}000{,}000$$
$$r = 5\% = 0.05$$
$$N = 30$$
$$\text{PV} = A\left[\frac{1 - \frac{1}{(1+r)^N}}{r}\right]$$
$$= €1{,}000{,}000\left[\frac{1 - \frac{1}{(1.05)^{30}}}{0.05}\right]$$
$$= €1{,}000{,}000(15.372451)$$
$$= €15{,}372{,}451.03$$

Figure 7 The Present Value of an Ordinary Annuity with First Payment at Time t = 10 (in Millions)



On the time line, we have shown the pension payments of €1 million extending from $t = 10$ to $t = 39$. The bracket and arrow indicate the process of finding the present value of the annuity, discounted back to $t = 9$. The present value of the pension benefits as of $t = 9$ is €15,372,451.03. The problem is to find the present value today (at $t = 0$).

Now we can rely on the equivalence of present value and future value. As Figure 7 shows, we can view the amount at $t = 9$ as a future value from the vantage point of $t = 0$. We compute the present value of the amount at $t = 9$ as follows:

$$\begin{aligned} \text{FV}_N &= \text{€}15{,}372{,}451.03 \text{ (the present value at } t = 9) \\ N &= 9 \\ r &= 5\% = 0.05 \\ \text{PV} &= \text{FV}_N(1 + r)^{-N} \\ &= \text{€}15{,}372{,}451.03(1.05)^{-9} \\ &= \text{€}15{,}372{,}451.03(0.644609) \\ &= \text{€}9{,}909{,}219.00 \end{aligned}$$

The present value of the pension liability is €9,909,219.00.

Example 13 illustrates three procedures emphasized in this reading:

- finding the present or future value of any cash flow series;
- recognizing the equivalence of present value and appropriately discounted future value; and
- keeping track of the actual calendar time in a problem involving the time value of money.

9.2 The Present Value of a Series of Unequal Cash Flows

When we have unequal cash flows, we must first find the present value of each individual cash flow and then sum the respective present values. For a series with many cash flows, we usually use a spreadsheet. Table 3 lists a series of cash flows with the time periods in the first column, cash flows in the second column, and each cash flow's present value in the third column. The last row of Table 3 shows the sum of the five present values.

Table 3 A Series of Unequal Cash Flows and Their Present Values at 5 Percent

Time Period	Cash Flow ($)	Present Value at Year 0		
1	1,000	$\$1{,}000(1.05)^{-1}$	=	$952.38
2	2,000	$\$2{,}000(1.05)^{-2}$	=	$1,814.06
3	4,000	$\$4{,}000(1.05)^{-3}$	=	$3,455.35
4	5,000	$\$5{,}000(1.05)^{-4}$	=	$4,113.51
5	6,000	$\$6{,}000(1.05)^{-5}$	=	$4,701.16
		Sum	=	$15,036.46

We could calculate the future value of these cash flows by computing them one at a time using the single-payment future value formula. We already know the present value of this series, however, so we can easily apply time-value equivalence. The future value of the series of cash flows from Table 2, \$19,190.76, is equal to the single \$15,036.46 amount compounded forward to $t = 5$:

$$\begin{aligned} \mathrm{PV} &= \$15{,}036.46 \\ N &= 5 \\ r &= 5\% = 0.05 \\ \mathrm{FV}_N &= \mathrm{PV}(1+r)^N \\ &= \$15{,}036.46(1.05)^5 \\ &= \$15{,}036.46(1.276282) \\ &= \$19{,}190.76 \end{aligned}$$

PRESENT VALUE OF A PERPETUITY AND PRESENT VALUES INDEXED AT TIMES OTHER THAN T=0

10

e calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;

Consider the case of an ordinary annuity that extends indefinitely. Such an ordinary annuity is called a perpetuity (a perpetual annuity). To derive a formula for the present value of a perpetuity, we can modify Equation 10 to account for an infinite series of cash flows:

$$\mathrm{PV} = A\sum_{t=1}^{\infty}\left[\frac{1}{(1+r)^t}\right] \tag{12}$$

As long as interest rates are positive, the sum of present value factors converges and

$$\mathrm{PV} = \frac{A}{r} \tag{13}$$

To see this, look back at Equation 11, the expression for the present value of an ordinary annuity. As N (the number of periods in the annuity) goes to infinity, the term $1/(1 + r)^N$ approaches 0 and Equation 11 simplifies to Equation 13. This equation will reappear when we value dividends from stocks because stocks have no predefined life span. (A stock paying constant dividends is similar to a perpetuity.) With the first payment a year from now, a perpetuity of \$10 per year with a 20 percent required rate of return has a present value of \$10/0.2 = \$50.

Equation 13 is valid only for a perpetuity with level payments. In our development above, the first payment occurred at $t = 1$; therefore, we compute the present value as of $t = 0$.

Other assets also come close to satisfying the assumptions of a perpetuity. Certain government bonds and preferred stocks are typical examples of financial assets that make level payments for an indefinite period of time.

EXAMPLE 14

The Present Value of a Perpetuity

The British government once issued a type of security called a consol bond, which promised to pay a level cash flow indefinitely. If a consol bond paid £100 per year in perpetuity, what would it be worth today if the required rate of return were 5 percent?

Solution:

To answer this question, we can use Equation 13 with the following data:

$$\begin{aligned} A &= £100 \\ r &= 5\% = 0.05 \\ \text{PV} &= A/r \\ &= £100/0.05 \\ &= £2{,}000 \end{aligned}$$

The bond would be worth £2,000.

10.1 Present Values Indexed at Times Other than $t = 0$

In practice with investments, analysts frequently need to find present values indexed at times other than $t = 0$. Subscripting the present value and evaluating a perpetuity beginning with \$100 payments in Year 2, we find PV_1 = \$100/0.05 = \$2,000 at a 5 percent discount rate. Further, we can calculate today's PV as PV_0 = \$2,000/1.05 = \$1,904.76.

Consider a similar situation in which cash flows of \$6 per year begin at the end of the 4th year and continue at the end of each year thereafter, with the last cash flow at the end of the 10th year. From the perspective of the end of the third year, we are facing a typical seven-year ordinary annuity. We can find the present value of the annuity from the perspective of the end of the third year and then discount that present value back to the present. At an interest rate of 5 percent, the cash flows of \$6 per year starting at the end of the fourth year will be worth \$34.72 at the end of the third year ($t = 3$) and \$29.99 today ($t = 0$).

The next example illustrates the important concept that an annuity or perpetuity beginning sometime in the future can be expressed in present value terms one period prior to the first payment. That present value can then be discounted back to today's present value.

EXAMPLE 15

The Present Value of a Projected Perpetuity

Consider a level perpetuity of £100 per year with its first payment beginning at $t = 5$. What is its present value today (at $t = 0$), given a 5 percent discount rate?

Solution:

First, we find the present value of the perpetuity at $t = 4$ and then discount that amount back to $t = 0$. (Recall that a perpetuity or an ordinary annuity has its first payment one period away, explaining the $t = 4$ index for our present value calculation.)

i. Find the present value of the perpetuity at $t = 4$:

$$\begin{aligned} A &= £100 \\ r &= 5\% = 0.05 \\ \text{PV} &= A/r \\ &= £100/0.05 \\ &= £2{,}000 \end{aligned}$$

ii. Find the present value of the future amount at $t = 4$. From the perspective of $t = 0$, the present value of £2,000 can be considered a future value. Now we need to find the present value of a lump sum:

$$\begin{aligned} \text{FV}_N &= £2{,}000 \text{ (the present value at } t = 4) \\ r &= 5\% = 0.05 \\ N &= 4 \\ \text{PV} &= \text{FV}_N (1 + r)^{-N} \\ &= £2{,}000(1.05)^{-4} \\ &= £2{,}000(0.822702) \\ &= £1{,}645.40 \end{aligned}$$

Today's present value of the perpetuity is £1,645.40.

As discussed earlier, an annuity is a series of payments of a fixed amount for a specified number of periods. Suppose we own a perpetuity. At the same time, we issue a perpetuity obligating us to make payments; these payments are the same size as those of the perpetuity we own. However, the first payment of the perpetuity we issue is at $t = 5$; payments then continue on forever. The payments on this second perpetuity exactly offset the payments received from the perpetuity we own at $t = 5$ and all subsequent dates. We are left with level nonzero net cash flows at $t = 1, 2, 3,$ and 4. This outcome exactly fits the definition of an annuity with four payments. Thus we can construct an annuity as the difference between two perpetuities with equal, level payments but differing starting dates. The next example illustrates this result.

EXAMPLE 16

The Present Value of an Ordinary Annuity as the Present Value of a Current Minus Projected Perpetuity

Given a 5 percent discount rate, find the present value of a four-year ordinary annuity of £100 per year starting in Year 1 as the difference between the following two level perpetuities:

Perpetuity 1	£100 per year starting in Year 1 (first payment at $t = 1$)
Perpetuity 2	£100 per year starting in Year 5 (first payment at $t = 5$)

Solution:

If we subtract Perpetuity 2 from Perpetuity 1, we are left with an ordinary annuity of £100 per period for four years (payments at t = 1, 2, 3, 4). Subtracting the present value of Perpetuity 2 from that of Perpetuity 1, we arrive at the present value of the four-year ordinary annuity:

$$\begin{aligned}
\text{PV}_0(\text{Perpetuity 1}) &= £100 / 0.05 = £2{,}000 \\
\text{PV}_4(\text{Perpetuity 2}) &= £100 / 0.05 = £2{,}000 \\
\text{PV}_0(\text{Perpetuity 2}) &= £2{,}000 / (1.05)^4 = £1{,}645.40 \\
\text{PV}_0(\text{Annuity}) &= \text{PV}_0(\text{Perpetuity 1}) - \text{PV}_0(\text{Perpetuity 2}) \\
&= £2{,}000 - £1{,}645.40 \\
&= £354.60
\end{aligned}$$

The four-year ordinary annuity's present value is equal to £2,000 – £1,645.40 = £354.60.

11 SOLVING FOR INTEREST RATES, GROWTH RATES, AND NUMBER OF PERIODS

e calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;

In the previous examples, certain pieces of information have been made available. For instance, all problems have given the rate of interest, r, the number of time periods, N, the annuity amount, A, and either the present value, PV, or future value, FV. In real-world applications, however, although the present and future values may be given, you may have to solve for either the interest rate, the number of periods, or the annuity amount. In the subsections that follow, we show these types of problems.

11.1 Solving for Interest Rates and Growth Rates

Suppose a bank deposit of €100 is known to generate a payoff of €111 in one year. With this information, we can infer the interest rate that separates the present value of €100 from the future value of €111 by using Equation 2, $\text{FV}_N = \text{PV}(1 + r)^N$, with $N = 1$. With PV, FV, and N known, we can solve for r directly:

$$\begin{aligned}
1 + r &= \text{FV}/\text{PV} \\
1 + r &= €111/€100 = 1.11 \\
r &= 0.11, \text{ or } 11\%
\end{aligned}$$

The interest rate that equates €100 at $t = 0$ to €111 at $t = 1$ is 11 percent. Thus we can state that €100 grows to €111 with a growth rate of 11 percent.

As this example shows, an interest rate can also be considered a growth rate. The particular application will usually dictate whether we use the term "interest rate" or "growth rate." Solving Equation 2 for r and replacing the interest rate r with the growth rate g produces the following expression for determining growth rates:

$$g = (\text{FV}_N/\text{PV})^{1/N} - 1 \tag{14}$$

Below are two examples that use the concept of a growth rate.

EXAMPLE 17

Calculating a Growth Rate (1)

Hyundai Steel, the first Korean steelmaker, was established in 1953. Hyundai Steel's sales increased from ₩14,146.4 billion in 2012 to ₩19,166.0 billion in 2017. However, its net profit declined from ₩796.4 billion in 2012 to ₩727.5 billion in 2017. Calculate the following growth rates for Hyundai Steel for the five-year period from the end of 2012 to the end of 2017:

1. Sales growth rate.
2. Net profit growth rate.

Solution to 1:

To solve this problem, we can use Equation 14, $g = (\mathrm{FV}_N/\mathrm{PV})^{1/N} - 1$. We denote sales in 2012 as PV and sales in 2017 as FV_5. We can then solve for the growth rate as follows:

$$\begin{aligned} g &= \sqrt[5]{₩19{,}166.0/₩14{,}146.4} - 1 \\ &= \sqrt[5]{1.354832} - 1 \\ &= 1.062618 - 1 \\ &= 0.062618 \text{ or about } 6.3\% \end{aligned}$$

The calculated growth rate of about 6.3 percent a year shows that Hyundai Steel's sales grew during the 2012–2017 period.

Solution to 2:

In this case, we can speak of a positive compound rate of decrease or a negative compound growth rate. Using Equation 14, we find

$$\begin{aligned} g &= \sqrt[5]{₩727.5/₩796.4} - 1 \\ &= \sqrt[5]{0.913486} - 1 \\ &= 0.982065 - 1 \\ &= -0.017935 \text{ or about } -1.8\% \end{aligned}$$

In contrast to the positive sales growth, the rate of growth in net profit was approximately −1.8 percent during the 2012–2017 period.

EXAMPLE 18

Calculating a Growth Rate (2)

Toyota Motor Corporation, one of the largest automakers in the world, had consolidated vehicle sales of 8.96 million units in 2018 (fiscal year ending 31 March 2018). This is substantially more than consolidated vehicle sales of 7.35 million units six years earlier in 2012. What was the growth rate in number of vehicles sold by Toyota from 2012 to 2018?

Solution:

Using Equation 14, we find

$$\begin{aligned} g &= \sqrt[6]{8.96/7.35} - 1 \\ &= \sqrt[6]{1.219048} - 1 \\ &= 1.033563 - 1 \\ &= 0.033563 \text{ or about } 3.4\% \end{aligned}$$

The rate of growth in vehicles sold was approximately 3.4 percent during the 2012–2018 period. Note that we can also refer to 3.4 percent as the compound annual growth rate because it is the single number that compounds the number of vehicles sold in 2012 forward to the number of vehicles sold in 2018. Table 4 lists the number of vehicles sold by Toyota from 2012 to 2018.

Table 4 Number of Vehicles Sold, 2012–2018

Year	Number of Vehicles Sold (Millions)	$(1 + g)_t$	t
2012	7.35		0
2013	8.87	8.87/7.35 = 1.206803	1
2014	9.12	9.12/8.87 = 1.028185	2
2015	8.97	8.97/9.12 = 0.983553	3
2016	8.68	8.68/8.97 = 0.967670	4
2017	8.97	8.97/8.68 = 1.033410	5
2018	8.96	8.96/8.97 = 0.998885	6

Source: www.toyota.com.

Table 4 also shows 1 plus the one-year growth rate in number of vehicles sold. We can compute the 1 plus six-year cumulative growth in number of vehicles sold from 2012 to 2018 as the product of quantities (1 + one-year growth rate). We arrive at the same result as when we divide the ending number of vehicles sold, 8.96 million, by the beginning number of vehicles sold, 7.35 million:

$$\begin{aligned} \frac{8.96}{7.35} &= \left(\frac{8.87}{7.35}\right)\left(\frac{9.12}{8.87}\right)\left(\frac{8.97}{9.12}\right)\left(\frac{8.68}{8.97}\right)\left(\frac{8.97}{8.68}\right)\left(\frac{8.96}{8.97}\right) \\ &= (1 + g_1)(1 + g_2)(1 + g_3)(1 + g_4)(1 + g_5)(1 + g_6) \\ 1.219048 &= (1.206803)(1.028185)(0.983553)(0.967670)(1.033410)(0.998885) \end{aligned}$$

The right-hand side of the equation is the product of 1 plus the one-year growth rate in number of vehicles sold for each year. Recall that, using Equation 14, we took the sixth root of 8.96/7.35 = 1.219048. In effect, we were solving for the single value of g which, when compounded over six periods, gives the correct product of 1 plus the one-year growth rates.[8]

In conclusion, we do not need to compute intermediate growth rates as in Table 4 to solve for a compound growth rate g. Sometimes, however, the intermediate growth rates are interesting or informative. For example, most of the 21.9 percent increase in vehicles sold by Toyota from 2012 to 2018 occurred in

---

[8] The compound growth rate that we calculate here is an example of a geometric mean, specifically the geometric mean of the growth rates. We define the geometric mean in the reading on statistical concepts.

2013 as sales increased by 20.7 percent from 2012 to 2013. Elsewhere in Toyota Motor's disclosures, the company noted that all regions except Europe showed a substantial increase in sales in 2013. We can also analyze the variability in growth rates when we conduct an analysis as in Table 4. Sales continued to increase in 2014 but then declined in 2015 and 2016. Sales then increased but the sales in 2017 and 2018 are about the same as in 2015.

The compound growth rate is an excellent summary measure of growth over multiple time periods. In our Toyota Motors example, the compound growth rate of 3.4 percent is the single growth rate that, when added to 1, compounded over six years, and multiplied by the 2012 number of vehicles sold, yields the 2018 number of vehicles sold.

11.2 Solving for the Number of Periods

In this section, we demonstrate how to solve for the number of periods given present value, future value, and interest or growth rates.

EXAMPLE 19

The Number of Annual Compounding Periods Needed for an Investment to Reach a Specific Value

You are interested in determining how long it will take an investment of €10,000,000 to double in value. The current interest rate is 7 percent compounded annually. How many years will it take €10,000,000 to double to €20,000,000?

Solution:

Use Equation 2, $FV_N = PV(1 + r)^N$, to solve for the number of periods, N, as follows:

$$\begin{aligned}(1+r)^N &= FV_N/PV = 2\\ N\ln(1+r) &= \ln(2)\\ N &= \ln(2)/\ln(1+r)\\ &= \ln(2)/\ln(1.07) = 10.24\end{aligned}$$

With an interest rate of 7 percent, it will take approximately 10 years for the initial €10,000,000 investment to grow to €20,000,000. Solving for N in the expression $(1.07)^N = 2.0$ requires taking the natural logarithm of both sides and using the rule that $\ln(x^N) = N\ln(x)$. Generally, we find that $N = [\ln(FV/PV)]/\ln(1 + r)$. Here, $N = \ln(€20{,}000{,}000/€10{,}000{,}000)/\ln(1.07) = \ln(2)/\ln(1.07) = 10.24$.[9]

---

[9] To quickly approximate the number of periods, practitioners sometimes use an ad hoc rule called the **Rule of 72**: Divide 72 by the stated interest rate to get the approximate number of years it would take to double an investment at the interest rate. Here, the approximation gives 72/7 = 10.3 years. The Rule of 72 is loosely based on the observation that it takes 12 years to double an amount at a 6 percent interest rate, giving 6 × 12 = 72. At a 3 percent rate, one would guess it would take twice as many years, 3 × 24 = 72.

12 SOLVING FOR SIZE OF ANNUITY PAYMENTS (COMBINING FUTURE VALUE AND PRESENT VALUE ANNUITIES)

e calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;

f demonstrate the use of a time line in modeling and solving time value of money problems.

In this section, we discuss how to solve for annuity payments. Mortgages, auto loans, and retirement savings plans are classic examples of applications of annuity formulas.

EXAMPLE 20

Calculating the Size of Payments on a Fixed-Rate Mortgage

You are planning to purchase a $120,000 house by making a down payment of $20,000 and borrowing the remainder with a 30-year fixed-rate mortgage with monthly payments. The first payment is due at $t = 1$. Current mortgage interest rates are quoted at 8 percent with monthly compounding. What will your monthly mortgage payments be?

Solution:

The bank will determine the mortgage payments such that at the stated periodic interest rate, the present value of the payments will be equal to the amount borrowed (in this case, $100,000). With this fact in mind, we can use Equation 11, $\text{PV} = A\left[\dfrac{1 - \dfrac{1}{(1+r)^N}}{r}\right]$, to solve for the annuity amount, A, as the present value divided by the present value annuity factor:

$$\begin{aligned}
\text{PV} &= \$100{,}000 \\
r_s &= 8\% = 0.08 \\
m &= 12 \\
r_s/m &= 0.08/12 = 0.006667 \\
N &= 30 \\
mN &= 12 \times 30 = 360
\end{aligned}$$

$$\text{Present value annuity factor} = \frac{1 - \dfrac{1}{\left[1 + (r_s/m)\right]^{mN}}}{r_s/m} = \frac{1 - \dfrac{1}{(1.006667)^{360}}}{0.006667}$$

$$\begin{aligned}
&= 136.283494 \\
A &= \text{PV}/\text{Present value annuity factor} \\
&= \$100{,}000/136.283494 \\
&= \$733.76
\end{aligned}$$

The amount borrowed, \$100,000, is equivalent to 360 monthly payments of \$733.76 with a stated interest rate of 8 percent. The mortgage problem is a relatively straightforward application of finding a level annuity payment.

Next, we turn to a retirement-planning problem. This problem illustrates the complexity of the situation in which an individual wants to retire with a specified retirement income. Over the course of a life cycle, the individual may be able to save only a small amount during the early years but then may have the financial resources to save more during later years. Savings plans often involve uneven cash flows, a topic we will examine in the last part of this reading. When dealing with uneven cash flows, we take maximum advantage of the principle that dollar amounts indexed at the same point in time are additive—the **cash flow additivity principle**.

EXAMPLE 21

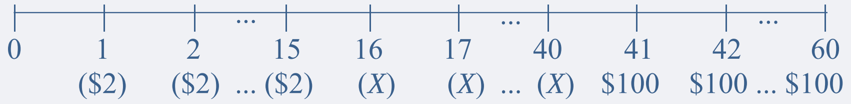
The Projected Annuity Amount Needed to Fund a Future-Annuity Inflow

Jill Grant is 22 years old (at t = 0) and is planning for her retirement at age 63 (at t = 41). She plans to save \$2,000 per year for the next 15 years (t = 1 to t = 15). She wants to have retirement income of \$100,000 per year for 20 years, with the first retirement payment starting at t = 41. How much must Grant save each year from t = 16 to t = 40 in order to achieve her retirement goal? Assume she plans to invest in a diversified stock-and-bond mutual fund that will earn 8 percent per year on average.

Solution:

To help solve this problem, we set up the information on a time line. As Figure 8 shows, Grant will save \$2,000 (an outflow) each year for Years 1 to 15. Starting in Year 41, Grant will start to draw retirement income of \$100,000 per year for 20 years. In the time line, the annual savings is recorded in parentheses (\$2) to show that it is an outflow. The problem is to find the savings, recorded as X, from Year 16 to Year 40.

Figure 8 Solving for Missing Annuity Payments (in Thousands)



Solving this problem involves satisfying the following relationship: the present value of savings (outflows) equals the present value of retirement income (inflows). We could bring all the dollar amounts to t = 40 or to t = 15 and solve for X.

Let us evaluate all dollar amounts at t = 15 (we encourage the reader to repeat the problem by bringing all cash flows to t = 40). As of t = 15, the first payment of X will be one period away (at t = 16). Thus we can value the stream of Xs using the formula for the present value of an ordinary annuity.

This problem involves three series of level cash flows. The basic idea is that the present value of the retirement income must equal the present value of Grant's savings. Our strategy requires the following steps:

1 Find the future value of the savings of \$2,000 per year and index it at t = 15. This value tells us how much Grant will have saved.

2 Find the present value of the retirement income at t = 15. This value tells us how much Grant needs to meet her retirement goals (as of t = 15). Two substeps are necessary. First, calculate the present value of the annuity of \$100,000 per year at t = 40. Use the formula for the present value of an annuity. (Note that the present value is indexed at t = 40 because the first payment is at t = 41.) Next, discount the present value back to t = 15 (a total of 25 periods).

3 Now compute the difference between the amount Grant has saved (Step 1) and the amount she needs to meet her retirement goals (Step 2). Her savings from t = 16 to t = 40 must have a present value equal to the difference between the future value of her savings and the present value of her retirement income.

Our goal is to determine the amount Grant should save in each of the 25 years from t = 16 to t = 40. We start by bringing the \$2,000 savings to t = 15, as follows:

$$
\begin{aligned}
A &= \$2{,}000 \\
r &= 8\% = 0.08 \\
N &= 15 \\
\mathrm{FV} &= A\left[\frac{(1+r)^N - 1}{r}\right] \\
&= \$2{,}000\left[\frac{(1.08)^{15} - 1}{0.08}\right] \\
&= \$2{,}000(27.152114) \\
&= \$54{,}304.23
\end{aligned}
$$

At t = 15, Grant's initial savings will have grown to \$54,304.23.

Now we need to know the value of Grant's retirement income at t = 15. As stated earlier, computing the retirement present value requires two substeps. First, find the present value at t = 40 with the formula in Equation 11; second, discount this present value back to t = 15. Now we can find the retirement income present value at t = 40:

$$
\begin{aligned}
A &= \$100{,}000 \\
r &= 8\% = 0.08 \\
N &= 20 \\
\mathrm{PV} &= A\left[\frac{1 - \dfrac{1}{(1+r)^N}}{r}\right] \\
&= \$100{,}000\left[\frac{1 - \dfrac{1}{(1.08)^{20}}}{0.08}\right] \\
&= \$100{,}000(9.818147) \\
&= \$981{,}814.74
\end{aligned}
$$

The present value amount is as of t = 40, so we must now discount it back as a lump sum to t = 15:

$$\begin{aligned} \mathrm{FV}_N &= \$981{,}814.74 \\ N &= 25 \\ r &= 8\% = 0.08 \\ \mathrm{PV} &= \mathrm{FV}_N (1 + r)^{-N} \\ &= \$981{,}814.74(1.08)^{-25} \\ &= \$981{,}814.74(0.146018) \\ &= \$143{,}362.53 \end{aligned}$$

Now recall that Grant will have saved \$54,304.23 by t = 15. Therefore, in present value terms, the annuity from t = 16 to t = 40 must equal the difference between the amount already saved (\$54,304.23) and the amount required for retirement (\$143,362.53). This amount is equal to \$143,362.53 − \$54,304.23 = \$89,058.30. Therefore, we must now find the annuity payment, A, from t = 16 to t = 40 that has a present value of \$89,058.30. We find the annuity payment as follows:

$$\begin{aligned} \mathrm{PV} &= \$89{,}058.30 \\ r &= 8\% = 0.08 \\ N &= 25 \\ \text{Present value annuity factor} &= \left[\frac{1 - \dfrac{1}{(1 + r)^N}}{r}\right] \\ &= \left[\frac{1 - \dfrac{1}{(1.08)^{25}}}{0.08}\right] \\ &= 10.674776 \\ A &= \mathrm{PV}/\text{Present value annuity factor} \\ &= \$89{,}058.30/10.674776 \\ &= \$8{,}342.87 \end{aligned}$$

Grant will need to increase her savings to \$8,342.87 per year from t = 16 to t = 40 to meet her retirement goal of having a fund equal to \$981,814.74 after making her last payment at t = 40.

PRESENT VALUE AND FUTURE VALUE EQUIVALENCE, ADDITIVITY PRINCIPLE

13

e calculate and interpret the future value (FV) and present value (PV) of a single sum of money, an ordinary annuity, an annuity due, a perpetuity (PV only), and a series of unequal cash flows;

f demonstrate the use of a time line in modeling and solving time value of money problems.

As we have demonstrated, finding present and future values involves moving amounts of money to different points on a time line. These operations are possible because present value and future value are equivalent measures separated in time. Table 5 illustrates this equivalence; it lists the timing of five cash flows, their present values at $t = 0$, and their future values at $t = 5$.

To interpret Table 5, start with the third column, which shows the present values. Note that each \$1,000 cash payment is discounted back the appropriate number of periods to find the present value at $t = 0$. The present value of \$4,329.48 is exactly equivalent to the series of cash flows. This information illustrates an important point: A lump sum can actually generate an annuity. If we place a lump sum in an account that earns the stated interest rate for all periods, we can generate an annuity that is equivalent to the lump sum. Amortized loans, such as mortgages and car loans, are examples of this principle.

Table 5 The Equivalence of Present and Future Values

Time	Cash Flow ($)	Present Value at $t = 0$			Future Value at $t = 5$		
1	1,000	$\$1,000(1.05)^{-1}$	=	\$952.38	$\$1,000(1.05)^{4}$	=	\$1,215.51
2	1,000	$\$1,000(1.05)^{-2}$	=	\$907.03	$\$1,000(1.05)^{3}$	=	\$1,157.63
3	1,000	$\$1,000(1.05)^{-3}$	=	\$863.84	$\$1,000(1.05)^{2}$	=	\$1,102.50
4	1,000	$\$1,000(1.05)^{-4}$	=	\$822.70	$\$1,000(1.05)^{1}$	=	\$1,050.00
5	1,000	$\$1,000(1.05)^{-5}$	=	\$783.53	$\$1,000(1.05)^{0}$	=	\$1,000.00
		Sum:		\$4,329.48	Sum:		\$5,525.64

To see how a lump sum can fund an annuity, assume that we place \$4,329.48 in the bank today at 5 percent interest. We can calculate the size of the annuity payments by using Equation 11. Solving for A, we find

$$A = \frac{\text{PV}}{\dfrac{1 - \left[1/(1+r)^N\right]}{r}}$$

$$= \frac{\$4,329.48}{\dfrac{1 - \left[1/(1.05)^5\right]}{0.05}}$$

$$= \$1,000$$

Table 6 shows how the initial investment of \$4,329.48 can actually generate five \$1,000 withdrawals over the next five years.

To interpret Table 6, start with an initial present value of \$4,329.48 at $t = 0$. From $t = 0$ to $t = 1$, the initial investment earns 5 percent interest, generating a future value of \$4,329.48(1.05) = \$4,545.95. We then withdraw \$1,000 from our account, leaving \$4,545.95 – \$1,000 = \$3,545.95 (the figure reported in the last column for time period 1). In the next period, we earn one year's worth of interest and then make a \$1,000 withdrawal. After the fourth withdrawal, we have \$952.38, which earns 5 percent. This amount then grows to \$1,000 during the year, just enough for us to make the last withdrawal. Thus the initial present value, when invested at 5 percent for five years, generates the \$1,000 five-year ordinary annuity. The present value of the initial investment is exactly equivalent to the annuity.

Now we can look at how future value relates to annuities. In Table 5, we reported that the future value of the annuity was \$5,525.64. We arrived at this figure by compounding the first \$1,000 payment forward four periods, the second \$1,000 forward three periods, and so on. We then added the five future amounts at $t = 5$. The annuity is equivalent to \$5,525.64 at $t = 5$ and \$4,329.48 at $t = 0$. These two dollar measures are thus equivalent. We can verify the equivalence by finding the present value of \$5,525.64, which is $\$5,525.64 \times (1.05)^{-5} = \$4,329.48$. We found this result above when we showed that a lump sum can generate an annuity.

Table 6 How an Initial Present Value Funds an Annuity

Time Period	Amount Available at the Beginning of the Time Period (\$)	Ending Amount before Withdrawal			Withdrawal (\$)	Amount Available after Withdrawal (\$)
1	4,329.48	\$4,329.48(1.05)	=	\$4,545.95	1,000	3,545.95
2	3,545.95	\$3,545.95(1.05)	=	\$3,723.25	1,000	2,723.25
3	2,723.25	\$2,723.25(1.05)	=	\$2,859.41	1,000	1,859.41
4	1,859.41	\$1,859.41(1.05)	=	\$1,952.38	1,000	952.38
5	952.38	\$952.38(1.05)	=	\$1,000	1,000	0

To summarize what we have learned so far: A lump sum can be seen as equivalent to an annuity, and an annuity can be seen as equivalent to its future value. Thus present values, future values, and a series of cash flows can all be considered equivalent as long as they are indexed at the same point in time.

13.1 The Cash Flow Additivity Principle

The cash flow additivity principle—the idea that amounts of money indexed at the same point in time are additive—is one of the most important concepts in time value of money mathematics. We have already mentioned and used this principle; this section provides a reference example for it.

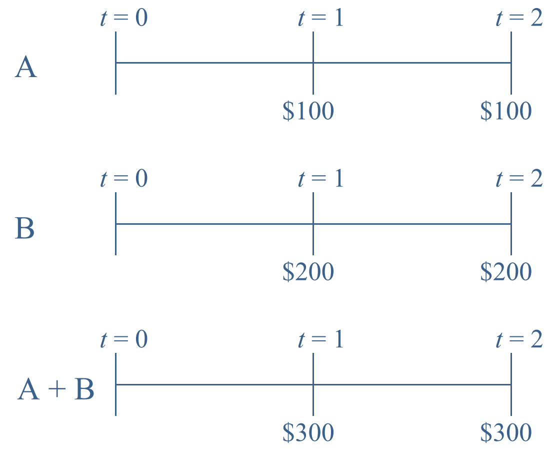
Consider the two series of cash flows shown on the time line in Figure 9. The series are denoted A and B. If we assume that the annual interest rate is 2 percent, we can find the future value of each series of cash flows as follows. Series A's future value is \$100(1.02) + \$100 = \$202. Series B's future value is \$200(1.02) + \$200 = \$404. The future value of (A + B) is \$202 + \$404 = \$606 by the method we have used up to this point. The alternative way to find the future value is to add the cash flows of each series, A and B (call it A + B), and then find the future value of the combined cash flow, as shown in Figure 9.

The third time line in Figure 9 shows the combined series of cash flows. Series A has a cash flow of \$100 at $t = 1$, and Series B has a cash flow of \$200 at $t = 1$. The combined series thus has a cash flow of \$300 at $t = 1$. We can similarly calculate the cash flow of the combined series at $t = 2$. The future value of the combined series (A + B) is \$300(1.02) + \$300 = \$606—the same result we found when we added the future values of each series.

The additivity and equivalence principles also appear in another common situation. Suppose cash flows are \$4 at the end of the first year and \$24 (actually separate payments of \$4 and \$20) at the end of the second year. Rather than finding present values of the first year's \$4 and the second year's \$24, we can treat this situation as a

$4 annuity for two years and a second-year $20 lump sum. If the discount rate were 6 percent, the $4 annuity would have a present value of $7.33 and the $20 lump sum a present value of $17.80, for a total of $25.13.

Figure 9 The Additivity of Two Series of Cash Flows



SUMMARY

In this reading, we have explored a foundation topic in investment mathematics, the time value of money. We have developed and reviewed the following concepts for use in financial applications:

- The interest rate, r, is the required rate of return; r is also called the discount rate or opportunity cost.
- An interest rate can be viewed as the sum of the real risk-free interest rate and a set of premiums that compensate lenders for risk: an inflation premium, a default risk premium, a liquidity premium, and a maturity premium.
- The future value, FV, is the present value, PV, times the future value factor, $(1 + r)^N$.
- The interest rate, r, makes current and future currency amounts equivalent based on their time value.
- The stated annual interest rate is a quoted interest rate that does not account for compounding within the year.
- The periodic rate is the quoted interest rate per period; it equals the stated annual interest rate divided by the number of compounding periods per year.
- The effective annual rate is the amount by which a unit of currency will grow in a year with interest on interest included.
- An annuity is a finite set of level sequential cash flows.
- There are two types of annuities, the annuity due and the ordinary annuity. The annuity due has a first cash flow that occurs immediately; the ordinary annuity has a first cash flow that occurs one period from the present (indexed at $t = 1$).

- On a time line, we can index the present as 0 and then display equally spaced hash marks to represent a number of periods into the future. This representation allows us to index how many periods away each cash flow will be paid.
- Annuities may be handled in a similar approach as single payments if we use annuity factors rather than single-payment factors.
- The present value, PV, is the future value, FV, times the present value factor, $(1 + r)^{-N}$.
- The present value of a perpetuity is A/r, where A is the periodic payment to be received forever.
- It is possible to calculate an unknown variable, given the other relevant variables in time value of money problems.
- The cash flow additivity principle can be used to solve problems with uneven cash flows by combining single payments and annuities.

PRACTICE PROBLEMS

1 The table below gives current information on the interest rates for two two-year and two eight-year maturity investments. The table also gives the maturity, liquidity, and default risk characteristics of a new investment possibility (Investment 3). All investments promise only a single payment (a payment at maturity). Assume that premiums relating to inflation, liquidity, and default risk are constant across all time horizons.

Investment	Maturity (in Years)	Liquidity	Default Risk	Interest Rate (%)
1	2	High	Low	2.0
2	2	Low	Low	2.5
3	7	Low	Low	r_3
4	8	High	Low	4.0
5	8	Low	High	6.5

Based on the information in the above table, address the following:

A Explain the difference between the interest rates on Investment 1 and Investment 2.

B Estimate the default risk premium.

C Calculate upper and lower limits for the interest rate on Investment 3, r_3.

2 A couple plans to set aside $20,000 per year in a conservative portfolio projected to earn 7 percent a year. If they make their first savings contribution one year from now, how much will they have at the end of 20 years?

3 Two years from now, a client will receive the first of three annual payments of $20,000 from a small business project. If she can earn 9 percent annually on her investments and plans to retire in six years, how much will the three business project payments be worth at the time of her retirement?

4 To cover the first year's total college tuition payments for his two children, a father will make a $75,000 payment five years from now. How much will he need to invest today to meet his first tuition goal if the investment earns 6 percent annually?

5 A client can choose between receiving 10 annual $100,000 retirement payments, starting one year from today, or receiving a lump sum today. Knowing that he can invest at a rate of 5 percent annually, he has decided to take the lump sum. What lump sum today will be equivalent to the future annual payments?

6 You are considering investing in two different instruments. The first instrument will pay nothing for three years, but then it will pay $20,000 per year for four years. The second instrument will pay $20,000 for three years and $30,000 in the fourth year. All payments are made at year-end. If your required rate of return on these investments is 8 percent annually, what should you be willing to pay for:

A The first instrument?

B The second instrument (use the formula for a four-year annuity)?

© 2016 CFA Institute. All rights reserved.

7 Suppose you plan to send your daughter to college in three years. You expect her to earn two-thirds of her tuition payment in scholarship money, so you estimate that your payments will be $10,000 a year for four years. To estimate whether you have set aside enough money, you ignore possible inflation in tuition payments and assume that you can earn 8 percent annually on your investments. How much should you set aside now to cover these payments?

8 A client plans to send a child to college for four years starting 18 years from now. Having set aside money for tuition, she decides to plan for room and board also. She estimates these costs at $20,000 per year, payable at the beginning of each year, by the time her child goes to college. If she starts next year and makes 17 payments into a savings account paying 5 percent annually, what annual payments must she make?

9 A couple plans to pay their child's college tuition for 4 years starting 18 years from now. The current annual cost of college is C$7,000, and they expect this cost to rise at an annual rate of 5 percent. In their planning, they assume that they can earn 6 percent annually. How much must they put aside each year, starting next year, if they plan to make 17 equal payments?

10 The nominal risk-free rate is *best* described as the sum of the real risk-free rate and a premium for:

A maturity.

B liquidity.

C expected inflation.

11 Which of the following risk premiums is most relevant in explaining the difference in yields between 30-year bonds issued by the US Treasury and 30-year bonds issued by a small private issuer?

A Inflation

B Maturity

C Liquidity

12 A bank quotes a stated annual interest rate of 4.00%. If that rate is equal to an effective annual rate of 4.08%, then the bank is compounding interest:

A daily.

B quarterly.

C semiannually.

13 The value in six years of $75,000 invested today at a stated annual interest rate of 7% compounded quarterly is *closest* to:

A $112,555.

B $113,330.

C $113,733.

14 A client requires £100,000 one year from now. If the stated annual rate is 2.50% compounded weekly, the deposit needed today is *closest* to:

A £97,500.

B £97,532.

C £97,561.

15 For a lump sum investment of ¥250,000 invested at a stated annual rate of 3% compounded daily, the number of months needed to grow the sum to ¥1,000,000 is *closest* to:

A 555.

B 563.

C 576.

16 Given a €1,000,000 investment for four years with a stated annual rate of 3% compounded continuously, the difference in its interest earnings compared with the same investment compounded daily is *closest* to:

A €1.

B €6.

C €455.

17 An investment pays €300 annually for five years, with the first payment occurring today. The present value (PV) of the investment discounted at a 4% annual rate is *closest* to:

A €1,336.

B €1,389.

C €1,625.

18 A perpetual preferred stock makes its first quarterly dividend payment of $2.00 in five quarters. If the required annual rate of return is 6% compounded quarterly, the stock's present value is *closest* to:

A $31.

B $126.

C $133.

19 A saver deposits the following amounts in an account paying a stated annual rate of 4%, compounded semiannually:

Year	End of Year Deposits ($)
1	4,000
2	8,000
3	7,000
4	10,000

At the end of Year 4, the value of the account is *closest* to:

A $30,432

B $30,447

C $31,677

20 An investment of €500,000 today that grows to €800,000 after six years has a stated annual interest rate *closest* to:

A 7.5% compounded continuously.

B 7.7% compounded daily.

C 8.0% compounded semiannually.

21 A sweepstakes winner may select either a perpetuity of £2,000 a month beginning with the first payment in one month or an immediate lump sum payment of £350,000. If the annual discount rate is 6% compounded monthly, the present value of the perpetuity is:

A less than the lump sum.

B equal to the lump sum.

C greater than the lump sum.

22 At a 5% interest rate per year compounded annually, the present value (PV) of a 10-year ordinary annuity with annual payments of $2,000 is $15,443.47. The PV of a 10-year annuity due with the same interest rate and payments is *closest* to:

A $14,708.

B $16,216.

C $17,443.

23 Grandparents are funding a newborn's future university tuition costs, estimated at $50,000/year for four years, with the first payment due as a lump sum in 18 years. Assuming a 6% effective annual rate, the required deposit today is *closest* to:

A $60,699.

B $64,341.

C $68,201.

24 The present value (PV) of an investment with the following year-end cash flows (CF) and a 12% required annual rate of return is *closest* to:

Year	Cash Flow (€)
1	100,000
2	150,000
5	–10,000

A €201,747.

B €203,191.

C €227,573.

25 A sports car, purchased for £200,000, is financed for five years at an annual rate of 6% compounded monthly. If the first payment is due in one month, the monthly payment is *closest* to:

A £3,847.

B £3,867.

C £3,957.

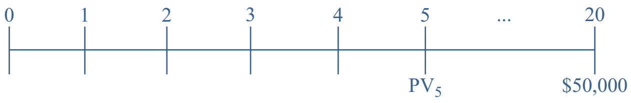
26 Given a stated annual interest rate of 6% compounded quarterly, the level amount that, deposited quarterly, will grow to £25,000 at the end of 10 years is *closest* to:

A £461.

B £474.

C £836.

27 Given the following timeline and a discount rate of 4% a year compounded annually, the present value (PV), as of the end of Year 5 (PV_5), of the cash flow received at the end of Year 20 is *closest* to:



A $22,819.

B $27,763.

C $28,873.

28 A client invests €20,000 in a four-year certificate of deposit (CD) that annually pays interest of 3.5%. The annual CD interest payments are automatically reinvested in a separate savings account at a stated annual interest rate of 2% compounded monthly. At maturity, the value of the combined asset is *closest* to:

A €21,670.

B €22,890.

C €22,950.

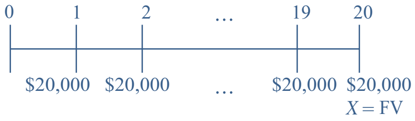
SOLUTIONS

1 **A** Investment 2 is identical to Investment 1 except that Investment 2 has low liquidity. The difference between the interest rate on Investment 2 and Investment 1 is 0.5 percentage point. This amount represents the liquidity premium, which represents compensation for the risk of loss relative to an investment's fair value if the investment needs to be converted to cash quickly.

B To estimate the default risk premium, find the two investments that have the same maturity but different levels of default risk. Both Investments 4 and 5 have a maturity of eight years. Investment 5, however, has low liquidity and thus bears a liquidity premium. The difference between the interest rates of Investments 5 and 4 is 2.5 percentage points. The liquidity premium is 0.5 percentage point (from Part A). This leaves 2.5 − 0.5 = 2.0 percentage points that must represent a default risk premium reflecting Investment 5's high default risk.

C Investment 3 has liquidity risk and default risk comparable to Investment 2, but with its longer time to maturity, Investment 3 should have a higher maturity premium. The interest rate on Investment 3, r_3, should thus be above 2.5 percent (the interest rate on Investment 2). If the liquidity of Investment 3 were high, Investment 3 would match Investment 4 except for Investment 3's shorter maturity. We would then conclude that Investment 3's interest rate should be less than the interest rate on Investment 4, which is 4 percent. In contrast to Investment 4, however, Investment 3 has low liquidity. It is possible that the interest rate on Investment 3 exceeds that of Investment 4 despite 3's shorter maturity, depending on the relative size of the liquidity and maturity premiums. However, we expect r_3 to be less than 4.5 percent, the expected interest rate on Investment 4 if it had low liquidity. Thus 2.5 percent $< r_3 <$ 4.5 percent.

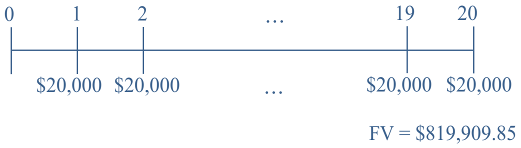
2 **i.** Draw a time line.



ii. Identify the problem as the future value of an annuity.

iii. Use the formula for the future value of an annuity.

$$\begin{aligned}\text{FV}_N &= A\left[\frac{(1+r)^N - 1}{r}\right]\\ &= \$20{,}000\left[\frac{(1+0.07)^{20} - 1}{0.07}\right]\\ &= \$819{,}909.85\end{aligned}$$



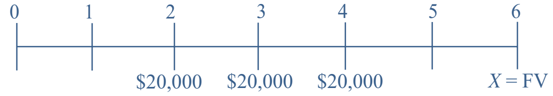
iv. Alternatively, use a financial calculator.

Notation Used on Most Calculators	**Numerical Value for This Problem**
N	20
%i	7
PV	n/a (= 0)
FV **compute**	X
PMT	$20,000

Enter 20 for N, the number of periods. Enter 7 for the interest rate and 20,000 for the payment size. The present value is not needed, so enter 0. Calculate the future value. Verify that you get $819,909.85 to make sure you have mastered your calculator's keystrokes.

In summary, if the couple sets aside $20,000 each year (starting next year), they will have $819,909.85 in 20 years if they earn 7 percent annually.

3 **i.** Draw a time line.



ii. Recognize the problem as the future value of a delayed annuity. Delaying the payments requires two calculations.

iii. Use the formula for the future value of an annuity (Equation 7).

$$\mathrm{FV}_N = A\left[\frac{(1+r)^N - 1}{r}\right]$$

to bring the three $20,000 payments to an equivalent lump sum of $65,562.00 four years from today.

Notation Used on Most Calculators	**Numerical Value for This Problem**
N	3
%i	9
PV	n/a (= 0)
FV **compute**	X
PMT	$20,000

iv. Use the formula for the future value of a lump sum (Equation 2), $\mathrm{FV}_N = \mathrm{PV}(1 + r)^N$, to bring the single lump sum of $65,562.00 to an equivalent lump sum of $77,894.21 six years from today.

Notation Used on Most Calculators	**Numerical Value for This Problem**
N	2

PV = $772,173.49

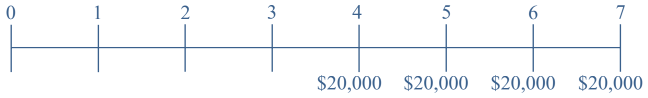
iv. Alternatively, use a financial calculator.

Notation Used on Most Calculators	**Numerical Value for This Problem**
N	10
$\%i$	5
PV **compute**	X
FV	n/a (= 0)
PMT	$100,000

In summary, the present value of 10 payments of $100,000 is $772,173.49 if the first payment is received in one year and the rate is 5 percent compounded annually. Your client should accept no less than this amount for his lump sum payment.

6 **A** To evaluate the first instrument, take the following steps:

i. Draw a time line.



ii.

$$\begin{aligned} \text{PV}_3 &= A\left[\frac{1-\dfrac{1}{(1+r)^N}}{r}\right] \\ &= \$20{,}000\left[\frac{1-\dfrac{1}{(1+0.08)^4}}{0.08}\right] \\ &= \$66{,}242.54 \end{aligned}$$

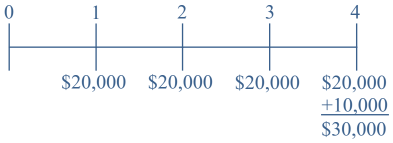
iii.

$$\text{PV}_0 = \frac{\text{PV}_3}{(1+r)^N} = \frac{\$66{,}242.54}{1.08^3} = \$52{,}585.46$$

You should be willing to pay $52,585.46 for this instrument.

B To evaluate the second instrument, take the following steps:

i. Draw a time line.



The time line shows that this instrument can be analyzed as an ordinary annuity of $20,000 with four payments (valued in Step ii below) and a $10,000 payment to be received at t = 4 (valued in Step iii below).

ii.

$$\begin{aligned}\text{PV} &= A\left[\frac{1-\dfrac{1}{(1+r)^N}}{r}\right]\\ &= \$20{,}000\left[\frac{1-\dfrac{1}{(1+0.08)^4}}{0.08}\right]\\ &= \$66{,}242.54\end{aligned}$$

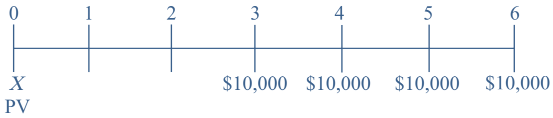
iii.

$$\text{PV} = \frac{\text{FV}_4}{(1+r)^N} = \frac{\$10{,}000}{(1+0.08)^4} = \$7{,}350.30$$

iv. Total = \$66,242.54 + \$7,350.30 = \$73,592.84

You should be willing to pay \$73,592.84 for this instrument.

7 **i.** Draw a time line.



ii. Recognize the problem as a delayed annuity. Delaying the payments requires two calculations.

iii. Use the formula for the present value of an annuity (Equation 11).

$$\text{PV} = A\left[\frac{1-\dfrac{1}{(1+r)^N}}{r}\right]$$

to bring the four payments of \$10,000 back to a single equivalent lump sum of \$33,121.27 at $t = 2$. Note that we use $t = 2$ because the first annuity payment is then one period away, giving an ordinary annuity.

Notation Used on Most Calculators	Numerical Value for This Problem
N	4
%i	8
PV **compute**	X
PMT	\$10,000

iv. Then use the formula for the present value of a lump sum (Equation 8), $\text{PV} = \text{FV}_N(1 + r)^{-N}$, to bring back the single payment of \$33,121.27 (at $t = 2$) to an equivalent single payment of \$28,396.15 (at $t = 0$).

Notation Used on Most Calculators	Numerical Value for This Problem

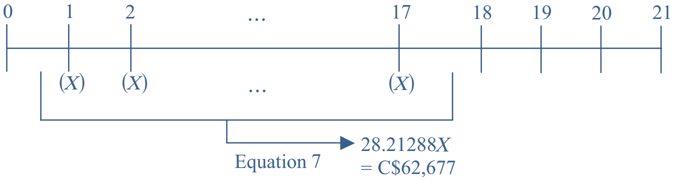
iv. Using the formula for the present value of a lump sum (r = 6%), equate the four college payments to single payments as of t = 17 and add them together. $C\$16{,}846(1.06)^{-1} + C\$17{,}689(1.06)^{-2} + C\$18{,}573(1.06)^{-3} + C\$19{,}502(1.06)^{-4} = C\$62{,}677$

v. Equate the sum of C$62,677 at t = 17 to the 17 payments of X, using the formula for the future value of an annuity (Equation 7). Then solve for X.

$$C\$62{,}677 = X\left[\frac{(1.06)^{17} - 1}{0.06}\right] = 28.21288X$$

$$X = C\$2{,}221.58$$

Notation Used on Most Calculators	**Numerical Value for This Problem**
N	17
$\%i$	6
PV	n/a (= 0)
FV	C$62,677
PMT **compute**	X



In summary, the couple will need to put aside C$2,221.58 each year if they start next year and make 17 equal payments.

10 C is correct. The sum of the real risk-free interest rate and the inflation premium is the nominal risk-free rate.

11 C is correct. US Treasury bonds are highly liquid, whereas the bonds of small issuers trade infrequently and the interest rate includes a liquidity premium. This liquidity premium reflects the relatively high costs (including the impact on price) of selling a position.

12 A is correct. The effective annual rate (EAR) when compounded daily is 4.08%.

$$\text{EAR} = (1 + \text{Periodic interest rate})^m - 1$$

$$\text{EAR} = (1 + 0.04/365)^{365} - 1$$

$$\text{EAR} = (1.0408) - 1 = 0.04081 \approx 4.08\%.$$

13 C is correct, as shown in the following (where FV is future value and PV is present value):

$$\text{FV} = \text{PV}\left(1 + \frac{r_s}{m}\right)^{mN}$$

$$\text{FV}_6 = \$75{,}000\left(1 + \frac{0.07}{4}\right)^{(4\times6)}$$

$$\text{FV}_6 = \$113{,}733.21.$$

14 B is correct because £97,531 represents the present value (PV) of £100,000 received one year from today when today's deposit earns a stated annual rate of 2.50% and interest compounds weekly, as shown in the following equation (where FV is future value):

$$\text{PV} = \text{FV}_N\left(1 + \frac{r_s}{m}\right)^{-mN}$$

$$\text{PV} = £100{,}000\left(1 + \frac{0.025}{52}\right)^{-52}$$

$$\text{PV} = £97{,}531.58.$$

15 A is correct. The effective annual rate (EAR) is calculated as follows:

$$\text{EAR} = (1 + \text{Periodic interest rate})^m - 1$$

$$\text{EAR} = (1 + 0.03/365)^{365} - 1$$

$$\text{EAR} = (1.03045) - 1 = 0.030453 \approx 3.0453\%.$$

Solving for N on a financial calculator results in (where FV is future value and PV is present value):

$(1 + 0.030453)^N = \text{FV}_N/\text{PV} = ¥1{,}000{,}000/¥250{,}000$

= 46.21 years, which multiplied by 12 to convert to months results in 554.5, or ≈ 555 months.

16 B is correct. The difference between continuous compounding and daily compounding is

€127,496.85 – €127,491.29 = €5.56, or ≈ €6, as shown in the following calculations.

With continuous compounding, the investment earns (where PV is present value)

$$\begin{aligned} \text{PV}e^{r_s N} - \text{PV} &= €1{,}000{,}000e^{0.03(4)} - €1{,}000{,}000 \\ &= €1{,}127{,}496.85 - €1{,}000{,}000 \\ &= €127{,}496.85 \end{aligned}$$

With daily compounding, the investment earns:

$€1{,}000{,}000(1 + 0.03/365)^{365(4)} - €1{,}000{,}000 = €1{,}127{,}491.29 - €1{,}000{,}000 = €127{,}491.29$.

17 B is correct, as shown in the following calculation for an annuity (A) due:

$$\text{PV} = A\left[\frac{1 - \dfrac{1}{(1+r)^N}}{r}\right](1 + r)$$

where A = €300, r = 0.04, and N = 5.

$$\text{PV} = €300\left[\frac{1 - \dfrac{1}{(1+.04)^5}}{.04}\right](1.04)$$

PV = €1,388.97, or ≈ €1,389.

18 B is correct. The value of the perpetuity one year from now is calculated as:

PV = A/r, where PV is present value, A is annuity, and r is expressed as a quarterly required rate of return because the payments are quarterly.

PV = \$2.00/(0.06/4)

PV = \$133.33.

The value today is (where FV is future value)

$\text{PV} = \text{FV}_N(1 + r)^{-N}$

$\text{PV} = \$133.33(1 + 0.015)^{-4}$

PV = \$125.62 ≈ \$126.

19 B is correct. To solve for the future value of unequal cash flows, compute the future value of each payment as of Year 4 at the semiannual rate of 2%, and then sum the individual future values, as follows:

Year	End of Year Deposits ($)	Factor	Future Value ($)
1	4,000	$(1.02)^6$	4,504.65
2	8,000	$(1.02)^4$	8,659.46
3	7,000	$(1.02)^2$	7,282.80
4	10,000	$(1.02)^0$	10,000.00
		Sum =	30,446.91

20 C is correct, as shown in the following (where FV is future value and PV is present value):

If:

$$\mathrm{FV}_N = \mathrm{PV}\left(1+\frac{r_s}{m}\right)^{mN}$$

Then:

$$\left(\frac{\mathrm{FV}_N}{\mathrm{PV}}\right)^{\frac{1}{mN}} - 1 = \frac{r_s}{m}$$

$$\left(\frac{800{,}000}{500{,}000}\right)^{\frac{1}{2\times 6}} - 1 = \frac{r_s}{2}$$

$r_s = 0.07988$ (rounded to 8.0%).

21 C is correct. As shown below, the present value (PV) of a £2,000 per month perpetuity is worth approximately £400,000 at a 6% annual rate compounded monthly. Thus, the present value of the annuity (A) is worth more than the lump sum offers.

A = £2,000

r = (6%/12) = 0.005

PV = (A/r)

PV = (£2,000/0.005)

PV = £400,000

22 B is correct.

The present value of a 10-year annuity (A) due with payments of $2,000 at a 5% discount rate is calculated as follows:

$$\mathrm{PV} = A\left[\frac{1-\frac{1}{(1+r)^N}}{r}\right] + \$2{,}000$$

$$PV = \$2{,}000\left[\frac{1-\dfrac{1}{(1+0.05)^9}}{0.05}\right] + \$2{,}000$$

PV = \$16,215.64.

Alternatively, the PV of a 10-year annuity due is simply the PV of the ordinary annuity multiplied by 1.05:

$PV = \$15{,}443.47 \times 1.05$

PV = \$16,215.64.

23 B is correct. First, find the present value (PV) of an ordinary annuity in Year 17 that represents the tuition costs:

$$\$50{,}000\left[\frac{1-\dfrac{1}{(1+0.06)^4}}{0.06}\right]$$

$= \$50{,}000 \times 3.4651$

= \$173,255.28.

Then, find the PV of the annuity in today's dollars (where FV is future value):

$$PV_0 = \frac{FV}{(1+0.06)^{17}}$$

$$PV_0 = \frac{\$173{,}255.28}{(1+0.06)^{17}}$$

$PV_0 = \$64{,}340.85 \approx \$64{,}341.$

24 B is correct, as shown in the following table.

Year	Cash Flow (€)	Formula CF × (1 + *r*)^t	PV at Year 0
1	100,000	$100{,}000(1.12)^{-1}$ =	89,285.71
2	150,000	$150{,}000(1.12)^{-2}$ =	119,579.08
5	–10,000	$-10{,}000(1.12)^{-5}$ =	–5,674.27
			203,190.52

25 B is correct, calculated as follows (where A is annuity and PV is present value):

$$A = (\text{PV of annuity}) \Bigg/ \left[\frac{1 - \dfrac{1}{(1 + r_s/m)^{mN}}}{r_s/m} \right]$$

$$= (£200{,}000) \Bigg/ \left[\frac{1 - \dfrac{1}{(1 + r_s/m)^{mN}}}{r_s/m} \right]$$

$$(£200{,}000) \Bigg/ \left[\frac{1 - \dfrac{1}{(1 + 0.06/12)^{12(5)}}}{0.06/12} \right]$$

$$= (£200{,}000)/51.72556$$

$$= £3{,}866.56$$

26 A is correct. To solve for an annuity (A) payment, when the future value (FV), interest rate, and number of periods is known, use the following equation:

$$\text{FV} = A \left[\frac{\left(1 + \dfrac{r_s}{m}\right)^{mN} - 1}{\dfrac{r}{m}} \right]$$

$$£25{,}000 = A \left[\frac{\left(1 + \dfrac{0.06}{4}\right)^{4 \times 10} - 1}{\dfrac{0.06}{4}} \right]$$

$$A = £460.68$$

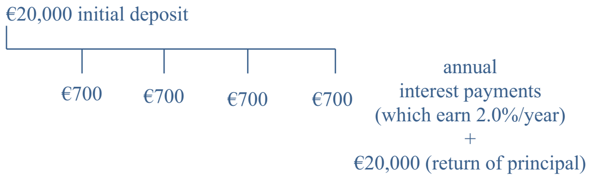
27 B is correct. The PV in Year 5 of a \$50,000 lump sum paid in Year 20 is \$27,763.23 (where FV is future value):

$$\text{PV} = \text{FV}_N(1 + r)^{-N}$$

$$\text{PV} = \$50{,}000(1 + 0.04)^{-15}$$

$$\text{PV} = \$27{,}763.23$$

28 B is correct, as the following cash flows show:



€20,000 initial deposit
€700
€700
€700
€700
annual
interest payments
(which earn 2.0%/year)
+
€20,000 (return of principal)

The four annual interest payments are based on the CD's 3.5% annual rate.

The first payment grows at 2.0% compounded monthly for three years (where FV is future value):

$$\text{FV}_N = €700\left(1 + \frac{0.02}{12}\right)^{3\times12}$$

$$\text{FV}_N = 743.25$$

The second payment grows at 2.0% compounded monthly for two years:

$$\text{FV}_N = €700\left(1 + \frac{0.02}{12}\right)^{2\times12}$$

$$\text{FV}_N = 728.54$$

The third payment grows at 2.0% compounded monthly for one year:

$$\text{FV}_N = €700\left(1 + \frac{0.02}{12}\right)^{1\times12}$$

$$\text{FV}_N = 714.13$$

The fourth payment is paid at the end of Year 4. Its future value is €700.

The sum of all future value payments is as follows:

€20,000.00	CD
€743.25	First payment's *FV*
€728.54	Second payment's *FV*
€714.13	Third payment's *FV*
€700.00	Fourth payment's *FV*
€22,885.92	Total *FV*

Organizing, Visualizing, and Describing Data

by Pamela Peterson Drake, PhD, CFA, and Jian Wu, PhD

Pamela Peterson Drake, PhD, CFA, is at James Madison University (USA). Jian Wu, PhD, is at State Street (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** identify and compare data types;
☐	**b.** describe how data are organized for quantitative analysis;
☐	**c.** interpret frequency and related distributions;
☐	**d.** interpret a contingency table;
☐	**e.** describe ways that data may be visualized and evaluate uses of specific visualizations;
☐	**f.** describe how to select among visualization types;
☐	**g.** calculate and interpret measures of central tendency;
☐	**h.** evaluate alternative definitions of mean to address an investment problem;
☐	**i.** calculate quantiles and interpret related visualizations;
☐	**j.** calculate and interpret measures of dispersion;
☐	**k.** calculate and interpret target downside deviation;
☐	**l.** interpret skewness;
☐	**m.** interpret kurtosis;
☐	**n.** interpret correlation between two variables.

1 INTRODUCTION

Data have always been a key input for securities analysis and investment management, but the acceleration in the availability and the quantity of data has also been driving the rapid evolution of the investment industry. With the rise of big data and machine learning techniques, investment practitioners are embracing an era featuring large volume, high velocity, and a wide variety of data—allowing them to explore and exploit this abundance of information for their investment strategies.

While this data-rich environment offers potentially tremendous opportunities for investors, turning data into useful information is not so straightforward. Organizing, cleaning, and analyzing data are crucial to the development of successful investment strategies; otherwise, we end up with "garbage in and garbage out" and failed investments. It is often said that 80% of an analyst's time is spent on finding, organizing, cleaning, and analyzing data, while just 20% of her/his time is taken up by model development. So, the importance of having a properly organized, cleansed, and well-analyzed dataset cannot be over-emphasized. With this essential requirement met, an appropriately executed data analysis can detect important relationships within data, uncover underlying structures, identify outliers, and extract potentially valuable insights. Utilizing both visual tools and quantitative methods, like the ones covered in this reading, is the first step in summarizing and understanding data that will be crucial inputs to an investment strategy.

This reading provides a foundation for understanding important concepts that are an indispensable part of the analytical tool kit needed by investment practitioners, from junior analysts to senior portfolio managers. These basic concepts pave the way for more sophisticated tools that will be developed as the quantitative methods topic unfolds and that are integral to gaining competencies in the investment management techniques and asset classes that are presented later in the CFA curriculum.

Section 2 covers core data types, including continuous and discrete numerical data, nominal and ordinal categorical data, and structured versus unstructured data. Organizing data into arrays and data tables and summarizing data in frequency distributions and contingency tables are discussed in Sections 3–5. Section 6 introduces the important topic of data visualization using a range of charts and graphics to summarize, explore, and better understand data. Section 7 covers the key measures of central tendency, including several variants of mean that are especially useful in investments. Quantiles and their investment applications are the focus of Section 8. Key measures of dispersion are discussed in Sections 9 and 10. The shape of data distributions—specifically, skewness and kurtosis—are covered in Section 11. Section 12 provides a graphical introduction to covariance and correlation between two variables. The reading concludes with a Summary.

2 DATA TYPES

a Identify and compare data types

Data can be defined as a collection of numberpanel datas, characters, words, and text—as well as images, audio, and video—in a raw or organized format to represent facts or information. To choose the appropriate statistical methods for summarizing and analyzing data and to select suitable charts for visualizing data, we need to distinguish among different data types. We will discuss data types under three different perspectives of classifications: numerical versus categorical data; cross-sectional vs. time-series vs. panel data; and structured vs. unstructured data.

2.1 Numerical versus Categorical Data

From a statistical perspective, data can be classified into two basic groups: numerical data and categorical data.

2.1.1 *Numerical Data*

Numerical data are values that represent measured or counted quantities as a number and are also called **quantitative data**. Numerical (quantitative) data can be split into two types: continuous data and discrete data.

Continuous data are data that can be measured and can take on any numerical value in a specified range of values. For example, the future value of a lump-sum investment measures the amount of money to be received after a certain period of time bearing an interest rate. The future value could take on a range of values depending on the time period and interest rate. Another common example of continuous data is the price returns of a stock that measures price change over a given period in percentage terms.

Discrete data are numerical values that result from a counting process. So, practically speaking, the data are limited to a finite number of values. For example, the frequency of discrete compounding, m, counts the number of times that interest is accrued and paid out in a given year. The frequency could be monthly ($m = 12$), quarterly ($m = 4$), semi-yearly ($m = 2$), or yearly ($m = 1$).

2.1.2 *Categorical Data*

Categorical data (also called **qualitative data**) are values that describe a quality or characteristic of a group of observations and therefore can be used as labels to divide a dataset into groups to summarize and visualize. Usually they can take only a limited number of values that are mutually exclusive. Examples of categorical data for classifying companies include bankrupt vs. not bankrupt and dividends increased vs. no dividend action.

Nominal data are categorical values that are not amenable to being organized in a logical order. An example of nominal data is the classification of publicly listed stocks into 11 sectors, as shown in Exhibit 1, that are defined by the Global Industry Classification Standard (GICS). GICS, developed by Morgan Stanley Capital International (MSCI) and Standard & Poor's (S&P), is a four-tiered, hierarchical industry classification system consisting of 11 sectors, 24 industry groups, 69 industries, and 158 sub-industries. Each sector is defined by a unique text label, as shown in the column named "Sector."

Exhibit 1 Equity Sector Classification by GICS

Sector (Text Label)	Code (Numerical Label)
Energy	10
Materials	15
Industrials	20
Consumer Discretionary	25
Consumer Staples	30
Health Care	35
Financials	40
Information Technology	45
Communication Services	50

(continued)

Exhibit 1 (Continued)

Sector (Text Label)	Code (Numerical Label)
Utilities	55
Real Estate	60

Source: S&P Global Market Intelligence.

Text labels are a common format to represent nominal data, but nominal data can also be coded with numerical labels. As shown below, the column named "Code" contains a corresponding GICS code of each sector as a numerical value. However, the nominal data in numerical format do not indicate ranking, and any arithmetic operations on nominal data are not meaningful. In this example, the energy sector with the code 10 does not represent a lower or higher rank than the real estate sector with the code 60. Often, financial models, such as regression models, require input data to be numerical; so, nominal data in the input dataset must be coded numerically before applying an algorithm (that is, a process for problem solving) for performing the analysis. This would be mainly to identify the category (here, sector) in the model.

Ordinal data are categorical values that can be logically ordered or ranked. For example, the Morningstar and Standard & Poor's star ratings for investment funds are ordinal data in which one star represents a group of funds judged to have had relatively the worst performance, with two, three, four, and five stars representing groups with increasingly better performance or quality as evaluated by those firms.

Ordinal data may also involve numbers to identify categories. For example, in ranking growth-oriented investment funds based on their five-year cumulative returns, we might assign the number 1 to the top performing 10% of funds, the number 2 to next best performing 10% of funds, and so on; the number 10 represents the bottom performing 10% of funds. Despite the fact that categories represented by ordinal data can be ranked higher or lower compared to each other, they do not necessarily establish a numerical difference between each category. Importantly, such investment fund ranking tells us nothing about the difference in performance between funds ranked 1 and 2 compared with the difference in performance between funds ranked 3 and 4 or 9 and 10.

Having discussed different data types from a statistical perspective, it is important to note that at first glance, identifying data types may seem straightforward. In some situations, where categorical data are coded in numerical format, they should be distinguished from numerical data. A sound rule of thumb: Meaningful arithmetic operations can be performed on numerical data but not on categorical data.

EXAMPLE 1

Identifying Data Types (I)

Identify the data type for each of the following kinds of investment-related information:

1 *Number of coupon payments for a corporate bond.* As background, a corporate bond is a contractual obligation between an issuing corporation (i.e., borrower) and bondholders (i.e., lenders) in which the issuer agrees to pay interest—in the form of fixed coupon payments—on specified dates, typically semi-annually, over the life of the bond (i.e., to its maturity date) and to repay principal (i.e., the amount borrowed) at maturity.

2 *Cash dividends per share paid by a public company.* Note that cash dividends are a distribution paid to shareholders based on the number of shares owned.

3 *Credit ratings for corporate bond issues.* As background, credit ratings gauge the bond issuer's ability to meet the promised payments on the bond. Bond rating agencies typically assign bond issues to discrete categories that are in descending order of credit quality (i.e., increasing probability of non-payment or default).

4 *Hedge fund classification types.* Note that hedge funds are investment vehicles that are relatively unconstrained in their use of debt, derivatives, and long and short investment strategies. Hedge fund classification types group hedge funds by the kind of investment strategy they pursue.

Solution to 1

Number of coupon payments are discrete data. For example, a newly-issued 5-year corporate bond paying interest semi-annually (quarterly) will make 10 (20) coupon payments during its life. In this case, coupon payments are limited to a finite number of values; so, they are discrete.

Solution to 2

Cash dividends per share are continuous data since they can take on any non-negative values.

Solution to 3

Credit ratings are ordinal data. A rating places a bond issue in a category, and the categories are ordered with respect to the expected probability of default. But arithmetic operations cannot be done on credit ratings, and the difference in the expected probability of default between categories of highly rated bonds, for example, is not necessarily equal to that between categories of lowly rated bonds.

Solution to 4

Hedge fund classification types are nominal data. Each type groups together hedge funds with similar investment strategies. In contrast to credit ratings for bonds, however, hedge fund classification schemes do not involve a ranking. Thus, such classification schemes are not ordinal data.

2.2 Cross-Sectional versus Time-Series versus Panel Data

Another data classification standard is based on how data are collected, and it categorizes data into three types: cross-sectional, time series, and panel.

Prior to the description of the data types, we need to explain two data-related terminologies: variable and observation. A **variable** is a characteristic or quantity that can be measured, counted, or categorized and is subject to change. A variable can also be called a field, an attribute, or a feature. For example, stock price, market capitalization, dividend and dividend yield, earnings per share (EPS), and price-to-earnings ratio (P/E) are basic data variables for the financial analysis of a public company. An **observation** is the value of a specific variable collected at a point in time or over a specified period of time. For example, last year DEF, Inc. recorded EPS of $7.50. This value represented a 15% annual increase.

Cross-sectional data are a list of the observations of a specific variable from multiple observational units at a given point in time. The observational units can be individuals, groups, companies, trading markets, regions, etc. For example, January inflation rates (i.e., the variable) for each of the euro-area countries (i.e., the observational units) in the European Union for a given year constitute cross-sectional data.

Time-series data are a sequence of observations for a single observational unit of a specific variable collected over time and at discrete and typically equally spaced intervals of time, such as daily, weekly, monthly, annually, or quarterly. For example, the daily closing prices (i.e., the variable) of a particular stock recorded for a given month constitute time-series data.

Panel data are a mix of time-series and cross-sectional data that are frequently used in financial analysis and modeling. Panel data consist of observations through time on one or more variables for multiple observational units. The observations in panel data are usually organized in a matrix format called a data table. Exhibit 2 is an example of panel data showing quarterly earnings per share (i.e., the variable) for three companies (i.e., the observational units) in a given year by quarter. Each column is a time series of data that represents the quarterly EPS observations from Q1 to Q4 of a specific company, and each row is cross-sectional data that represent the EPS of all three companies of a particular quarter.

Exhibit 2 Earnings per Share in Euros of Three Eurozone Companies in a Given Year

Time Period	Company A	Company B	Company C
Q1	13.53	0.84	−0.34
Q2	4.36	0.96	0.08
Q3	13.16	0.79	−2.72
Q4	12.95	0.19	0.09

2.3 Structured versus Unstructured Data

Categorizing data into structured and unstructured types is based on whether or not the data are in a highly organized form.

Structured data are highly organized in a pre-defined manner, usually with repeating patterns. The typical forms of structured data are one-dimensional arrays, such as a time series of a single variable, or two-dimensional data tables, where each column represents a variable or an observation unit and each row contains a set of values for the same columns. Structured data are relatively easy to enter, store, query, and analyze without much manual processing. Typical examples of structured company financial data are:

- Market data: data issued by stock exchanges, such as intra-day and daily closing stock prices and trading volumes.
- Fundamental data: data contained in financial statements, such as earnings per share, price to earnings ratio, dividend yield, and return on equity.
- Analytical data: data derived from analytics, such as cash flow projections or forecasted earnings growth.

Unstructured data, in contrast, are data that do not follow any conventionally organized forms. Some common types of unstructured data are text—such as financial news, posts in social media, and company filings with regulators—and also audio/video, such as managements' earnings calls and presentations to analysts.

Unstructured data are a relatively new classification driven by the rise of alternative data (i.e., data generated from unconventional sources, like electronic devices, social media, sensor networks, and satellites, but also by companies in the normal course of business) and its growing adoption in the financial industry. Unstructured data are typically alternative data as they are usually collected from unconventional sources. By indicating the source from which the data are generated, such data can be classified into three groups:

- Produced by individuals (i.e., via social media posts, web searches, etc.);
- Generated by business processes (i.e., via credit card transactions, corporate regulatory filings, etc.); and
- Generated by sensors (i.e., via satellite imagery, foot traffic by mobile devices, etc.).

Unstructured data may offer new market insights not normally contained in data from traditional sources and may provide potential sources of returns for investment processes. Unlike structured data, however, utilizing unstructured data in investment analysis is challenging. Typically, financial models are able to take only structured data as inputs; therefore, unstructured data must first be transformed into structured data that models can process.

Exhibit 3 shows an excerpt from Form 10-Q (Quarterly Report) filed by Company XYZ with the US Securities and Exchange Commission (SEC) for the fiscal quarter ended 31 March 20XX. The form is an unstructured mix of text and tables, so it cannot be directly used by computers as input to financial models. The SEC has utilized eXtensible Business Reporting Language (XBRL) to structure such data. The data extracted from the XBRL submission can be organized into five tab-delimited TXT format files that contain information about the submission, including taxonomy tags (i.e., financial statement items), dates, units of measure (uom), values (i.e., for the tag items), and more—making it readable by computer. Exhibit 4 shows an excerpt from one of the now structured data tables downloaded from the SEC's EDGAR (Electronic Data Gathering, Analysis, and Retrieval) database.

EXAMPLE 2

Identifying Data Types (II)

1 Which of the following is *most likely* to be structured data?

- **A** Social media posts where consumers are commenting on what they think of a company's new product.
- **B** Daily closing prices during the past month for all companies listed on Japan's Nikkei 225 stock index.
- **C** Audio and video of a CFO explaining her company's latest earnings announcement to securities analysts.

2 Which of the following statements describing panel data is *most accurate*?

- **A** It is a sequence of observations for a single observational unit of a specific variable collected over time at discrete and equally spaced intervals.
- **B** It is a list of observations of a specific variable from multiple observational units at a given point in time.
- **C** It is a mix of time-series and cross-sectional data that are frequently used in financial analysis and modeling.

3 Which of the following data series is *least likely* to be sortable by values?

- **A** Daily trading volumes for stocks listed on the Shanghai Stock Exchange.
- **B** EPS for a given year for technology companies included in the S&P 500 Index.
- **C** Dates of first default on bond payments for a group of bankrupt European manufacturing companies.

4 Which of the following best describes a time series?

- **A** Daily stock prices of the XYZ stock over a 60-month period.
- **B** Returns on four-star rated Morningstar investment funds at the end of the most recent month.
- **C** Stock prices for all stocks in the FTSE100 on 31 December of the most recent calendar year.

Solution to 1

B is correct as daily closing prices constitute structured data. A is incorrect as social media posts are unstructured data. C is incorrect as audio and video are unstructured data.

Solution to 2

C is correct as it most accurately describes panel data. A is incorrect as it describes time-series data. B is incorrect as it describes cross-sectional data.

Solution to 3

C is correct as dates are ordinal data that can be sorted by chronological order but not by value. A and B are incorrect as both daily trading volumes and earnings per share (EPS) are numerical data, so they can be sorted by values.

Solution to 4

A is correct since a time series is a sequence of observations of a specific variable (XYZ stock price) collected over time (60 months) and at discrete intervals of time (daily). B and C are both incorrect as they are cross-sectional data.

2.4 Data Summarization

b Describe how data are organized for quantitative analysis

Given the wide variety of possible formats of **raw data**, which are data available in their original form as collected, such data typically cannot be used by humans or computers to directly extract information and insights. Organizing data into a one-dimensional array or a two-dimensional array is typically the first step in data analytics and modeling. In this section, we will illustrate the construction of these typical data organization formats. We will also introduce two useful tools that can efficiently summarize one-variable and two-variable data: frequency distributions and contingency tables, respectively. Both of them can give us a quick snapshot of the data and allow us to find patterns in the data and associations between variables.

3 ORGANIZING DATA FOR QUANTITATIVE ANALYSIS

b Describe how data are organized for quantitative analysis

Quantitative analysis and modeling typically require input data to be in a clean and formatted form, so raw data are usually not suitable for use directly by analysts. Depending upon the number of variables, raw data can be organized into two typical formats for quantitative analysis: one-dimensional arrays and two-dimensional rectangular arrays.

A **one-dimensional array** is the simplest format for representing a collection of data of the same data type, so it is suitable for representing a single variable. Exhibit 5 is an example of a one-dimensional array that shows the closing price for the first 10 trading days for ABC Inc. stock after the company went public. Closing prices are time-series data collected at daily intervals, so it is natural to organize them into a time-ordered sequence. The time-series format also facilitates future data updates to the existing dataset. In this case, closing prices for future trading sessions can be easily added to the end of the array with no alteration of previously formatted data.

More importantly, in contrast to compiling the data randomly in an unorganized manner, organizing such data by its time-series nature preserves valuable information beyond the basic **descriptive statistics** that summarize central tendency and spread variation in the data's distribution. For example, by simply plotting the data against time, we can learn whether the data demonstrate any increasing or decreasing trends over time or whether the time series repeats certain patterns in a systematic way over time.

Exhibit 5 One-Dimensional Array: Daily Closing Price of ABC Inc. Stock

Observation by Day	Stock Price ($)
1	57.21
2	58.26
3	58.64
4	56.19
5	54.78
6	54.26
7	56.88
8	54.74
9	52.42
10	50.14

A **two-dimensional rectangular array** (also called a **data table**) is one of the most popular forms for organizing data for processing by computers or for presenting data visually for consumption by humans. Similar to the structure in an Excel spreadsheet, a data table is comprised of columns and rows to hold multiple variables and multiple observations, respectively. When a data table is used to organize the data of one single observational unit (i.e., a single company), each column represents a different variable (feature or attribute) of that observational unit, and each row holds an observation for the different variables; successive rows represent the observations for successive time periods. In other words, observations of each variable are a time-series sequence that is sorted in either ascending or descending time order. Consequently, observations of different variables must be sorted and aligned to the same time scale. Example 3 shows how to organize a raw dataset for a company collected online into a machine-readable data table.

EXAMPLE 3

Organizing a Company's Raw Data into a Data Table

Suppose you are conducting a valuation analysis of ABC Inc., which has been listed on the stock exchange for two years. The metrics to be used in your valuation include revenue, earnings per share (EPS), and dividends paid per share (DPS). You have retrieved the last two years of ABC's quarterly data from the exchange's website, which is shown in Exhibit 6. The data available online are pre-organized into a tabular format, where each column represents a fiscal year and each row represents a particular quarter with values of the three measures clustered together.

Exhibit 6 Metrics of ABC Inc. Retrieved Online

Fiscal Quarter	Year 1 (Fiscal Year)	Year 2 (Fiscal Year)
March		
Revenue	$3,784(M)	$4,097(M)
EPS	1.37	−0.34
DPS	N/A	N/A
June		
Revenue	$4,236(M)	$5,905(M)
EPS	1.78	3.89
DPS	N/A	0.25
September		
Revenue	$4,187(M)	$4,997(M)
EPS	−3.38	−2.88
DPS	N/A	0.25
December		
Revenue	$3,889(M)	$4,389(M)
EPS	−8.66	−3.98
DPS	N/A	0.25

Use the data to construct a two-dimensional rectangular array (i.e., data table) with the columns representing the metrics for valuation and the observations arranged in a time-series sequence.

Solution:

To construct a two-dimensional rectangular array, we first need to determine the data table structure. The columns have been specified to represent the three valuation metrics (i.e., variables): revenue, EPS and DPS. The rows should be the observations for each variable in a time ordered sequence. In this example, the data for the valuation measures will be organized in the same quarterly intervals as the raw data retrieved online, starting from Q1 Year 1 to Q4 Year 2. Then, the observations from the original table can be placed accordingly into the data table by variable name and by filing quarter. Exhibit 7 shows the raw data reorganized in the two-dimensional rectangular array (by date and associated valuation metric), which can now be used in financial analysis and is readable by a computer.

It is worth pointing out that in case of missing values while organizing data, how to handle them depends largely on why the data are missing. In this example, dividends (DPS) in the first five quarters are missing because ABC Inc. did not authorize (and pay) any dividends. So, filling the dividend column with zeros is appropriate. If revenue, EPS, and DPS of a given quarter are missing due to particular data source issues, however, these missing values cannot be simply replaced with zeros; this action would result in incorrect interpretation. Instead, the missing values might be replaced with the latest available data or with interpolated values, depending on how the data will be consumed or modeled.

Exhibit 7 Data Table for ABC Inc.

	Revenue ($ Million)	EPS ($)	DPS ($)
Q1 Year 1	3,784	1.37	0
Q2 Year 1	4,236	1.78	0
Q3 Year 1	4,187	−3.38	0
Q4 Year 1	3,889	−8.66	0
Q1 Year 2	4,097	−0.34	0
Q2 Year 2	5,905	3.89	0.25
Q3 Year 2	4,997	−2.88	0.25
Q4 Year 2	4,389	−3.98	0.25

SUMMARIZING DATA USING FREQUENCY DISTRIBUTIONS

4

c **Interpret frequency and related distributions**

We now discuss various tabular formats for describing data based on the count of observations. These tables are a necessary step toward building a true visualization of a dataset. Later, we shall see how bar charts, tree-maps, and heat maps, among other graphic tools, are used to visualize important properties of a dataset.

A **frequency distribution** (also called a one-way table) is a tabular display of data constructed either by counting the observations of a variable by distinct values or groups or by tallying the values of a numerical variable into a set of numerically ordered bins. It is an important tool for initially summarizing data by groups or bins for easier interpretation.

Constructing a frequency distribution of a categorical variable is relatively straightforward and can be stated in the following two basic steps:

1 Count the number of observations for each unique value of the variable.

2 Construct a table listing each unique value and the corresponding counts, and then sort the records by number of counts in descending or ascending order to facilitate the display.

Exhibit 8 shows a frequency distribution of a portfolio's stock holdings by sectors (the variables), which are defined by GICS. The portfolio contains a total of 479 stocks that have been individually classified into 11 GICS sectors (first column). The stocks are counted by sector and are summarized in the second column, absolute frequency. The **absolute frequency**, or simply the raw frequency, is the actual number of observations counted for each unique value of the variable (i.e., each sector). Often it is desirable to express the frequencies in terms of percentages, so we also show the **relative frequency** (in the third column), which is calculated as the absolute frequency of each unique value of the variable divided by the total number of observations. The relative frequency provides a normalized measure of the distribution of the data, allowing comparisons between datasets with different numbers of total observations.

Exhibit 8 Frequency Distribution for a Portfolio by Sector

Sector (Variable)	Absolute Frequency	Relative Frequency
Industrials	73	15.2%
Information Technology	69	14.4%
Financials	67	14.0%
Consumer Discretionary	62	12.9%
Health Care	54	11.3%
Consumer Staples	33	6.9%
Real Estate	30	6.3%
Energy	29	6.1%
Utilities	26	5.4%
Materials	26	5.4%
Communication Services	10	2.1%
Total	**479**	**100.0%**

A frequency distribution table provides a snapshot of the data, and it facilitates finding patterns. Examining the distribution of absolute frequency in Exhibit 8, we see that the largest number of stocks (73), accounting for 15.2% of the stocks in the portfolio, are held in companies in the industrials sector. The sector with the least number of stocks (10) is communication services, which represents just 2.1% of the stocks in the portfolio.

It is also easy to see that the top four sectors (i.e., industrials, information technology, financials, and consumer discretionary) have very similar relative frequencies, between 15.2% and 12.9%. Similar relative frequencies, between 6.9% and 5.4%, are also seen among several other sectors. Note that the absolute frequencies add up to the total number of stocks in the portfolio (479), and the sum of the relative frequencies should be equal to 100%.

Frequency distributions also help in the analysis of large amounts of numerical data. The procedure for summarizing numerical data is a bit more involved than that for summarizing categorical data because it requires creating non-overlapping bins (also called **intervals** or buckets) and then counting the observations falling into each bin. One procedure for constructing a frequency distribution for numerical data can be stated as follows:

1. Sort the data in ascending order.
2. Calculate the range of the data, defined as Range = Maximum value − Minimum value.
3. Decide on the number of bins (k) in the frequency distribution.
4. Determine bin width as Range/k.
5. Determine the first bin by adding the bin width to the minimum value. Then, determine the remaining bins by successively adding the bin width to the prior bin's end point and stopping after reaching a bin that includes the maximum value.

6. Determine the number of observations falling into each bin by counting the number of observations whose values are equal to or exceed the bin minimum value yet are less than the bin's maximum value. The exception is in the last bin, where the maximum value is equal to the last bin's maximum, and therefore, the observation with the maximum value is included in this bin's count.
7. Construct a table of the bins listed from smallest to largest that shows the number of observations falling into each bin.

In Step 4, when rounding the bin width, round up (rather than down) to ensure that the final bin includes the maximum value of the data.

These seven steps are basic guidelines for constructing frequency distributions. In practice, however, we may want to refine the above basic procedure. For example, we may want the bins to begin and end with whole numbers for ease of interpretation. Another practical refinement that promotes interpretation is to start the first bin at the nearest whole number below the minimum value.

As this procedure implies, a frequency distribution groups data into a set of bins, where each bin is defined by a unique set of values (i.e., beginning and ending points). Each observation falls into only one bin, and the total number of bins covers all the values represented in the data. The frequency distribution is the list of the bins together with the corresponding measures of frequency.

To illustrate the basic procedure, suppose we have 12 observations sorted in ascending order (*Step 1*):

−4.57, −4.04, −1.64, 0.28, 1.34, 2.35, 2.38, 4.28, 4.42, 4.68, 7.16, and 11.43.

The minimum observation is −4.57, and the maximum observation is +11.43. So, the range is +11.43 − (−4.57) = 16 (*Step 2*).

If we set $k = 4$ (*Step 3*), then the bin width is 16/4 = 4 (*Step 4*).

Exhibit 9 shows the repeated addition of the bin width of 4 to determine the endpoint for each of the bins (*Step 5*).

Exhibit 9 Determining Endpoints of the Bins

−4.57	+	4.0	=	−0.57
−0.57	+	4.0	=	3.43
3.43	+	4.0	=	7.43
7.40	+	4.0	=	11.43

Thus, the bins are [−4.57 to −0.57), [−0.57 to 3.43), [3.43 to 7.43), and [7.43 to 11.43], where the notation [−4.57 to −0.57) indicates −4.57 ≤ observation < −0.57. The parentheses indicate that the endpoints are not included in the bins, and the square brackets indicate that the beginning points and the last endpoint are included in the bin. Exhibit 10 summarizes Steps 5 through 7.

Exhibit 10 Frequency Distribution

Bin				Absolute Frequency
A	−4.57	≤ observation <	−0.57	3
B	−0.57	≤ observation <	3.43	4
C	3.43	≤ observation <	7.43	4
D	7.43	≤ observation ≤	11.43	1

Note that the bins do not overlap, so each observation can be placed uniquely into one bin, and the last bin includes the maximum value.

We turn to these issues in discussing the construction of frequency distributions for daily returns of the fictitious Euro-Asia-Africa (EAA) Equity Index. The dataset of daily returns of the EAA Equity Index spans a five-year period and consists of 1,258 observations with a minimum value of −4.1% and a maximum value of 5.0%. Thus, the range of the data is 5% − (−4.1%) = 9.1%, approximately. [The mean daily return—mean as a measure of central tendency will be discussed shortly—is 0.04%.]

The decision on the number of bins (*k*) into which we should group the observations often involves inspecting the data and exercising judgment. How much detail should we include? If we use too few bins, we will summarize too much and may lose pertinent characteristics. Conversely, if we use too many bins, we may not summarize enough and may introduce unnecessary noise.

We can establish an appropriate value for *k* by evaluating the usefulness of the resulting bin width. A large number of empty bins may indicate that we are attempting to over-organize the data to present too much detail. Starting with a relatively small bin width, we can see whether or not the bins are mostly empty and whether or not the value of *k* associated with that bin width is too large. If the bins are mostly empty, implying that *k* is too large, we can consider increasingly larger bins (i.e., smaller values of *k*) until we have a frequency distribution that effectively summarizes the distribution.

Suppose that for ease of interpretation we want to use a bin width stated in whole rather than fractional percentages. In the case of the daily EAA Equity Index returns, a 1% bin width would be associated with 9.1/1 = 9.1 bins, which can be rounded up to *k* = 10 bins. That number of bins will cover a range of 1% × 10 = 10%. By constructing the frequency distribution in this manner, we will also have bins that end and begin at a value of 0%, thereby allowing us to count the negative and positive returns in the data. Without too much work, we have found an effective way to summarize the data.

Exhibit 11 shows the frequency distribution for the daily returns of the EAA Equity Index using return bins of 1%, where the first bin includes returns from −5.0% to −4.0% (exclusive, meaning < −4%) and the last bin includes daily returns from 4.0% to 5.0% (inclusive, meaning ≤ 5%). Note that to facilitate interpretation, the first bin starts at the nearest whole number below the minimum value (so, at −5.0%).

Exhibit 11 includes two other useful ways to present the data (which can be computed in a straightforward manner once we have established the absolute and relative frequency distributions): the cumulative absolute frequency and the cumulative relative frequency. The **cumulative absolute frequency** cumulates (meaning, adds up) the absolute frequencies as we move from the first bin to the last bin. Similarly, the **cumulative relative frequency** is a sequence of partial sums of the relative frequencies. For the last bin, the cumulative absolute frequency will equal the number observations in the dataset (1,258), and the cumulative relative frequency will equal 100%.

Exhibit 11 Frequency Distribution for Daily Returns of EAA Equity Index

Return Bin (%)	Absolute Frequency	Relative Frequency (%)	Cumulative Absolute Frequency	Cumulative Relative Frequency (%)
−5.0 to −4.0	1	0.08	1	0.08
−4.0 to −3.0	7	0.56	8	0.64
−3.0 to −2.0	23	1.83	31	2.46
−2.0 to −1.0	77	6.12	108	8.59
−1.0 to 0.0	470	37.36	578	45.95
0.0 to 1.0	555	44.12	1,133	90.06

Exhibit 11 (Continued)

Return Bin (%)	Absolute Frequency	Relative Frequency (%)	Cumulative Absolute Frequency	Cumulative Relative Frequency (%)
1.0 to 2.0	110	8.74	1,243	98.81
2.0 to 3.0	13	1.03	1,256	99.84
3.0 to 4.0	1	0.08	1,257	99.92
4.0 to 5.0	1	0.08	1,258	100.00

As Exhibit 11 shows, the absolute frequencies vary widely, ranging from 1 to 555. The bin encompassing returns between 0% and 1% has the most observations (555), and the corresponding relative frequency tells us these observations account for 44.12% of the total number of observations. The frequency distribution gives us a sense of not only where most of the observations lie but also whether the distribution is evenly spread. It is easy to see that the vast majority of observations (37.36% + 44.12% = 81.48%) lie in the middle two bins spanning −1% to 1%. We can also see that not many observations are greater than 3% or less than −4%. Moreover, as there are bins with 0% as ending or beginning points, we are able to count positive and negative returns in the data. Looking at the cumulative relative frequency in the last column, we see that the bin of −1% to 0% shows a cumulative relative frequency of 45.95%. This indicates that 45.95% of the observations lie below the daily return of 0% and that 54.05% of the observations are positive daily returns.

It is worth noting that other than being summarized in tables, frequency distributions also can be effectively represented in visuals, which will be discussed shortly in the section on data visualization.

EXAMPLE 4

Constructing a Frequency Distribution of Country Index Returns

Suppose we have the annual equity index returns of a given year for 18 different countries, as shown in Exhibit 12, and we are asked to summarize the data.

Exhibit 12 Annual Equity Index Returns for 18 Countries

Market	Index Return (%)
Country A	7.7
Country B	8.5
Country C	9.1
Country D	5.5
Country E	7.1
Country F	9.9
Country G	6.2
Country H	6.8
Country I	7.5

(continued)

Exhibit 12 (Continued)

Market	Index Return (%)
Country J	8.9
Country K	7.4
Country L	8.6
Country M	9.6
Country N	7.7
Country O	6.8
Country P	6.1
Country Q	8.8
Country R	7.9

Construct a frequency distribution table from these data and state some key findings from the summarized data.

Solution:

The first step in constructing a frequency distribution table is to sort the return data in ascending order:

Market	Index Return (%)
Country D	5.5
Country P	6.1
Country G	6.2
Country H	6.8
Country O	6.8
Country E	7.1
Country K	7.4
Country I	7.5
Country A	7.7
Country N	7.7
Country R	7.9
Country B	8.5
Country L	8.6
Country Q	8.8
Country J	8.9
Country C	9.1
Country M	9.6
Country F	9.9

The second step is to calculate the range of the data, which is 9.9% – 5.5% = 4.4%.
The third step is to decide on the number of bins. Here, we will use $k = 5$.
The fourth step is to determine the bin width. Here, it is 4.4%/5 = 0.88%, which we will round up to 1.0%.
The fifth step is to determine the bins, which are as follows:

5.0% + 1.0% = 6.0%
6.0% + 1.0% = 7.0%
7.0% + 1.0% = 8.0%

8.0% + 1.0% = 9.0%
9.0% + 1.0% = 10.0%

For ease of interpretation, the first bin is set to begin with the nearest whole number (5.0%) below the minimum value (5.5%) of the data series.

The sixth step requires counting the return observations falling into each bin, and the seventh (last) step is use these results to construct the final frequency distribution table.

Exhibit 13 presents the frequency distribution table, which summarizes the data in Exhibit 12 into five bins spanning 5% to 10%. Note that with 18 countries, the relative frequency for one observation is calculated as 1/18 = 5.56%.

Exhibit 13 Frequency Distribution of Equity Index Returns

Return Bin (%)	Absolute Frequency	Relative Frequency (%)	Cumulative Absolute Frequency	Cumulative Relative Frequency (%)
5.0 to 6.0	1	5.56	1	5.56
6.0 to 7.0	4	22.22	5	27.78
7.0 to 8.0	6	33.33	11	61.11
8.0 to 9.0	4	22.22	15	83.33
9.0 to 10.0	3	16.67	18	100.00

As Exhibit 13 shows, there is substantial variation in these equity index returns. One-third of the observations fall in the 7.0 to 8.0% bin, making it the bin with the most observations. Both the 6.0 to 7.0% bin and the 8.0 to 9.0% bin hold four observations each, accounting for 22.22% of the total number of the observations, respectively. The two remaining bins have fewer observations, one or three observations, respectively.

SUMMARIZING DATA USING A CONTINGENCY TABLE

5

d Interpret a contingency table

We have shown that the frequency distribution table is a powerful tool to summarize data for one variable. How can we summarize data for two variables simultaneously? A contingency table provides a solution to this question.

A **contingency table** is a tabular format that displays the frequency distributions of two or more categorical variables simultaneously and is used for finding patterns between the variables. A contingency table for two categorical variables is also known as a two-way table. Contingency tables are constructed by listing all the levels (i.e., categories) of one variable as rows and all the levels of the other variable as columns in the table. A contingency table having R levels of one variable in rows and C levels of the other variable in columns is referred to as an $R \times C$ table. Note that each variable in a contingency table must have a finite number of levels, which can be either ordered (ordinal data) or unordered (nominal data). Importantly, the data displayed in the cells of the contingency table can be either a frequency (count) or a relative frequency (percentage) based on either overall total, row totals, or column totals.

Exhibit 14 presents a 5 × 3 contingency table that summarizes the number of stocks (i.e., frequency) in a particular portfolio of 1,000 stocks by two variables, sector and company market capitalization. Sector has five levels, with each one being a GICS-defined sector. Market capitalization (commonly referred to as "market cap") is defined for a company as the number of shares outstanding times the price per share. The stocks in this portfolio are categorized by three levels of market capitalization: large cap, more than $10 billion; mid cap, $10 billion to $2 billion; and small cap, less than $2 billion.

Exhibit 14 Portfolio Frequencies by Sector and Market Capitalization

	Market Capitalization Variable (3 Levels)			
Sector Variable (5 Levels)	**Small**	**Mid**	**Large**	**Total**
Communication Services	55	35	20	110
Consumer Staples	50	30	30	110
Energy	175	95	20	290
Health Care	275	105	55	435
Utilities	20	25	10	55
Total	**575**	**290**	**135**	**1,000**

The entries in the cells of the contingency table show the number of stocks of each sector with a given level of market cap. For example, there are 275 small-cap health care stocks, making it the portfolio's largest subgroup in terms of frequency. These data are also called **joint frequencies** because you are joining one variable from the row (i.e., sector) and the other variable from the column (i.e., market cap) to count observations. The joint frequencies are then added across rows and across columns, and these corresponding sums are called **marginal frequencies**. For example, the marginal frequency of health care stocks in the portfolio is the sum of the joint frequencies across all three levels of market cap, so 435 (= 275 + 105 + 55). Similarly, adding the joint frequencies of small-cap stocks across all five sectors gives the marginal frequency of small-cap stocks of 575 (= 55 + 50 + 175 + 275 + 20).

Clearly, health care stocks and small-cap stocks have the largest marginal frequencies among sector and market cap, respectively, in this portfolio. Note the marginal frequencies represent the frequency distribution for each variable. Finally, the marginal frequencies for each variable must sum to the total number of stocks (overall total) in the portfolio—here, 1,000 (shown in the lower right cell).

Similar to the one-way frequency distribution table, we can express frequency in percentage terms as relative frequency by using one of three options. We can divide the joint frequencies by: a) the total count; b) the marginal frequency on a row; or c) the marginal frequency on a column.

Exhibit 15 shows the contingency table using relative frequencies based on total count. It is readily apparent that small-cap health care and energy stocks comprise the largest portions of the total portfolio, at 27.5% (= 275/1,000) and 17.5% (= 175/1,000), respectively, followed by mid-cap health care and energy stocks, at 10.5% and 9.5%, respectively. Together, these two sectors make up nearly three-quarters of the portfolio (43.5% + 29.0% = 72.5%).

Exhibit 15 Relative Frequencies as Percentage of Total

	Market Capitalization Variable (3 Levels)			
Sector Variable (5 Levels)	**Small**	**Mid**	**Large**	**Total**
Communication Services	5.5%	3.5%	2.0%	11.0%
Consumer Staples	5.0%	3.0%	3.0%	11.0%
Energy	17.5%	9.5%	2.0%	29.0%
Health Care	27.5%	10.5%	5.5%	43.5%
Utilities	2.0%	2.5%	1.0%	5.5%
Total	**57.5%**	**29.0%**	**13.5%**	**100%**

Exhibit 16 shows relative frequencies based on marginal frequencies of market cap (i.e., columns). From this perspective, it is clear that the health care and energy sectors dominate the other sectors at each level of market capitalization: 78.3% (= 275/575 + 175/575), 69.0% (= 105/290 + 95/290), and 55.6% (= 55/135 + 20/135), for small, mid, and large caps, respectively. Note that there may be a small rounding error difference between these results and the numbers shown in Exhibit 15.

Exhibit 16 Relative Frequencies: Sector as Percentage of Market Cap

	Market Capitalization Variable (3 Levels)			
Sector Variable (5 Levels)	**Small**	**Mid**	**Large**	**Total**
Communication Services	9.6%	12.1%	14.8%	11.0%
Consumer Staples	8.7%	10.3%	22.2%	11.0%
Energy	30.4%	32.8%	14.8%	29.0%
Health Care	47.8%	36.2%	40.7%	43.5%
Utilities	3.5%	8.6%	7.4%	5.5%
Total	100.0%	100.0%	100.0%	**100.0%**

In conclusion, the findings from these contingency tables using frequencies and relative frequencies indicate that in terms of the number of stocks, the portfolio can be generally described as a small- to mid-cap-oriented health care and energy sector portfolio that also includes stocks of several other defensive sectors.

As an analytical tool, contingency tables can be used in different applications. One application is for evaluating the performance of a classification model (in this case, the contingency table is called a **confusion matrix**). Suppose we have a model for classifying companies into two groups: those that default on their bond payments and those that do not default. The confusion matrix for displaying the model's results will be a 2 × 2 table showing the frequency of actual defaults versus the model's predicted frequency of defaults. Exhibit 17 shows such a confusion matrix for a sample of 2,000 non-investment-grade bonds. Using company characteristics and other inputs, the model correctly predicts 300 cases of bond defaults and 1,650 cases of no defaults.

Exhibit 17 Confusion Matrix for Bond Default Prediction Model

Predicted Default	Actual Default Yes	Actual Default No	Total
Yes	300	40	**340**
No	10	1,650	**1,660**
Total	**310**	**1,690**	**2,000**

We can also observe that this classification model incorrectly predicts default in 40 cases where no default actually occurred and also incorrectly predicts no default in 10 cases where default actually did occur. Later in the CFA Program curriculum you will learn how to construct a confusion matrix, how to calculate related model performance metrics, and how to use them to evaluate and tune a classification model.

Another application of contingency tables is to investigate potential association between two categorical variables. For example, revisiting Exhibit 14, one may ask whether the distribution of stocks by sectors is independent of the levels of market capitalization? Given the dominance of small-cap and mid-cap health care and energy stocks, the answer is likely, no.

One way to test for a potential association between categorical variables is to perform a **chi-square test of independence**. Essentially, the procedure involves using the marginal frequencies in the contingency table to construct a table with expected values of the observations. The actual values and expected values are used to derive the chi-square test statistic. This test statistic is then compared to a value from the chi-square distribution for a given level of significance. If the test statistic is greater than the chi-square distribution value, then there is evidence to reject the claim of independence, implying a significant association exists between the categorical variables. The following example describes how a contingency table is used to set up this test of independence.

EXAMPLE 5

Contingency Tables and Association between Two Categorical Variables

Suppose we randomly pick 315 investment funds and classify them two ways: by fund style, either a growth fund or a value fund; and by risk level, either low risk or high risk. Growth funds primarily invest in stocks whose earnings are expected to grow at a faster rate than earnings for the broad stock market. Value funds primarily invest in stocks that appear to be undervalued relative to their fundamental values. Risk here refers to volatility in the return of a given investment fund, so low (high) volatility implies low (high) risk. The data are summarized in a 2 × 2 contingency table shown in Exhibit 18.

Exhibit 18 Contingency Table by Investment Fund Style and Risk Level

	Low Risk	High Risk
Growth	73	26
Value	183	33

1 Calculate the number of growth funds and number of value funds out of the total funds.

2 Calculate the number of low-risk and high-risk funds out of the total funds.

3 Describe how the contingency table is used to set up a test for independence between fund style and risk level.

Solution to 1

The task is to calculate the marginal frequencies by fund style, which is done by adding joint frequencies across the rows. Therefore, the marginal frequency for growth is 73 + 26 = 99, and the marginal frequency for value is 183 + 33 = 216.

Solution to 2

The task is to calculate the marginal frequencies by fund risk, which is done by adding joint frequencies down the columns. Therefore, the marginal frequency for low risk is 73 + 183 = 256, and the marginal frequency for high risk is 26 + 33 = 59.

Solution to 3

Based on the procedure mentioned for conducting a chi-square test of independence, we would perform the following three steps.

Step 1: Add the marginal frequencies and overall total to the contingency table. We have also included the relative frequency table for observed values.

Exhibit 19a Observed Marginal Frequencies and Relative Frequencies

	Observed Values		
	Low Risk	**High Risk**	
Growth	73	26	**99**
Value	183	33	**216**
	256	**59**	**315**

	Observed Values		
	Low Risk	**High Risk**	
Growth	74%	26%	**100%**
Value	85%	15%	**100%**

Step 2: Use the marginal frequencies in the contingency table to construct a table with expected values of the observations. To determine expected values for each cell, multiply the respective row total by the respective column total, then divide by the overall total. So, for $cell_{i,j}$ (in *ith* row and *jth* column):

$$\text{Expected Value}_{i,j} = (\text{Total Row } i \times \text{Total Column } j)/\text{Overall Total} \tag{1}$$

For example,

Expected value for Growth/Low Risk is: (99 × 256)/ 315 = 80.46; and

Expected value for Value/High Risk is: (216 × 59) / 315 = 40.46.

The table of expected values (and accompanying relative frequency table) are:

Exhibit 19b Expected Marginal Frequencies and Relative Frequencies

Observed Values	Low Risk	High Risk		Observed Values	Low Risk	High Risk	
Growth	80.457	18.543	**99**	Growth	81%	19%	**100%**
Value	175.543	40.457	**216**	Value	81%	19%	**100%**
	256	**59**	**315**				

Step 3: Use the actual values and the expected values of observation counts to derive the chi-square test statistic, which is then compared to a value from the chi-square distribution for a given level of significance. If the test statistic is greater than the chi-square distribution value, then there is evidence of a significant association between the categorical variables.

6 DATA VISUALIZATION

e Describe ways that data may be visualized and evaluate uses of specific visualizations

Visualization is the presentation of data in a pictorial or graphical format for the purpose of increasing understanding and for gaining insights into the data. As has been said, "a picture is worth a thousand words." In this section, we discuss a variety of charts that are useful for understanding distributions, making comparisons, and exploring potential relationships among data. Specifically, we will cover visualizing frequency distributions of numerical and categorical data by using plots that represent multi-dimensional data for discovering relationships and by interpreting visuals that display unstructured data.

6.1 Histogram and Frequency Polygon

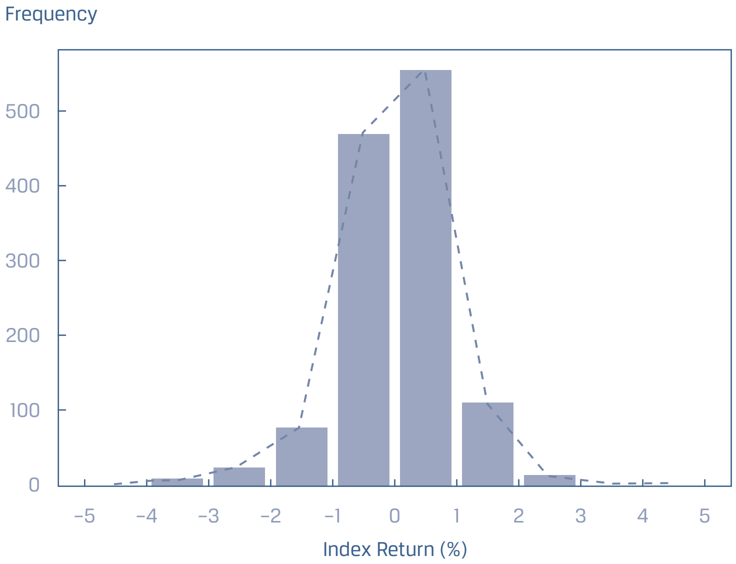
A **histogram** is a chart that presents the distribution of numerical data by using the height of a bar or column to represent the absolute frequency of each bin or interval in the distribution.

To construct a histogram from a continuous variable, we first need to split the data into bins and summarize the data into a frequency distribution table, such as the one we constructed in Exhibit 11. In a histogram, the y-axis generally represents the absolute frequency or the relative frequency in percentage terms, while the x-axis usually represents the bins of the variable. Using the frequency distribution table in Exhibit 11, we plot the histogram of daily returns of the EAA Equity Index, as shown in Exhibit 20. The bars are of equal width, representing the bin width of 1% for each return interval. The bars are usually drawn with no spaces in between, but small gaps can also be added between adjacent bars to increase readability, as in this exhibit. In this case, the height of each bar represents the absolute frequency for each return bin. A quick glance can tell us that the return bin 0% to 1% (exclusive) has the highest frequency, with more than 500 observations (555, to be exact), and it is represented by the tallest bar in the histogram.

An advantage of the histogram is that it can effectively present a large amount of numerical data that has been grouped into a frequency distribution and can allow a quick inspection of the shape, center, and spread of the distribution to better understand it. For example, in Exhibit 20, despite the histogram of daily EAA Equity Index returns appearing bell-shaped and roughly symmetrical, most bars to the right side of the origin (i.e., zero) are taller than those on the left side, indicating that more observations lie in the bins in positive territory. Remember that in the earlier discussion of this return distribution, it was noted that 54.1% of the observations are positive daily returns.

As mentioned, histograms can also be created with relative frequencies—the choice of using absolute versus relative frequency depends on the question being answered. An absolute frequency histogram best answers the question of how many items are in each bin, while a relative frequency histogram gives the proportion or percentage of the total observations in each bin.

Exhibit 20 Histogram Overlaid with Frequency Polygon for Daily Returns of EAA Equity Index

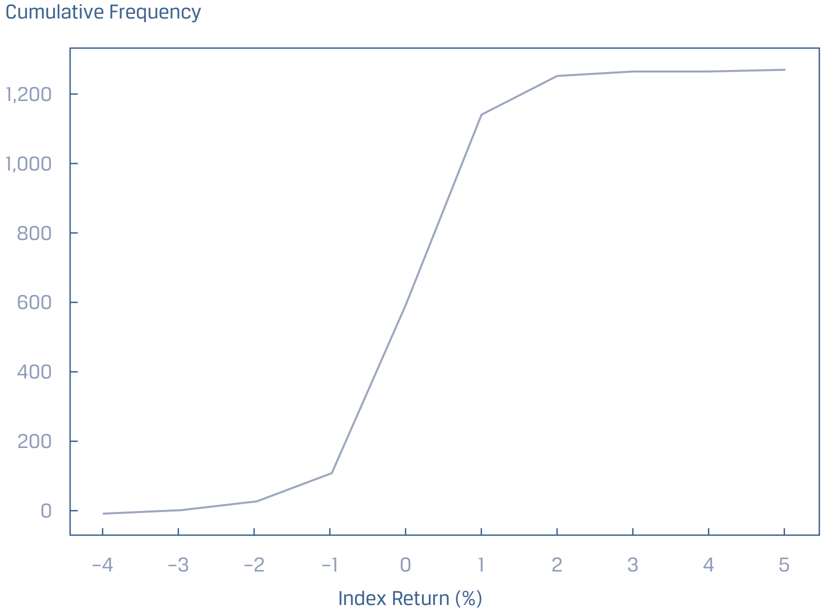


Another graphical tool for displaying frequency distributions is the frequency polygon. To construct a **frequency polygon**, we plot the midpoint of each return bin on the x-axis and the absolute frequency for that bin on the y-axis. We then connect neighboring points with a straight line. Exhibit 20 shows the frequency polygon that overlays the histogram. In the graph, for example, the return interval 1% to 2% (exclusive) has a frequency of 110, so we plot the return-interval midpoint of 0.5% (which is 1.50% on the x-axis) and a frequency of 110 (on the y-axis). Importantly, the frequency polygon can quickly convey a visual understanding of the distribution since it displays frequency as an area under the curve.

Another form for visualizing frequency distributions is the **cumulative frequency distribution chart**. Such a chart can plot either the cumulative absolute frequency or the cumulative relative frequency on the y-axis against the upper limit of the interval. The cumulative frequency distribution chart allows us to see the number or the percentage of the observations that lie below a certain value. To construct the cumulative frequency distribution, we graph the returns in the fourth (i.e., Cumulative Absolute Frequency) or fifth (i.e., Cumulative Relative Frequency) column of Exhibit 11 against the upper limit of each return interval.

Exhibit 21 presents the graph of the cumulative absolute frequency distribution for the daily returns on the EAA Equity Index. Notice that the cumulative distribution tends to flatten out when returns are extremely negative or extremely positive because the frequencies in these bins are quite small. The steep slope in the middle of Exhibit 21 reflects the fact that most of the observations—[(470 + 555)/1,258], or 81.5%—lie in the neighborhood of −1.0% to 1.0%.

Exhibit 21 Cumulative Absolute Frequency Distribution of Daily Returns of EAA Equity Index



6.2 Bar Chart

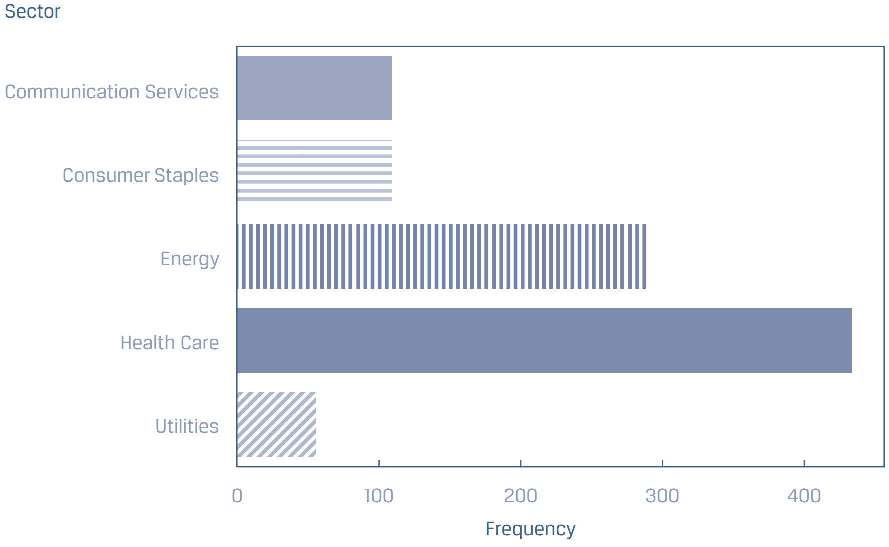
As we have demonstrated, the histogram is an efficient graphical tool to present the frequency distribution of numerical data. The frequency distribution of categorical data can be plotted in a similar type of graph called a **bar chart**. In a bar chart, each bar represents a distinct category, with the bar's height proportional to the frequency of the corresponding category.

Similar to plotting a histogram, the construction of a bar chart with one categorical variable first requires a frequency distribution table summarized from the variable. Note that the bars can be plotted vertically or horizontally. In a vertical bar chart, the y-axis still represents the absolute frequency or the relative frequency. Different from the histogram, however, is that the x-axis in a bar chart represents the mutually exclusive categories to be *compared* rather than bins that group numerical data.

For example, using the marginal frequencies for the five GICS sectors shown in the last column in Exhibit 14, we plot a horizontal bar chart in Exhibit 22 to show the frequency of stocks by sector in the portfolio. The bars are of equal width to represent each sector, and sufficient space should be between adjacent bars to separate them from each other. Because this is a horizontal bar chart—in this case, the x-axis shows the absolute frequency and the y-axis represents the sectors—the length of each bar represents the absolute frequency of each sector. Since sectors are nominal data with no logical ordering, the bars representing sectors may be arranged in any order. However, in the particular case where the categories in a bar chart are ordered by frequency in descending order and the chart includes a line displaying cumulative relative frequency, then it is called a Pareto Chart. The chart is often used to highlight dominant categories or the most important groups.

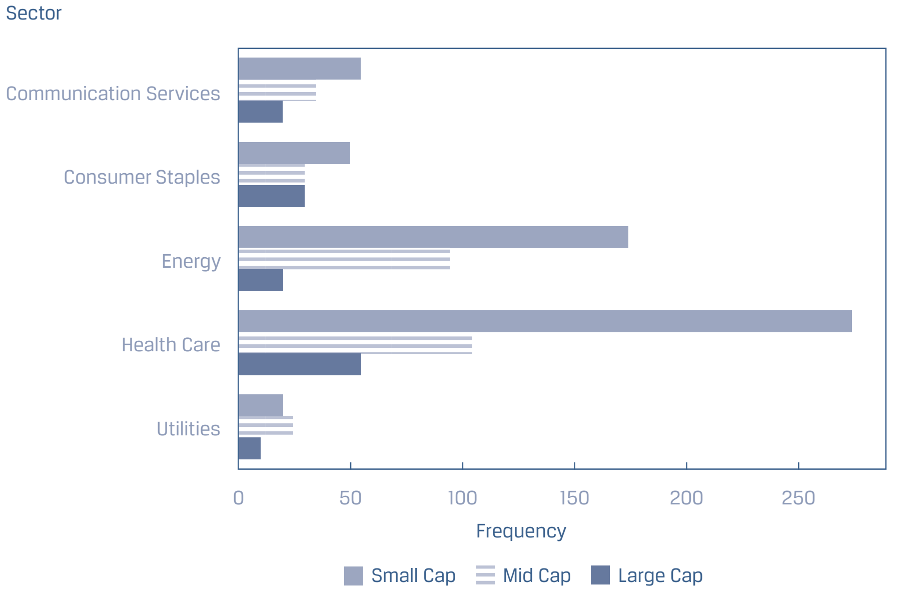
Bar charts provide a snapshot to show the comparison between categories of data. As shown in Exhibit 22, the sector in which the portfolio holds most stocks is the health care sector, with 435 stocks, followed by the energy sector, with 290 stocks. The sector in which the portfolio has the least number of stocks is utilities, with 55 stocks. To compare categories more accurately, in some cases we may add the frequency count to the right end of each bar (or the top end of each bar in the case of a vertical bar chart).

Exhibit 22 Frequency by Sector for Stocks in a Portfolio



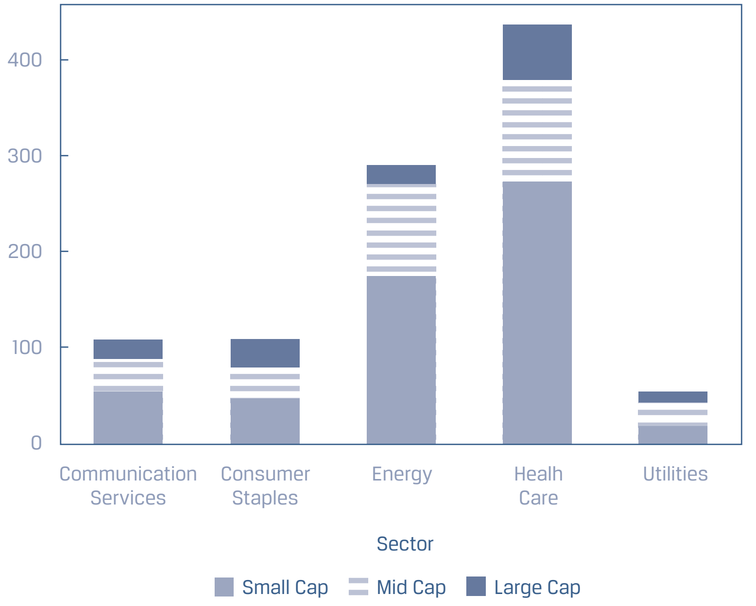
The bar chart shown in Exhibit 22 can present the frequency distribution of only one categorical variable. In the case of two categorical variables, we need an enhanced version of the bar chart, called a **grouped bar chart** (also known as a **clustered bar chart**), to show joint frequencies. Using the joint frequencies by sector and by level of market capitalization given in Exhibit 14, for example, we show how a grouped bar chart is constructed in Exhibit 23. While the *y*-axis still represents the same categorical variable (the distinct GICS sectors as in Exhibit 22), in Exhibit 23 three bars are clustered side-by-side within the same sector to represent the three respective levels of market capitalization. The bars within each cluster should be colored differently to distinguish between them, but the color schemes for the sub-groups must be identical across the sector clusters, as shown by the legend at the upper right of Exhibit 23. Additionally, the bars in each sector cluster must always be placed in the same order throughout the chart. It is easy to see that the small-cap heath care stocks are the sub-group with the highest frequency (275), and we can also see that small-cap stocks are the largest sub-group within each sector—except for utilities, where mid cap is the largest.

Exhibit 23 **Frequency by Sector and Level of Market Capitalization for Stocks in a Portfolio**



An alternative form for presenting the joint frequency distribution of two categorical variables is a **stacked bar chart**. In the vertical version of a stacked bar chart, the bars representing the sub-groups are placed on top of each other to form a single bar. Each subsection of the bar is shown in a different color to represent the contribution of each sub-group, and the overall height of the stacked bar represents the marginal frequency for the category. Exhibit 23 can be replotted in a stacked bar chart, as shown in Exhibit 24.

Exhibit 24 **Frequency by Sector and Level of Market Capitalization in a Stacked Bar Chart**

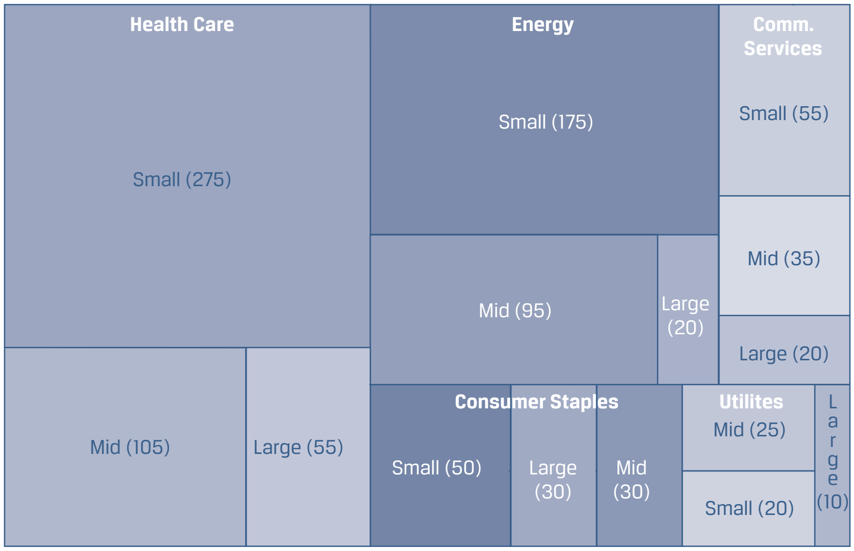


We have shown that the frequency distribution of categorical data can be clearly and efficiently presented by using a bar chart. However, it is worth noting that applications of bar charts may be extended to more general cases when categorical data are associated with numerical data. For example, suppose we want to show a company's quarterly profits over the past one year. In this case, we can plot a vertical bar chart where each bar represents one of the four quarters in a time order and its height indicates the value of profits for that quarter.

6.3 Tree-Map

In addition to bar charts and grouped bar charts, another graphical tool for displaying categorical data is a **tree-map**. It consists of a set of colored rectangles to represent distinct groups, and the area of each rectangle is proportional to the value of the corresponding group. For example, referring back to the marginal frequencies by GICS sector in Exhibit 14, we plot a tree-map in Exhibit 25 to represent the frequency distribution by sector for stocks in the portfolio. The tree-map clearly shows that health care is the sector with the largest number of stocks in the portfolio, which is represented by the rectangle with the largest area.

Exhibit 25 Tree-Map for Frequency Distribution by Sector in a Portfolio



Note that this example also depicts one more categorical variable (i.e., level of market capitalization). The tree-map can represent data with additional dimensions by displaying a set of nested rectangles. To show the joint frequencies of sub-groups by sector and level of market capitalization, as given in Exhibit 14, we can split each existing rectangle for sector into three sub-rectangles to represent small-cap, mid-cap, and large-cap stocks, respectively. In this case, the area of each nested rectangle would be proportional to the number of stocks in each market capitalization sub-group. The exhibit clearly shows that small-cap health care is the sub-group with the largest number of stocks. It is worth noting a caveat for using tree-maps: Tree-maps become difficult to read if the hierarchy involves more than three levels.

6.4 Word Cloud

So far, we have shown how to visualize the frequency distribution of numerical data or categorical data. However, can we find a chart to depict the frequency of unstructured data—particularly, textual data? A **word cloud** (also known as **tag cloud**) is a visual device for representing textual data. A word cloud consists of words extracted from a source of textual data, with the size of each distinct word being proportional to the frequency with which it appears in the given text. Note that common words (e.g., "a," "it," "the") are generally stripped out to focus on key words that convey the most meaningful information. This format allows us to quickly perceive the most frequent terms among the given text to provide information about the nature of the text, including topic and whether or not the text conveys positive or negative news. Moreover, words conveying different sentiment may be displayed in different colors. For example, "profit" typically indicates positive sentiment so might be displayed in green, while "loss" typically indicates negative sentiment and may be shown in red.

Exhibit 26 is an excerpt from the Management's Discussion and Analysis (MDA) section of the 10-Q filing for QXR Inc. for the quarter ended 31 March 20XX. Taking this text, we can create a word cloud, as shown in Exhibit 27. A quick glance at the word cloud tells us that the following words stand out (i.e., they were used most frequently in the MDA text): "billion," "revenue," "year," "income," "growth," and "financial." Note that specific words, such as "income" and "growth," typically convey positive sentiment, as contrasted with such words as "loss" and "decline," which typically convey negative sentiment. In conclusion, word clouds are a useful tool for visualizing textual data that can facilitate understanding the topic of the text as well as the sentiment it may convey.

Exhibit 26 Excerpt of MDA Section in Form 10-Q of QXR Inc. for Quarter Ended 31 March 20XX

MANAGEMENT'S DISCUSSION AND ANALYSIS OF FINANCIAL CONDITION AND RESULTS OF OPERATIONS

Please read the following discussion and analysis of our financial condition and results of operations together with our consolidated financial statements and related notes included under Part I, Item 1 of this Quarterly Report on Form 10-Q

Executive Overview of Results

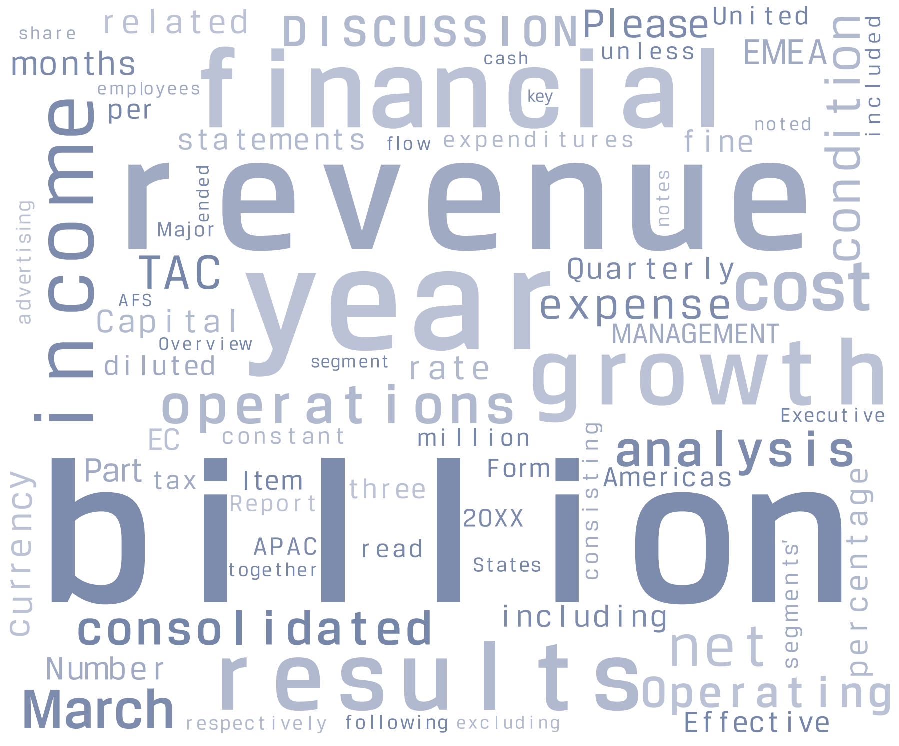
Below are our key financial results for the three months ended March 31, 20XX (consolidated unless otherwise noted):

- Revenues of $36.3 billion and revenue growth of 17% year over year, constant currency revenue growth of 19% year over year.
- Major segment revenues of $36.2 billion with revenue growth of 17% year over year and other segments' revenues of $170 million with revenue growth of 13% year over year.
- Revenues from the United States, EMEA, APAC, and Other Americas were $16.5 billion, $11.8 billion, $6.1 billion, and $1.9 billion, respectively.
- Cost of revenues was $16.0 billion, consisting of TAC of $6.9 billion and other cost of revenues of $9.2 billion. Our TAC as a percentage of advertising revenues were 22%.
- Operating expenses (excluding cost of revenues) were $13.7 billion, including the EC AFS fine of $1.7 billion.
- Income from operations was $6.6 billion
- Other income (expense), net, was $1.5 billion.

Exhibit 26 (Continued)

- Effective tax rate was 18%
- Net income was $6.7 billion with diluted net income per share of $9.50.
- Operating cash flow was $12.0 billion.
- Capital expenditures were $4.6 billion.

Exhibit 27 Word Cloud Visualizing Excerpted Text in MDA Section in Form 10-Q of QXR Inc.



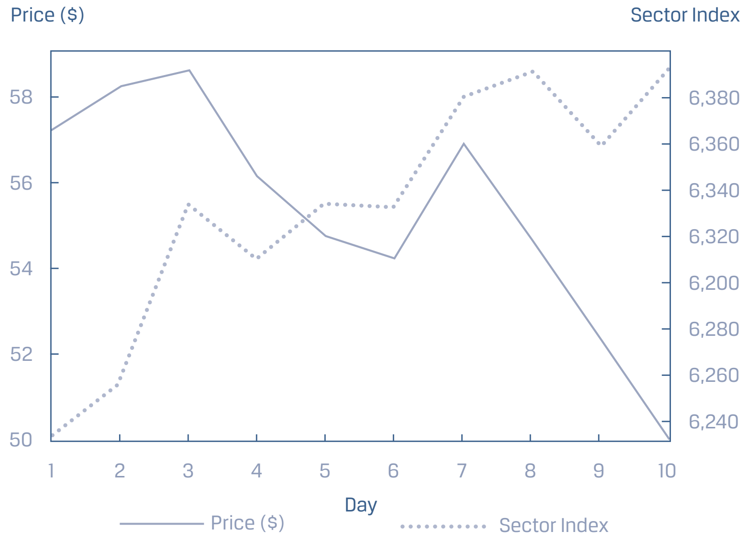
6.5 Line Chart

A **line chart** is a type of graph used to visualize ordered observations. Often a line chart is used to display the change of data series over time. Note that the frequency polygon in Exhibit 20 and the cumulative frequency distribution chart in Exhibit 21 are also line charts but used particularly in those instances for representing data frequency distributions.

Constructing a line chart is relatively straightforward: We first plot all the data points against horizontal and vertical axes and then connect the points by straight line segments. For example, to show the 10-day daily closing prices of ABC Inc. stock presented in Exhibit 5, we first construct a chart with the *x*-axis representing time (in days) and the *y*-axis representing stock price (in dollars). Next, plot each closing price as points against both axes, and then use straight line segments to join the points together, as shown in Exhibit 28.

An important benefit of a line chart is that it facilitates showing changes in the data and underlying trends in a clear and concise way. This helps to understand the current data and also helps with forecasting the data series. In Exhibit 28, for example, it is easy to spot the price changes over the first 10 trading days since ABC's initial public offering (IPO). We see that the stock price peaked on Day 3 and then traded lower. Following a partial recovery on Day 7, it declined steeply to around $50 on Day 10. In contrast, although the one-dimensional data array table in Exhibit 5 displays the same values as the line chart, the data table by itself does not provide a quick snapshot of changes in the data or facilitate understanding underlying trends. This is why line charts are helpful for visualization, particularly in cases of large amounts of data (i.e., hundreds, or even thousands, of data points).

Exhibit 28 Daily Closing Prices of ABC Inc.'s Stock and Its Sector Index



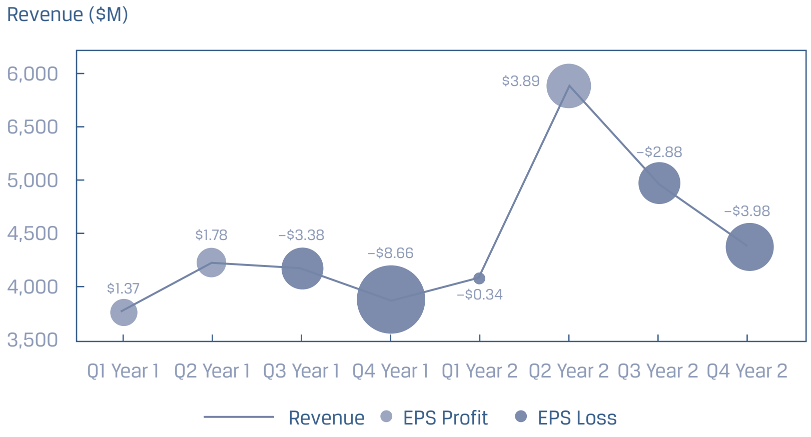
A line chart is also capable of accommodating more than one set of data points, which is especially helpful for making comparisons. We can add a line to represent each group of data (e.g., a competitor's stock price or a sector index), and each line would have a distinct color or line pattern identified in a legend. For example, Exhibit 28 also includes a plot of ABC's sector index (i.e., the sector index for which ABC stock is a member, like health care or energy) over the same period. The sector index is displayed with its own distinct color to facilitate comparison. Note also that because the sector index has a different range (approximately 6,230 to 6,390) than ABCs' stock ($50 to $59 per share), we need a secondary y-axis to correctly display the sector index, which is on the right-hand side of the exhibit.

This comparison can help us understand whether ABC's stock price movement over the period is due to potential mispricing of its share issuance or instead due to industry-specific factors that also affect its competitors' stock prices. The comparison shows that over the period, the sector index moved in a nearly opposite trend versus ABC's stock price movement. This indicates that the steep decline in ABC's stock price is less likely attributable to sector-specific factors and more likely due to potential over-pricing of its IPO or to other company-specific factors.

When an observational unit (here, ABC Inc.) has more than two features (or variables) of interest, it would be useful to show the multi-dimensional data all in one chart to gain insights from a more holistic view. How can we add an additional dimension to a two-dimensional line chart? We can replace the data points with varying-sized bubbles to represent a third dimension of the data. Moreover, these bubbles may even be color-coded to present additional information. This version of a line chart is called a **bubble line chart**.

Exhibit 7, for example, presented three types of quarterly data for ABC Inc. for use in a valuation analysis. We would like to plot two of them, revenue and earnings per share (EPS), over the two-year period. As shown in Exhibit 29, with the x-axis representing time (i.e., quarters) and the y-axis representing revenue in millions of dollars, we can plot the revenue data points against both axes to form a typical line chart. Next, each marker representing a revenue data point is replaced by a circular bubble with its size proportional to the magnitude of the EPS in the corresponding quarter. Moreover, the bubbles are colored in a binary scheme with green representing profits and red representing losses. In this way, the bubble line chart reflects the changes for both revenue and EPS simultaneously, and it also shows whether the EPS represents a profit or a loss.

Exhibit 29 Quarterly Revenue and EPS of ABC Incorporated



As depicted, ABC's earning were quite volatile during its initial two years as a public company. Earnings started off as a profit of $1.37/share but finished the first year with a big loss of –$8.66/share, during which time revenue experienced only small fluctuations. Furthermore, while revenues and earnings both subsequently recovered sharply—peaking in Q2 of Year 2—revenues then declined, and the company returned to significant losses (–3.98/share) by the end of Year 2.

6.6 Scatter Plot

A **scatter plot** is a type of graph for visualizing the joint variation in two numerical variables. It is a useful tool for displaying and understanding potential relationships between the variables.

A scatter plot is constructed with the x-axis representing one variable and the y-axis representing the other variable. It uses dots to indicate the values of the two variables for a particular point in time, which are plotted against the corresponding axes. Suppose an analyst is investigating potential relationships between sector index returns and returns for the broad market, such as the S&P 500 Index. Specifically, he or she is interested in the relative performance of two sectors, information technology (IT) and utilities, compared to the market index over a specific five-year period. The analyst has obtained the sector and market index returns for each month over the five years under investigation and plotted the data points in the scatter plots, shown in Exhibit 30 for IT versus the S&P 500 returns and in Exhibit 31 for utilities versus the S&P 500 returns.

Despite their relatively straightforward construction, scatter plots convey lots of valuable information. First, it is important to inspect for any potential association between the two variables. The pattern of the scatter plot may indicate no apparent relationship, a linear association, or a non-linear relationship. A scatter plot with randomly distributed data points would indicate no clear association between the two variables. However, if the data points seem to align along a straight line, then there may exist a significant relationship among the variables. A positive (negative) slope for the line of data points indicates a positive (negative) association, *meaning the variables move in the same (opposite) direction*. Furthermore, the strength of the association can be determined by how closely the data points are clustered around the line. Tight (loose) clustering signals a potentially stronger (weaker) relationship.

Exhibit 30 Scatter Plot of Information Technology Sector Index Return vs. S&P 500 Index Return

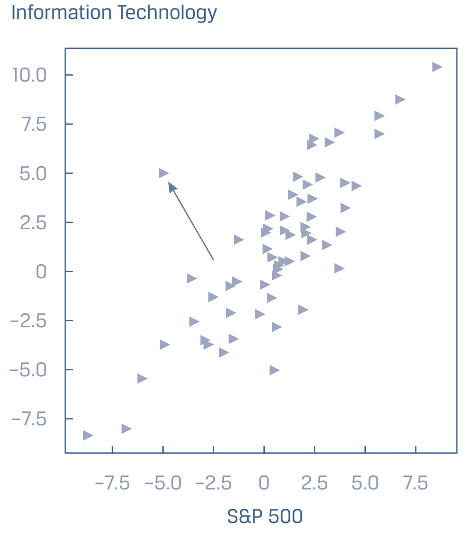


Exhibit 31 Scatter Plot of Utilities Sector Index Return vs. S&P 500 Index Return

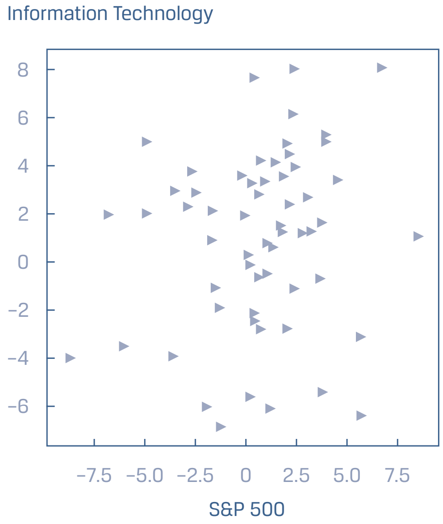
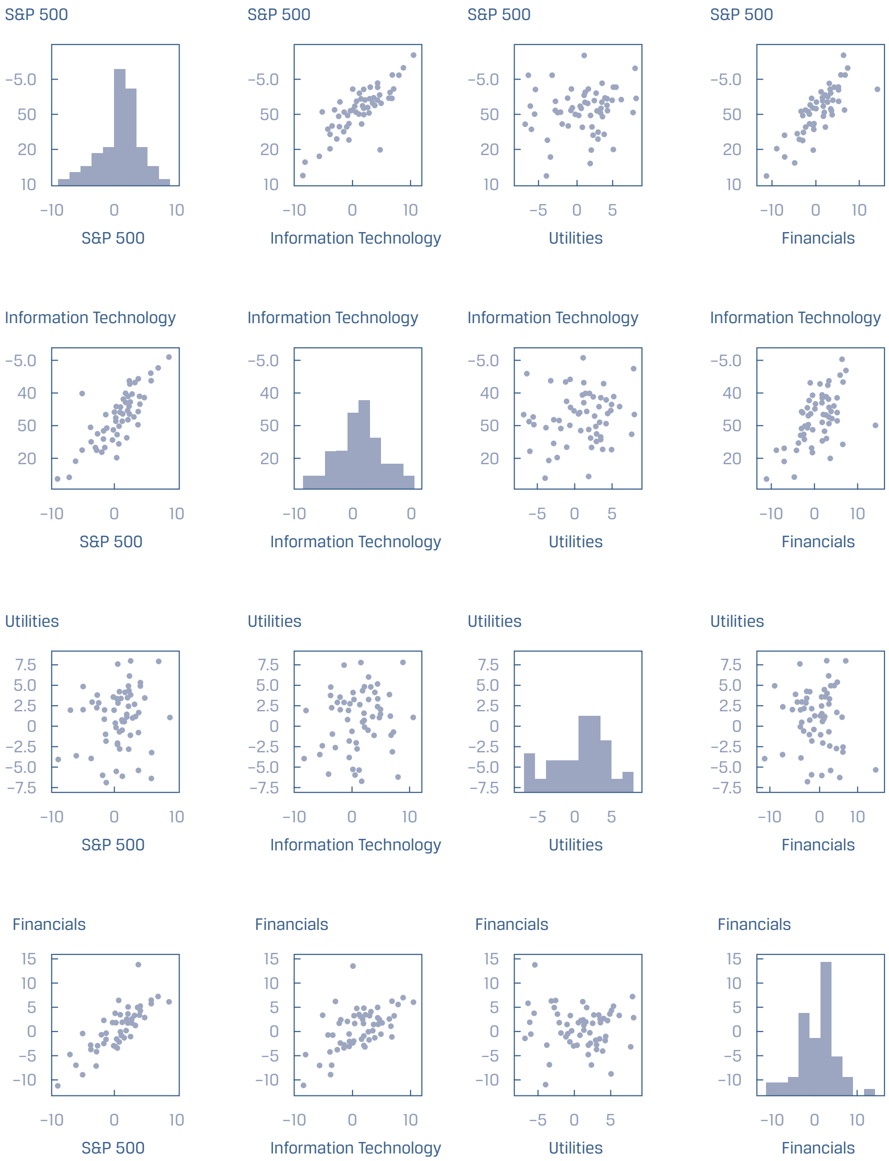


Examining Exhibit 30, we can see the returns of the IT sector are highly positively associated with S&P 500 Index returns because the data points are tightly clustered along a positively sloped line. Exhibit 31 tells a different story for relative performance of the utilities sector and S&P 500 index returns: The data points appear to be distributed in no discernable pattern, indicating no clear relationship among these variables. Second, observing the data points located toward the ends of each axis, which represent the maximum or minimum values, provides a quick sense of the data range. Third, assuming that a relationship among the variables is apparent, inspecting the scatter plot can help to spot extreme values (i.e., outliers). For example, an outlier data point is readily detected in Exhibit 30, as indicated by the arrow. As you will learn later in the CFA Program curriculum, finding these extreme values and handling them with appropriate measures is an important part of the financial modeling process.

Scatter plots are a powerful tool for finding patterns between two variables, for assessing data range, and for spotting extreme values. In practice, however, there are situations where we need to inspect for pairwise associations among many variables—for example, when conducting feature selection from dozens of variables to build a predictive model.

A **scatter plot matrix** is a useful tool for organizing scatter plots between pairs of variables, making it easy to inspect all pairwise relationships in one combined visual. For example, suppose the analyst would like to extend his or her investigation by adding another sector index. He or she can use a scatter plot matrix, as shown in Exhibit 32, which now incorporates four variables, including index returns for the S&P 500 and for three sectors: IT, utilities, and financials.

Exhibit 32 Pairwise Scatter Plot Matrix



The scatter plot matrix contains each combination of bivariate scatter plot (i.e., S&P 500 vs. each sector, IT vs. utilities, IT vs. financials, and financials vs. utilities) as well as univariate frequency distribution histograms for each variable plotted along the diagonal. In this way, the scatter plot matrix provides a concise visual summary of each variable and of potential relationships among them. Importantly, the construction of the scatter plot matrix is typically a built-in function in most major statistical software packages, so it is relatively easy to implement. It is worth pointing out that the upper triangle of the matrix is the mirror image of the lower triangle, so the compact form of the scatter plot matrix that uses only the lower triangle is also appropriate.

With the addition of the financial sector, the bottom panel of Exhibit 32 reveals the following additional information, which can support sector allocation in the portfolio construction process:

- Strong positive relationship between returns of financial and S&P 500;

- Positive relationship between returns of financial and IT; and
- No clear relationship between returns of financial and utilities.

It is important to note that despite their usefulness, scatter plots and scatter plot matrixes should not be considered as a substitute for robust statistical tests; rather, they should be used alongside such tests for best results.

6.7 Heat Map

A **heat map** is a type of graphic that organizes and summarizes data in a tabular format and represents them using a color spectrum. For example, given a portfolio, we can create a contingency table that summarizes the joint frequencies of the stock holdings by sector and by level of market capitalization, as in Exhibit 33.

Exhibit 33 Frequencies by Sector and Market Capitalization in Heat Map

	Small Cap	Mid Cap	Large Cap
Communication Services	21	43	83
Consumer Staples	36	81	45
Energy	99	95	29
Health Care	4	8	18
Utilities	81	37	58

Cells in the chart are color-coded to differentiate high values from low values by using the color scheme defined in the color spectrum on the right side of the chart. As shown by the heat map, this portfolio has the largest exposure (in terms of number of stocks) to small- and mid-cap energy stocks. It has substantial exposures to large-cap communications services, mid-cap consumer staples, and small-cap utilities; however, exposure to the health care sector is limited. In sum, the heat map reveals this portfolio to be relatively well-diversified among sectors and market-cap levels. Besides their use in displaying frequency distributions, heat maps are commonly used for visualizing the degree of correlation among different variables.

EXAMPLE 6

Evaluating Data Visuals

1 You have a cumulative absolute frequency distribution graph (similar to the one in Exhibit 21) of daily returns over a five-year period for an index of Asian equity markets.

Interpret the meaning of the slope of such a graph.

2 You are creating a word cloud for a visual representation of text on a company's quarterly earnings announcements over the past three years. The word cloud uses font size to indicate word frequency. This particular company has experienced both quarterly profits and losses during the period under investigation.

Describe how the word cloud might be used to convey information besides word frequency.

3 You are examining a scatter plot of monthly stock returns, similar to the one in Exhibit 30, for two technology companies: one is a hardware manufacturer, and the other is a software developer. The scatter plot shows a strong positive association among their returns.

Describe what other information the scatter plot can provide.

4 You are reading a vertical bar chart displaying the sales of a company over the past five years. The sales of the first four years seem nearly flat as the corresponding bars are nearly the same height, but the bar representing the sales of the most recent year is approximately three times as high as the other bars.

Explain whether we can conclude that the sales of the fifth year tripled compared to sales in the earlier years.

Solution 1

The slope of the graph of a cumulative absolute frequency distribution reflects the change in the number of observations between two adjacent return bins. A steep (flat) slope indicates a large (small) change in the frequency of observations between adjacent return bins.

Solution 2

Color can add an additional dimension to the information conveyed in the word cloud. For example, red can be used for "losses" and other words conveying negative sentiment, and green can be used for "profit" and other words indicative of positive sentiment.

Solution 3

Besides the sign and degree of association of the stocks' returns, the scatter plot can provide a visual representation of whether the association is linear or non-linear, the maximum and minimum values for the return observations, and an indication of which observations may have extreme values (i.e., are potential outliers).

Solution 4

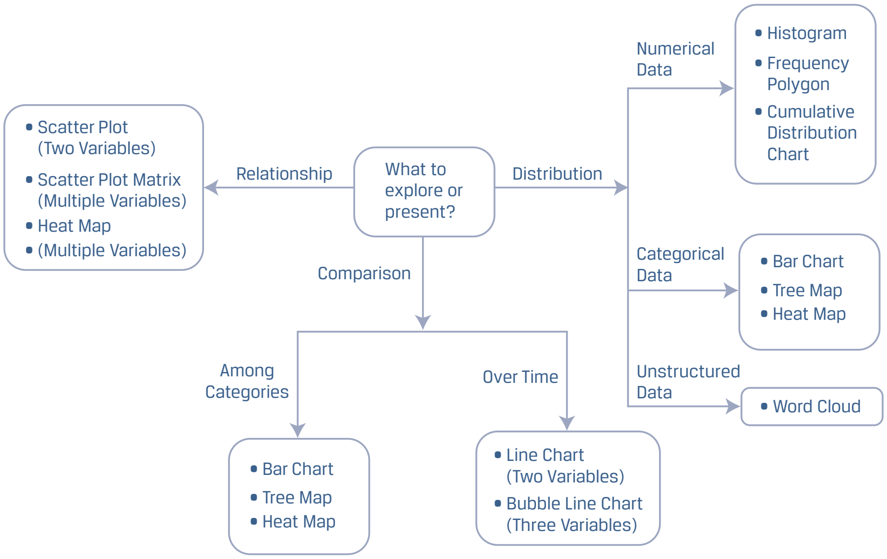
Typically, the heights of bars in a vertical bar chart are proportional to the values that they represent. However, if the graph is using a truncated y-axis (i.e., one that does not start at zero), then values are not accurately represented by the height of bars. Therefore, we need to examine the y-axis of the bar chart before concluding that sales in the fifth year were triple the sales of the prior years.

6.8 Guide to Selecting among Visualization Types

f Describe How to Select among Visualization Types

We have introduced and discussed a variety of different visualization types that are regularly used in investment practice. When it comes to selecting a chart for visualizing data, the intended purpose is the key consideration: Is it for exploring and/or presenting distributions or relationships, or is it for making comparisons? Given your intended purpose, the best selection is typically the simplest visual that conveys the message or achieves the specific goal. Exhibit 34 presents a flow chart for facilitating selection among the visualization types we have discussed. Finally, note that some visualization types, such as bar chart and heat map, may be suitable for several different purposes.

Exhibit 34 Flow Chart of Selecting Visualization Types



What to explore or present?
Relationship
Distribution
Comparison
Scatter Plot (Two Variables)
Scatter Plot Matrix (Multiple Variables)
Heat Map
(Multiple Variables)
Numerical Data
Histogram
Frequency Polygon
Cumulative Distribution Chart
Categorical Data
Bar Chart
Tree Map
Heat Map
Unstructured Data
Word Cloud
Among Categories
Bar Chart
Tree Map
Heat Map
Over Time
Line Chart (Two Variables)
Bubble Line Chart (Three Variables)

Data visualization is a powerful tool to show data and gain insights into data. However, we need to be cautious that a graph could be misleading if data are misrepresented or the graph is poorly constructed. There are numerous different ways that may lead to a misleading graph. We list four typical pitfalls here that analysts should avoid.

First, an improper chart type is selected to present data, which would hinder the accurate interpretation of data. For example, to investigate the correlation between two data series, we can construct a scatter plot to visualize the joint variation between two variables. In contrast, plotting the two data series separately in a line chart would make it rather difficult to examine the relationship.

Second, data are selectively plotted in favor of the conclusion an analyst intends to draw. For example, data presented for an overly short time period may appear to show a trend that is actually noise—that is, variation within the data's normal range if examining the data over a longer time period. So, presenting data for too short a time window may mistakenly point to a non-existing trend.

Third, data are improperly plotted in a truncated graph that has a y-axis that does not start at zero. In some situations, the truncated graph can create the false impression of significant differences when there is actually only a small difference. For example, suppose a vertical bar chart is used to compare annual revenues of two companies, one with \$9 billion and the other with \$10 billion. If the y-axis starts at \$8 billion, then the bar heights would inaccurately imply that the latter company's revenue is twice the former company's revenue.

Last, but not least, is the improper scaling of axes. For example, given a line chart, setting a higher than necessary maximum on the y-axis tends to compress the graph into an area close to the x-axis. This causes the graph to appear to be less steep and less volatile than if it was properly plotted. In sum, analysts need to avoid these misuses of visualization when charting data and must ensure the ethical use of data visuals.

EXAMPLE 7

Selecting Visualization Types

1 A portfolio manager plans to buy several stocks traded on a small emerging market exchange but is concerned whether the market can provide sufficient liquidity to support her purchase order size. As the first step, she wants to analyze the daily trading volumes of one of these stocks over the past five years.

Explain which type of chart can best provide a quick view of trading volume for the given period.

2 An analyst is building a model to predict stock market downturns. According to the academic literature and his practitioner knowledge and expertise, he has selected 10 variables as potential predictors. Before continuing to construct the model, the analyst would like to get a sense of how closely these variables are associated with the broad stock market index and whether any pair of variables are associated with each other.

Describe the most appropriate visual to select for this purpose.

3 Central Bank members meet regularly to assess the economy and decide on any interest rate changes. Minutes of their meetings are published on the Central Bank's website. A quantitative researcher wants to analyze the meeting minutes for use in building a model to predict future economic growth.

Explain which type of chart is most appropriate for creating an overview of the meeting minutes.

4 A private investor wants to add a stock to her portfolio, so she asks her financial adviser to compare the three-year financial performances (by quarter) of two companies. One company experienced consistent revenue and earnings growth, while the other experienced volatile revenue and earnings growth, including quarterly losses.

Describe the chart the adviser should use to best show these performance differences.

Solution to 1

The five-year history of daily trading volumes contains a large amount of numerical data. Therefore, a histogram is the best chart for grouping these data into frequency distribution bins and for showing a quick snapshot of the shape, center, and spread of the data's distribution.

Solution to 2

To inspect for a potential relationship between two variables, a scatter plot is a good choice. But with 10 variables, plotting individual scatter plots is not an efficient approach. Instead, utilizing a scatter plot matrix would give the analyst a good overview in one comprehensive visual of all the pairwise associations between the variables.

Solution to 3

Since the meeting minutes consist of textual data, a word cloud would be the most suitable tool to visualize the textual data and facilitate the researcher's understanding of the topic of the text as well as the sentiment, positive or negative, it may convey.

Solution to 4

The best chart for making this comparison would be a bubble line chart using two different color lines to represent the quarterly revenues for each company. The bubble sizes would then indicate the magnitude of each company's quarterly earnings, with green bubbles signifying profits and red bubbles indicating losses.

MEASURES OF CENTRAL TENDENCY

7

g Calculate and interpret measures of central tendency

So far, we have discussed methods we can use to organize and present data so that they are more understandable. The frequency distribution of an asset return series, for example, reveals much about the nature of the risks that investors may encounter in a particular asset. Although frequency distributions, histograms, and contingency tables provide a convenient way to summarize a series of observations, these methods are just a first step toward describing the data. In this section, we discuss the use of quantitative measures that explain characteristics of data. Our focus is on measures of central tendency and other measures of location. A **measure of central tendency** specifies where the data are centered. Measures of central tendency are probably more widely used than any other statistical measure because they can be computed and applied relatively easily. **Measures of location** include not only measures of central tendency but other measures that illustrate the location or distribution of data.

In the following subsections, we explain the common measures of central tendency—the arithmetic mean, the median, the mode, the weighted mean, the geometric mean, and the harmonic mean. We also explain other useful measures of location, including quartiles, quintiles, deciles, and percentiles.

A **statistic** is a summary measure of a set of observations, and descriptive statistics summarize the central tendency and spread variation in the distribution of data. If the statistic summarizes the set of all possible observations of a **population**, we refer to the statistic as a parameter. If the statistic summarizes a set of observations that is a subset of the population, we refer to the statistic as a **sample statistic**, often leav8ing off the word "sample" and simply referring to it as a statistic. While measures of central tendency and location can be calculated for populations and **samples**, our focus is on sample measures (i.e., sample statistics) as it is rare that an investment manager would be dealing with an entire population of data.

7.1 The Arithmetic Mean

Analysts and portfolio managers often want one number that describes a representative possible outcome of an investment decision. The arithmetic mean is one of the most frequently used measures of the center of data.

> **Definition of Arithmetic Mean.** The **arithmetic mean** is the sum of the values of the observations divided by the number of observations.

7.1.1 *The Sample Mean*

The sample mean is the arithmetic mean or arithmetic average computed for a sample. As you will see, we use the terms "mean" and "average" interchangeably. Often, we cannot observe every member of a population; instead, we observe a subset or sample of the population.

Sample Mean Formula. The **sample mean** or average, $\overline{X}$ (read “X-bar”), is the arithmetic mean value of a sample:

$$\overline{X} = \frac{\sum_{i=1}^{n} X_i}{n} \qquad (2)$$

where n is the number of observations in the sample.

Equation 2 tells us to sum the values of the observations (X_i) and divide the sum by the number of observations. For example, if a sample of market capitalizations for six publicly traded Australian companies contains the values (in AUD billions) 35, 30, 22, 18, 15, and 12, the sample mean market cap is 132/6 = A$22 billion. As previously noted, the sample mean is a statistic (that is, a descriptive measure of a sample).

Means can be computed for individual units or over time. For instance, the sample might be the return on equity (ROE) in a given year for a sample of 25 companies in the FTSE Eurotop 100, an index of Europe’s 100 largest companies. In this case, we calculate the mean ROE in that year as an average across 25 individual units. When we examine the characteristics of some units at a specific point in time (such as ROE for the FTSE Eurotop 100), we are examining cross-sectional data; the mean of these observations is the cross-sectional mean. If the sample consists of the historical monthly returns on the FTSE Eurotop 100 for the past five years, however, then we have time-series data; the mean of these observations is the time-series mean. We will examine specialized statistical methods related to the behavior of time series in the reading on time-series analysis.

Except in cases of large datasets with many observations, we should not expect any of the actual observations to equal the mean; sample means provide only a summary of the data being analyzed. Also, although in some cases the number of values below the mean is quite close to the number of values above the mean, this need not be the case. As an analyst, you will often need to find a few numbers that describe the characteristics of the distribution, and we will consider more later. The mean is generally the statistic that you use as a measure of the typical outcome for a distribution. You can then use the mean to compare the performance of two different markets. For example, you might be interested in comparing the stock market performance of investments in Asia Pacific with investments in Europe. You can use the mean returns in these markets to compare investment results.

EXAMPLE 8

Calculating a Cross-Sectional Mean

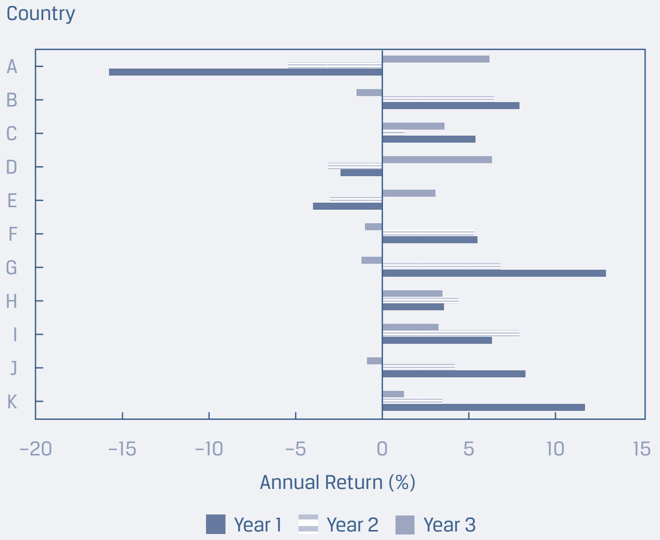
Suppose we want to examine the performance of a sample of selected stock indexes from 11 different countries. The 52-week percentage change is reported in Exhibit 35 for Year 1, Year 2, and Year 3 for the sample of indexes.

Exhibit 35 Annual Returns for Years 1 to 3 for Selected Countries’ Stock Indexes

	52-Week Return (%)		
Index	**Year 1**	**Year 2**	**Year 3**
Country A	−15.6	−5.4	6.1
Country B	7.8	6.3	−1.5

Exhibit 35 (Continued)

	52-Week Return (%)		
Index	**Year 1**	**Year 2**	**Year 3**
Country C	5.3	1.2	3.5
Country D	−2.4	−3.1	6.2
Country E	−4.0	−3.0	3.0
Country F	5.4	5.2	−1.0
Country G	12.7	6.7	−1.2
Country H	3.5	4.3	3.4
Country I	6.2	7.8	3.2
Country J	8.1	4.1	−0.9
Country K	11.5	3.4	1.2



Using the data provided, calculate the sample mean return for the 11 indexes for each year.

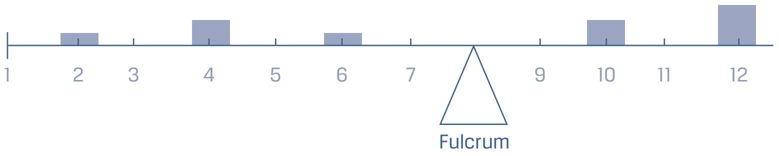
Solution:

For Year 3, the calculation applies Equation 2 to the returns for Year 3: (6.1 – 1.5 + 3.5 + 6.2 + 3.0 – 1.0 – 1.2 + 3.4 + 3.2 – 0.9 + 1.2)/11 = 22.0/11 = 2.0%. Using a similar calculation, the sample mean is 3.5% for Year 1 and 2.5% for Year 2.

7.1.2 *Properties of the Arithmetic Mean*

The arithmetic mean can be likened to the center of gravity of an object. Exhibit 36 expresses this analogy graphically by plotting nine hypothetical observations on a bar. The nine observations are 2, 4, 4, 6, 10, 10, 12, 12, and 12; the arithmetic mean is 72/9 = 8. The observations are plotted on the bar with various heights based on their frequency (that is, 2 is one unit high, 4 is two units high, and so on). When the bar is placed on a fulcrum, it balances only when the fulcrum is located at the point on the scale that corresponds to the arithmetic mean.

Exhibit 36 Center of Gravity Analogy for the Arithmetic Mean



As analysts, we often use the mean return as a measure of the typical outcome for an asset. As in Example 8, however, some outcomes are above the mean and some are below it. We can calculate the distance between the mean and each outcome, which is the deviation. Mathematically, it is always true that the sum of the deviations around the mean equals 0. We can see this by using the definition of the arithmetic mean shown in Equation 2, multiplying both sides of the equation by n: $n\overline{X} = \sum_{i=1}^{n} X_i$. The sum of the deviations from the mean is calculated as follows:

$$\sum_{i=1}^{n}\left(X_i - \overline{X}\right) = \sum_{i=1}^{n} X_i - \sum_{i=1}^{n} \overline{X} = \sum_{i=1}^{n} X_i - n\overline{X} = 0$$

Deviations from the arithmetic mean are important information because they indicate risk. The concept of deviations around the mean forms the foundation for the more complex concepts of variance, skewness, and kurtosis, which we will discuss later.

A property and potential drawback of the arithmetic mean is its sensitivity to extreme values, or outliers. Because all observations are used to compute the mean and are given equal weight (i.e., importance), the arithmetic mean can be pulled sharply upward or downward by extremely large or small observations, respectively. For example, suppose we compute the arithmetic mean of the following seven numbers: 1, 2, 3, 4, 5, 6, and 1,000. The mean is 1,021/7 = 145.86, or approximately 146. Because the magnitude of the mean, 146, is so much larger than most of the observations (the first six), we might question how well it represents the location of the data. Perhaps the most common approach in such cases is to report the median, or middle value, in place of or in addition to the mean.

7.1.3 *Outliers*

In practice, although an extreme value or outlier in a financial dataset may just represent a rare value in the population, it may also reflect an error in recording the value of an observation or an observation generated from a different population from that producing the other observations in the sample. In the latter two cases, in particular, the arithmetic mean could be misleading. So, what do we do? The first step is to examine the data, either by inspecting the sample observations if the sample is not too large or by using visualization approaches. Once we are comfortable that we have identified and eliminated errors (that is, we have "cleaned" the data), we can then address what to do with extreme values in the sample. When dealing with a sample that has extreme values, there may be a possibility of transforming the variable (e.g., a log transformation) or of selecting another variable that achieves the same purpose. However, if alternative model specifications or variable transformations are not possible, then here are three options for dealing with extreme values:

Option 1	Do nothing; use the data without any adjustment.
Option 2	Delete all the outliers.
Option 3	Replace the outliers with another value.

The first option is appropriate if the values are legitimate, correct observations, and it is important to reflect the whole of the sample distribution. Outliers may contain meaningful information, so excluding or altering these values may reduce valuable information. Further, because identifying a data point as extreme leaves it up to the judgment of the analyst, leaving in all observations eliminates that need to judge a value as extreme.

The second option excludes the extreme observations. One measure of central tendency in this case is the **trimmed mean**, which is computed by excluding a stated small percentage of the lowest and highest values and then computing an arithmetic mean of the remaining values. For example, a 5% trimmed mean discards the lowest 2.5% and the highest 2.5% of values and computes the mean of the remaining 95% of values. A trimmed mean is used in sports competitions when judges' lowest and highest scores are discarded in computing a contestant's score.

The third option involves substituting values for the extreme values. A measure of central tendency in this case is the **winsorized mean**. It is calculated by assigning a stated percentage of the lowest values equal to one specified low value and a stated percentage of the highest values equal to one specified high value, and then it computes a mean from the restated data. For example, a 95% winsorized mean sets the bottom 2.5% of values equal to the value at or below which 2.5% of all the values lie (as will be seen shortly, this is called the "2.5th percentile" value) and the top 2.5% of values equal to the value at or below which 97.5% of all the values lie (the "97.5th percentile" value).

In Exhibit 37, we show the differences among these options for handling outliers using daily returns for the fictitious Euro-Asia-Africa (EAA) Equity Index in Exhibit 11.

Exhibit 37 Handling Outliers: Daily Returns to an Index

Consider the fictitious EAA Equity Index. Using daily returns on the EAA Equity Index for the period of five years, consisting of 1,258 trading days, we can see the effect of trimming and winsorizing the data:

	Arithmetic Mean (%)	Trimmed Mean [Trimmed 5%] (%)	Winsorized Mean [95%] (%)
Mean	0.035	0.048	0.038
Number of Observations	1,258	1,194	1,258

The trimmed mean eliminates the lowest 2.5% of returns, which in this sample is any daily return less than −1.934%, and it eliminates the highest 2.5%, which in this sample is any daily return greater than 1.671%. The result of this trimming is that the mean is calculated using 1,194 observations instead of the original sample's 1,258 observations.

The winsorized mean substitutes −1.934% for any return below −1.934 and substitutes 1.671% for any return above 1.671. The result in this case is that the trimmed and winsorized means are above the arithmetic mean.

7.2 The Median

A second important measure of central tendency is the median.

Definition of Median. The **median** is the value of the middle item of a set of items that has been sorted into ascending or descending order. In an odd-numbered sample of n items, the median is the value of the item that occupies the $(n + 1)/2$ position. In an even-numbered sample, we define the median as the mean of the values of items occupying the $n/2$ and $(n + 2)/2$ positions (the two middle items).

Suppose we have a return on assets (in %) for each of three companies: 0.0, 2.0, and 2.1. With an odd number of observations ($n = 3$), the median occupies the $(n + 1)/2 = 4/2 =$ 2nd position. The median is 2.0%. The value of 2.0% is the "middlemost" observation: One lies above it, and one lies below it. Whether we use the calculation for an even- or odd-numbered sample, an equal number of observations lie above and below the median. A distribution has only one median.

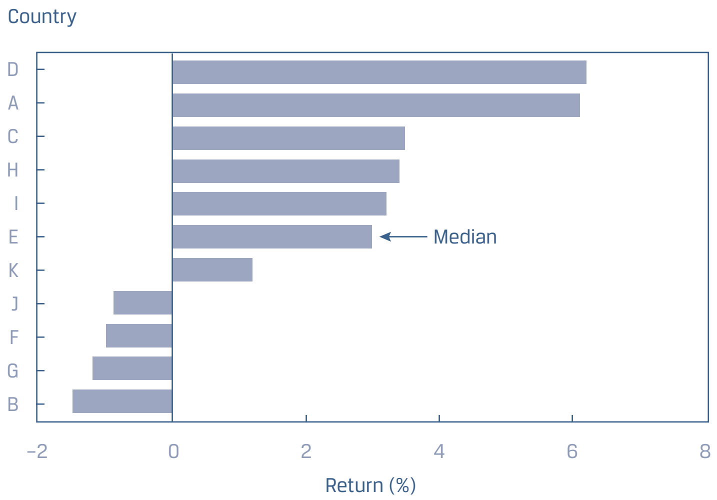
A potential advantage of the median is that, unlike the mean, extreme values do not affect it. For example, if a sample consists of the observations of 1, 2, 3, 4, 5, 6 and 1,000, the median is 4. The median is not influenced by the extremely large outcome of 1,000. In other words, the median is affected less by outliers than the mean and therefore is useful in describing data that follow a distribution that is not symmetric, such as revenues.

The median, however, does not use all the information about the size of the observations; it focuses only on the relative position of the ranked observations. Calculating the median may also be more complex. To do so, we need to order the observations from smallest to largest, determine whether the sample size is even or odd, and then on that basis, apply one of two calculations. Mathematicians express this disadvantage by saying that the median is less mathematically tractable than the mean.

We use the data from Exhibit 35 to demonstrate finding the median, reproduced in Exhibit 38 in ascending order of the return for Year 3, with the ranked position from 1 (lowest) to 11 (highest) indicated. Because this sample has 11 observations, the median is the value in the sorted array that occupies the $(11 + 1)/2 =$ 6th position. Country E's index occupies the sixth position and is the median. The arithmetic mean for Year 3 for this sample of indexes is 2.0%, whereas the median is 3.0.

Exhibit 38 Returns on Selected Country Stock Indexes for Year 3 in Ascending Order

Index	Year 3 Return (%)		Position
Country B	−1.5		1
Country G	−1.2		2
Country F	−1.0		3
Country J	−0.9		4
Country K	1.2		5
Country E	3.0	←	6
Country I	3.2		7
Country H	3.4		8
Country C	3.5		9
Country A	6.1		10
Country D	6.2		11



If a sample has an even number of observations, the median is the mean of the two values in the middle. For example, if our sample in Exhibit 38 had 12 indexes instead of 11, the median would be the mean of the values in the sorted array that occupy the sixth and the seventh positions.

7.3 The Mode

The third important measure of central tendency is the mode.

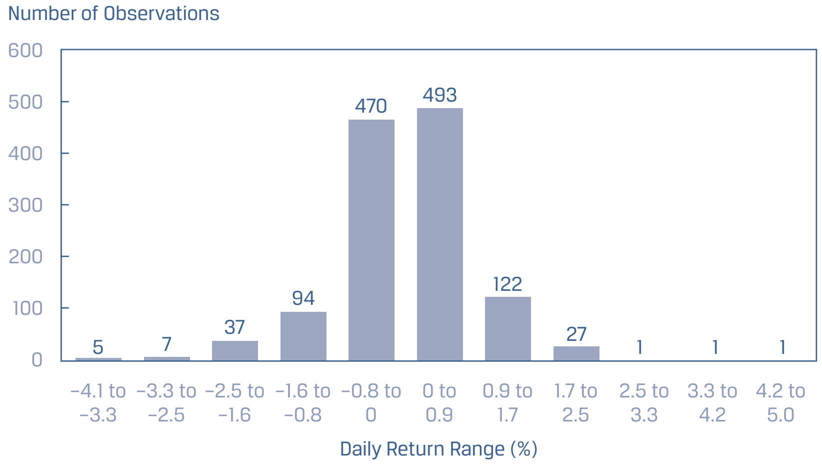
> **Definition of Mode.** The **mode** is the most frequently occurring value in a distribution.

A distribution can have more than one mode, or even no mode. When a distribution has a single value that is most frequently occurring, the distribution is said to be **unimodal**. If a distribution has two most frequently occurring values, then it has two modes and is called **bimodal**. If the distribution has three most frequently occurring values, then it is **trimodal**. When all the values in a dataset are different, the distribution has no mode because no value occurs more frequently than any other value.

Stock return data and other data from continuous distributions may not have a modal outcome. When such data are grouped into bins, however, we often find an interval (possibly more than one) with the highest frequency: the **modal interval** (or intervals). Consider the frequency distribution of the daily returns for the EAA Equity Index over five years that we looked at in Exhibit 11. A histogram for the frequency distribution of these daily returns is shown in Exhibit 39. The modal interval always has the highest bar in the histogram; in this case, the modal interval is 0.0 to 0.9%, and this interval has 493 observations out of a total of 1,258 observations.

Notice that this histogram in Exhibit 39 looks slightly different from the one in Exhibit 11, since this one has 11 bins and follows the seven-step procedure exactly. Thus, the bin width is 0.828 [= (5.00 – −4.11)/11], and the first bin begins at the minimum value of −4.11%. It was noted previously that for ease of interpretation, in practice bin width is often rounded up to the nearest whole number; the first bin can start at the nearest whole number below the minimum value. These refinements and the use of 10 bins were incorporated into the histogram in Exhibit 11, which has a modal interval of 0.0% to 1.0%.

Exhibit 39 Histogram of Daily Returns on the EAA Equity Index



The mode is the only measure of central tendency that can be used with nominal data. For example, when we categorize investment funds into different styles and assign a number to each style, the mode of these categorized data is the most frequent investment fund style.

7.4 Other Concepts of Mean

Earlier we explained the arithmetic mean, which is a fundamental concept for describing the central tendency of data. An advantage of the arithmetic mean over two other measures of central tendency, the median and mode, is that the mean uses all the information about the size of the observations. The mean is also relatively easy to work with mathematically.

However, other concepts of mean are very important in investments. In the following sections, we discuss such concepts.

7.4.1 *The Weighted Mean*

The concept of weighted mean arises repeatedly in portfolio analysis. In the arithmetic mean, all sample observations are equally weighted by the factor $1/n$. In working with portfolios, we often need the more general concept of weighted mean to allow for different (i.e., unequal) weights on different observations.

To illustrate the weighted mean concept, an investment manager with $100 million to invest might allocate $70 million to equities and $30 million to bonds. The portfolio, therefore, has a weight of 0.70 on stocks and 0.30 on bonds. How do we calculate the return on this portfolio? The portfolio's return clearly involves an averaging of the returns on the stock and bond investments. The mean that we compute, however, must reflect the fact that stocks have a 70% weight in the portfolio and bonds have a 30% weight. The way to reflect this weighting is to multiply the return on the stock investment by 0.70 and the return on the bond investment by 0.30, then sum the two results. This sum is an example of a weighted mean. It would be incorrect to take an arithmetic mean of the return on the stock and bond investments, equally weighting the returns on the two asset classes.

Weighted Mean Formula. The **weighted mean** $\overline{X}_w$ (read "X-bar sub-w"), for a set of observations $X_1, X_2, \ldots, X_n$ with corresponding weights of $w_1, w_2, \ldots, w_n$, is computed as:

$$\overline{X}_w = \sum_{i=1}^{n} w_i X_i \tag{3}$$

where the sum of the weights equals 1; that is, $\sum_i w_i = 1$.

In the context of portfolios, a positive weight represents an asset held long and a negative weight represents an asset held short.

The formula for the weighted mean can be compared to the formula for the arithmetic mean. For a set of observations $X_1, X_2, \ldots, X_n$, let the weights $w_1, w_2, \ldots, w_n$ all equal $1/n$. Under this assumption, the formula for the weighted mean is $(1/n)\sum_{i=1}^{n} X_i$. This is the formula for the arithmetic mean. Therefore, the arithmetic mean is a special case of the weighted mean in which all the weights are equal.

EXAMPLE 9

Calculating a Weighted Mean

Using the country index data shown in Exhibit 35, consider a portfolio that consists of three funds that track three countries' indexes: County C, Country G, and Country K. The portfolio weights and index returns are as follows:

Index Tracked by Fund	Allocation (%)	Annual Return (%) Year 1	Year 2	Year 3
Country C	25%	5.3	1.2	3.5
Country G	45%	12.7	6.7	−1.2
Country K	30%	11.5	3.4	1.2

Using the information provided, calculate the returns on the portfolio for each year.

Solution

Converting the percentage asset allocation to decimal form, we find the mean return as the weighted average of the funds' returns. We have:

Mean portfolio return for Year 1 $= 0.25\,(5.3) + 0.45\,(12.7) + 0.30(11.5)$
$= 10.50\%$

Mean portfolio return for Year 2 $= 0.25\,(1.2) + 0.45\,(6.7) + 0.30\,(3.4)$
$= 4.34\%$

Mean portfolio return for Year 3 $= 0.25\,(3.5) + 0.45\,(-1.2) + 0.30\,(1.2)$
$= 0.70\%$

This example illustrates the general principle that a portfolio return is a weighted sum. Specifically, a portfolio's return is the weighted average of the returns on the assets in the portfolio; the weight applied to each asset's return is the fraction of the portfolio invested in that asset.

Market indexes are computed as weighted averages. For market-capitalization weighted indexes, such as the CAC-40 in France, the TOPIX in Japan, or the S&P 500 in the United States, each included stock receives a weight corresponding to its market value divided by the total market value of all stocks in the index.

Our illustrations of weighted mean use past data, but they might just as well use forward-looking data. When we take a weighted average of forward-looking data, the weighted mean is the expected value. Suppose we make one forecast for the year-end level of the S&P 500 assuming economic expansion and another forecast for the year-end level of the S&P 500 assuming economic contraction. If we multiply the first forecast by the probability of expansion and the second forecast by the probability of contraction and then add these weighted forecasts, we are calculating the expected value of the S&P 500 at year-end. If we take a weighted average of possible future returns on the S&P 500, where the weights are the probabilities, we are computing the S&P 500's expected return. The probabilities must sum to 1, satisfying the condition on the weights in the expression for weighted mean, Equation 3.

7.4.2 *The Geometric Mean*

The geometric mean is most frequently used to average rates of change over time or to compute the growth rate of a variable. In investments, we frequently use the geometric mean to either average a time series of rates of return on an asset or a portfolio or to compute the growth rate of a financial variable, such as earnings or sales. The geometric mean is defined by the following formula.

> **Geometric Mean Formula.** The **geometric mean**, $\bar{X}_G$, of a set of observations $X_1, X_2, \ldots, X_n$ is:

$$\bar{X}_G = \sqrt[n]{X_1 X_2 X_3 \ldots X_n} \text{ with } X_i \geq 0 \text{ for } i = 1, 2, \ldots, n. \quad (4)$$

Equation 4 has a solution, and the geometric mean exists only if the product under the square root sign is non-negative. Therefore, we must impose the restriction that all the observations X_i are greater than or equal to zero. We can solve for the geometric mean directly with any calculator that has an exponentiation key (on most calculators, y^x). We can also solve for the geometric mean using natural logarithms. Equation 4 can also be stated as

$$ln\bar{X}_G = \frac{1}{n} ln\left(X_1 X_2 X_3 \ldots X_n\right)$$

or, because the logarithm of a product of terms is equal to the sum of the logarithms of each of the terms, as

$$ln\bar{X}_G = \frac{\sum_{i=1}^{n} lnX_i}{n}$$

When we have computed $ln\bar{X}_G$, then $\bar{X}_G = e^{ln\bar{X}_G}$ (on most calculators, the key for this step is e^x).

Risky assets can have negative returns up to −100% (if their price falls to zero), so we must take some care in defining the relevant variables to average in computing a geometric mean. We cannot just use the product of the returns for the sample and then take the nth root because the returns for any period could be negative. We must recast the returns to make them positive. We do this by adding 1.0 to the returns expressed as decimals, where R_t represents the return in period t. The term $(1 + R_t)$ represents the year-ending value relative to an initial unit of investment at the beginning of the year. As long as we use $(1 + R_t)$, the observations will never be negative because the biggest negative return is –100%. The result is the geometric mean of $1 + R_t$; by then subtracting 1.0 from this result, we obtain the geometric mean of the individual returns R_t.

An equation that summarizes the calculation of the geometric mean return, R_G, is a slightly modified version of Equation 4 in which X_i represents "1 + return in decimal form." Because geometric mean returns use time series, we use a subscript t indexing time as well. We calculate one plus the geometric mean return as:

$$1 + R_G = \sqrt[T]{(1 + R_1)(1 + R_2)\ldots(1 + R_T)}$$

We can represent this more compactly as:

$$1 + R_G = \left[\prod_{t=1}^{T}(1 + R_t)\right]^{\frac{1}{T}}$$

where the capital Greek letter 'pi,' Π, denotes the arithmetical operation of multiplication of the T terms. Once we subtract one, this becomes the formula for the geometric mean return.

For example, the returns on Country B's index are given in Exhibit 35 as 7.8, 6.3, and –1.5%. Putting the returns into decimal form and adding 1.0 produces 1.078, 1.063, and 0.985. Using Equation 4, we have $\sqrt[3]{(1.078)(1.063)(0.985)} = \sqrt[3]{1.128725} =$ 1.041189. This number is 1 plus the geometric mean rate of return. Subtracting 1.0 from this result, we have 1.041189 – 1.0 = 0.041189, or approximately 4.12%. This is lower than the arithmetic mean for County B's index of 4.2%.

Geometric Mean Return Formula. Given a time series of holding period returns R_t, $t = 1, 2, \ldots, T$, the geometric mean return over the time period spanned by the returns R_1 through R_T is:

$$R_G = \left[\prod_{t=1}^{T}(1 + R_t)\right]^{\frac{1}{T}} - 1 \qquad (5)$$

We can use Equation 5 to solve for the geometric mean return for any return data series. Geometric mean returns are also referred to as compound returns. If the returns being averaged in Equation 5 have a monthly frequency, for example, we may call the geometric mean monthly return the compound monthly return. The next example illustrates the computation of the geometric mean while contrasting the geometric and arithmetic means.

EXAMPLE 10

Geometric and Arithmetic Mean Returns

Using the data in Exhibit 35, calculate the arithmetic mean and the geometric mean returns over the three years for each of the three stock indexes: those of Country D, Country E, and Country F.

Solution

The arithmetic mean returns calculations are:

	Annual Return (%)			**Sum**	
	Year 1	**Year 2**	**Year 3**	$\sum_{i=1}^{3} R_i$	**Arithmetic Mean**
Country D	−2.4	−3.1	6.2	0.7	0.233
Country E	−4.0	−3.0	3.0	−4.0	−1.333
Country F	5.4	5.2	−1.0	9.6	3.200

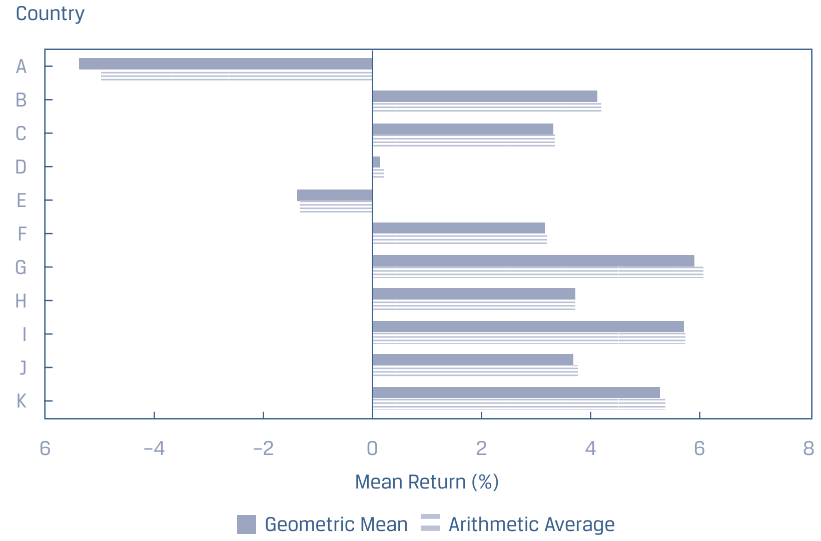
Geometric mean returns calculations are:

	1 + Return in Decimal Form (1 + R_t)			**Product**	**3rd root**	
	Year 1	**Year 2**	**Year 3**	$\prod_{t}^{T}(1+R_t)$	$\left[\prod_{t}^{3}(1+R_t)\right]^{\frac{1}{3}}$	**Geometric mean return (%)**
Country D	0.976	0.969	1.062	1.00438	1.00146	0.146
Country E	0.960	0.970	1.030	0.95914	0.98619	−1.381
Country F	1.054	1.052	0.990	1.09772	1.03157	3.157

In Example 10, the geometric mean return is less than the arithmetic mean return for each country's index returns. In fact, the geometric mean is always less than or equal to the arithmetic mean. The only time that the two means will be equal is when there is no variability in the observations—that is, when all the observations in the series are the same.

In general, the difference between the arithmetic and geometric means increases with the variability within the sample; the more disperse the observations, the greater the difference between the arithmetic and geometric means. Casual inspection of the returns in Exhibit 35 and the associated graph of means suggests a greater variability for Country A's index relative to the other indexes, and this is confirmed with the greater deviation of the geometric mean return (−5.38%) from the arithmetic mean return (−4.97%), as we show in Exhibit 40. How should the analyst interpret these results?

Exhibit 40 Arithmetic and Geometric Mean Returns for Country Stock Indexes: Years 1 to 3



The geometric mean return represents the growth rate or compound rate of return on an investment. One unit of currency invested in a fund tracking the Country B index at the beginning of Year 1 would have grown to $(1.078)(1.063)(0.985) = 1.128725$ units of currency, which is equal to 1 plus the geometric mean return compounded over three periods: $[1 + 0.041189]^3 = 1.128725$, confirming that the geometric mean is the compound rate of return. With its focus on the profitability of an investment over a multi-period horizon, the geometric mean is of key interest to investors. The arithmetic mean return, focusing on average single-period performance, is also of interest. Both arithmetic and geometric means have a role to play in investment management, and both are often reported for return series.

For reporting historical returns, the geometric mean has considerable appeal because it is the rate of growth or return we would have to earn each year to match the actual, cumulative investment performance. Suppose we purchased a stock for €100 and two years later it was worth €100, with an intervening year at €200. The geometric mean of 0% is clearly the compound rate of growth during the two years, which we can confirm by compounding the returns: $[(1 + 1.00)(1 - 0.50)]^{1/2} - 1 = 0\%$. Specifically, the ending amount is the beginning amount times $(1 + R_G)^2$. The geometric mean is an excellent measure of past performance.

The arithmetic mean, which is [100% + −50%]/2 = 25% in the above example, can distort our assessment of historical performance. As we noted previously, the arithmetic mean is always greater than or equal to the geometric mean. If we want to estimate the average return over a one-period horizon, we should use the arithmetic mean because the arithmetic mean is the average of one-period returns. If we want to estimate the average returns over more than one period, however, we should use the geometric mean of returns because the geometric mean captures how the total returns are linked over time. In a forward-looking context, a financial analyst calculating expected risk premiums may find that the weighted mean is appropriate, with the probabilities of the possible outcomes used as the weights.

Dispersion in cash flows or returns causes the arithmetic mean to be larger than the geometric mean. The more dispersion in the sample of returns, the more divergence exists between the arithmetic and geometric means. If there is zero variance in a sample of observations, the geometric and arithmetic return are equal.

7.4.3 *The Harmonic Mean*

The arithmetic mean, the weighted mean, and the geometric mean are the most frequently used concepts of mean in investments. A fourth concept, the **harmonic mean**, $\bar{X}_H$, is another measure of central tendency. The harmonic mean is appropriate in cases in which the variable is a rate or a ratio. The terminology "harmonic" arises from its use of a type of series involving reciprocals known as a harmonic series.

Harmonic Mean Formula. The harmonic mean of a set of observations X_1, X_2, …, X_n is:

$$\bar{X}_H = \frac{n}{\sum_{i=1}^{n}(1/X_i)} \text{ with } X_i > 0 \text{ for } i = 1, 2, \ldots, n. \tag{6}$$

The harmonic mean is the value obtained by summing the reciprocals of the observations—terms of the form $1/X_i$—then averaging that sum by dividing it by the number of observations n, and, finally, taking the reciprocal of the average.

The harmonic mean may be viewed as a special type of weighted mean in which an observation's weight is inversely proportional to its magnitude. For example, if there is a sample of observations of 1, 2, 3, 4, 5, 6, and 1,000, the harmonic mean is 2.8560. Compared to the arithmetic mean of 145.8571, we see the influence of the outlier (the 1,000) to be much less than in the case of the arithmetic mean. So, the harmonic mean is quite useful as a measure of central tendency in the presence of outliers.

The harmonic mean is used most often when the data consist of rates and ratios, such as P/Es. Suppose three peer companies have P/Es of 45, 15, and 15. The arithmetic mean is 25, but the harmonic mean, which gives less weight to the P/E of 45, is 19.3.

EXAMPLE 11

Harmonic Mean Returns and the Returns on Selected Country Stock Indexes

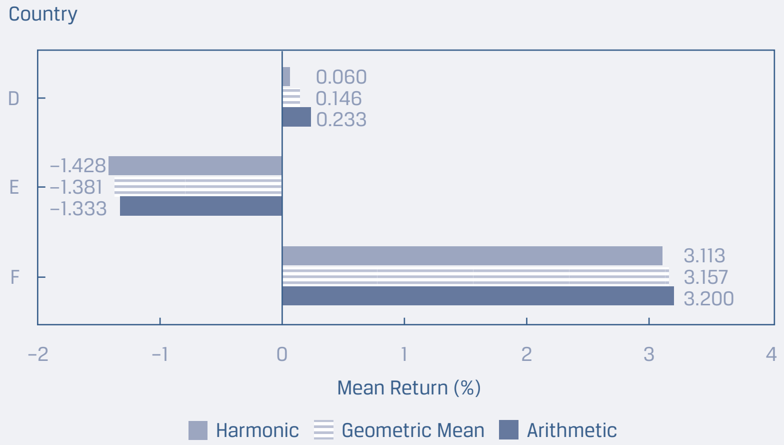
Using data in Exhibit 35, calculate the harmonic mean return over the 2016–2018 period for three stock indexes: Country D, Country E, and Country F.

Calculating the Harmonic Mean for the Indexes

	Inverse of 1 + Return, or $\frac{1}{(1+X_i)}$ where X_i is the return in decimal form					
Index	**Year 1**	**Year 2**	**Year 3**	$\sum_{i}^{n} 1/X_i$	$\frac{n}{\sum_{i}^{n} 1/X_i}$	**Harmonic Mean (%)**
Country D	1.02459	1.03199	0.94162	2.99820	1.00060	0.05999
Country E	1.04167	1.03093	0.97087	3.04347	0.98572	−1.42825
Country F	0.94877	0.95057	1.01010	2.90944	1.03113	3.11270

Comparing the three types of means, we see the arithmetic mean is higher than the geometric mean return, and the geometric mean return is higher than the harmonic mean return. We can see the differences in these means in the following graph:

Harmonic, Geometric, and Arithmetic Means of Selected Country Indexes



The harmonic mean is a relatively specialized concept of the mean that is appropriate for averaging ratios ("amount per unit") when the ratios are repeatedly applied to a fixed quantity to yield a variable number of units. The concept is best explained through an illustration. A well-known application arises in the investment strategy known as **cost averaging**, which involves the periodic investment of a fixed amount of money. In this application, the ratios we are averaging are prices per share at different purchase dates, and we are applying those prices to a constant amount of money to yield a variable number of shares. An illustration of the harmonic mean to cost averaging is provided in Example 12.

EXAMPLE 12

Cost Averaging and the Harmonic Mean

Suppose an investor purchases €1,000 of a security each month for $n = 2$ months. The share prices are €10 and €15 at the two purchase dates. What is the average price paid for the security?

Purchase in the first month = €1,000/€10 = 100 shares

Purchase in the second month = €1,000/€15 = 66.67 shares

The purchases are 166.67 shares in total, and the price paid per share is €2,000/166.67 = €12.

The average price paid is in fact the harmonic mean of the asset's prices at the purchase dates. Using Equation 6, the harmonic mean price is 2/[(1/10) + (1/15)] = €12. The value €12 is less than the arithmetic mean purchase price (€10 + €15)/2 = €12.5.

However, we could find the correct value of €12 using the weighted mean formula, where the weights on the purchase prices equal the shares purchased at a given price as a proportion of the total shares purchased. In our example, the calculation would be (100/166.67)€10.00 + (66.67/166.67)€15.00 = €12. If we had invested varying amounts of money at each date, we could not use the harmonic mean formula. We could, however, still use the weighted mean formula.

h Evaluate alternative definitions of mean to address an investment problem

Since they use the same data but involve different progressions in their respective calculations (that is, arithmetic, geometric, and harmonic progressions) the arithmetic, geometric, and harmonic means are mathematically related to one another. While we will not go into the proof of this relationship, the basic result follows:

Arithmetic mean × Harmonic mean = Geometric mean^2.

However, the key question is: Which mean to use in what circumstances?

EXAMPLE 13

Calculating the Arithmetic, Geometric, and Harmonic Means for P/Es

Each year in December, a securities analyst selects her 10 favorite stocks for the next year. Exhibit 41 gives the P/E, the ratio of share price to projected earnings per share (EPS), for her top-10 stock picks for the next year.

Exhibit 41 Analyst's 10 Favorite Stocks for Next Year

Stock	P/E
Stock 1	22.29
Stock 2	15.54
Stock 3	9.38
Stock 4	15.12
Stock 5	10.72
Stock 6	14.57
Stock 7	7.20
Stock 8	7.97
Stock 9	10.34
Stock 10	8.35

For these 10 stocks,

1 Calculate the arithmetic mean P/E.

2 Calculate the geometric mean P/E.

3 Calculate the harmonic mean P/E.

Solution

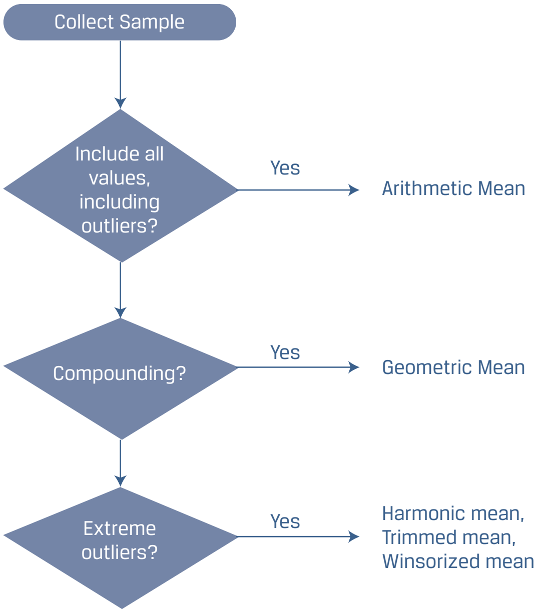
Stock	P/E	Natural Log of the P/E $ln(X_i)$	Inverse of the P/E $1/X_i$
Stock 1	22.29	3.1041	0.0449
Stock 2	15.54	2.7434	0.0644
Stock 3	9.38	2.2386	0.1066
Stock 4	15.12	2.7160	0.0661
Stock 5	10.72	2.3721	0.0933
Stock 6	14.57	2.6790	0.0686
Stock 7	7.20	1.9741	0.1389
Stock 8	7.97	2.0757	0.1255
Stock 9	10.34	2.3360	0.0967
Stock 10	8.35	2.1223	0.1198
Sum	121.48	24.3613	0.9247

1. The arithmetic mean is 121.48/10 = 12.1480.
2. The geometric mean is $e^{24.3613/10} = 11.4287$.
3. The harmonic mean is 10/0.9247 = 10.8142.

A mathematical fact concerning the harmonic, geometric, and arithmetic means is that unless all the observations in a dataset have the same value, the harmonic mean is less than the geometric mean, which, in turn, is less than the arithmetic mean. The choice of which mean to use depends on many factors, as we describe in Exhibit 42:

- Are there outliers that we want to include?
- Is the distribution symmetric?
- Is there compounding?
- Are there extreme outliers?

Exhibit 42 Deciding Which Central Tendency Measure to Use



8 QUANTILES

i. Calculate quantiles and interpret related visualizations

Having discussed measures of central tendency, we now examine an approach to describing the location of data that involves identifying values at or below which specified proportions of the data lie. For example, establishing that 25, 50, and 75% of the annual returns on a portfolio are at or below the values −0.05, 0.16, and 0.25, respectively, provides concise information about the distribution of portfolio returns. Statisticians use the word **quantile** (or **fractile**) as the most general term for a value at or below which a stated fraction of the data lies. In the following section, we describe the most commonly used quantiles—quartiles, quintiles, deciles, and percentiles—and their application in investments.

8.1 Quartiles, Quintiles, Deciles, and Percentiles

We know that the median divides a distribution of data in half. We can define other dividing lines that split the distribution into smaller sizes. **Quartiles** divide the distribution into quarters, **quintiles** into fifths, **deciles** into tenths, and **percentiles** into hundredths. Given a set of observations, the yth percentile is the value at or below which y% of observations lie. Percentiles are used frequently, and the other measures can be defined with respect to them. For example, the first quartile (Q_1) divides a distribution such that 25% of the observations lie at or below it; therefore, the first quartile is also the 25th percentile. The second quartile (Q_2) represents the 50th percentile, and the third quartile (Q_3) represents the 75th percentile (i.e., 75%of the observations lie at or below it). The **interquartile range** (IQR) is the difference between the third quartile and the first quartile, or IQR = $Q_3 - Q_1$.

When dealing with actual data, we often find that we need to approximate the value of a percentile. For example, if we are interested in the value of the 75th percentile, we may find that no observation divides the sample such that exactly 75% of the observations lie at or below that value. The following procedure, however, can help us determine or estimate a percentile. The procedure involves first locating the position of the percentile within the set of observations and then determining (or estimating) the value associated with that position.

Let P_y be the value at or below which y% of the distribution lies, or the yth percentile. (For example, P_{18} is the point at or below which 18% of the observations lie; this implies that 100 − 18 = 82% of the observations are greater than P_{18}.) The formula for the position (or location) of a percentile in an array with n entries sorted in ascending order is:

$$L_y = (n + 1)\frac{y}{100} \tag{7}$$

where y is the percentage point at which we are dividing the distribution, and L_y is the location (L) of the percentile (P_y) in the array sorted in ascending order. The value of L_y may or may not be a whole number. In general, as the sample size increases, the percentile location calculation becomes more accurate; in small samples it may be quite approximate.

To summarize:

- When the location, L_y, is a whole number, the location corresponds to an actual observation. For example, if we are determining the third quartile (Q_3) in a sample of size n = 11, then L_y would be L_{75} = (11 + 1)(75/100) = 9, and the third quartile would be $P_{75} = X_9$, where X_i is defined as the value of the observation in the ith ($i = L_{75}$, so 9th), position of the data sorted in ascending order.
- When L_y is not a whole number or integer, L_y lies between the two closest integer numbers (one above and one below), and we use **linear interpolation** between those two places to determine P_y. Interpolation means estimating an unknown value on the basis of two known values that surround it (i.e., lie above and below it); the term "linear" refers to a straight-line estimate.

Example 14 illustrates the calculation of various quantiles for the daily return on the EAA Equity Index.

EXAMPLE 14

Percentiles, Quintiles, and Quartiles for the EAA Equity Index

Using the daily returns on the fictitious EAA Equity Index over five years and ranking them by return, from lowest to highest daily return, we show the return bins from 1 (the lowest 5%) to 20 (the highest 5%) as follows:

Exhibit 43 EAA Equity Index Daily Returns Grouped by Size of Return

Bin	Cumulative Percentage of Sample Trading Days (%)	Daily Return (%) Between*		Number of Observations
		Lower Bound	Upper Bound	
1	5	−4.108	−1.416	63
2	10	−1.416	−0.876	63
3	15	−0.876	−0.629	63
4	20	−0.629	−0.432	63
5	25	−0.432	−0.293	63
6	30	−0.293	−0.193	63
7	35	−0.193	−0.124	62
8	40	−0.124	−0.070	63
9	45	−0.070	−0.007	63
10	50	−0.007	0.044	63
11	55	0.044	0.108	63
12	60	0.108	0.173	63
13	65	0.173	0.247	63
14	70	0.247	0.343	62
15	75	0.343	0.460	63
16	80	0.460	0.575	63
17	85	0.575	0.738	63
18	90	0.738	0.991	63
19	95	0.991	1.304	63
20	100	1.304	5.001	63

Note that because of the continuous nature of returns, it is not likely for a return to fall on the boundary for any bin other than the minimum (Bin = 1) and maximum (Bin = 20).

1. Identify the 10th and 90th percentiles.
2. Identify the first, second, and third quintiles.
3. Identify the first and third quartiles.
4. Identify the median.
5. Calculate the interquartile range.

Solution to 1

The 10th and 90th percentiles correspond to the bins or ranked returns that include 10% and 90% of the daily returns, respectively. The 10th percentile corresponds to the return of −0.876% (and includes returns of that much and lower), and the 90th percentile corresponds to the return of 0.991% (and lower).

Solution to 2

The first quintile corresponds to the lowest 20% of the ranked data, or −0.432% (and lower).

The second quintile corresponds to the lowest 40% of the ranked data, or −0.070% (and lower).

The third quintile corresponds to the lowest 60% of the ranked data, or 0.173% (and lower).

Solution to 3

The first quartile corresponds to the lowest 25% of the ranked data, or −0.293% (and lower).

The third quartile corresponds to the lowest 75% of the ranked data, or 0.460% (and lower).

Solution to 4

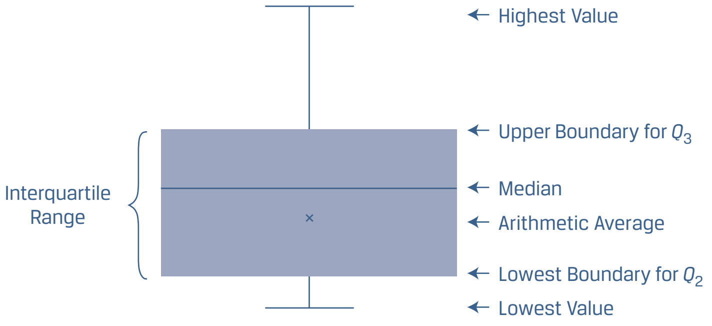
The median is the return for which 50% of the data lies on either side, which is 0.044%, the highest daily return in the 10th bin out of 20.

Solution to 5

The interquartile range is the difference between the third and first quartiles, 0.460% and −0.293%, or 0.753%.

One way to visualize the dispersion of data across quartiles is to use a diagram, such as a box and whisker chart. A **box and whisker plot** consists of a "box" with "whiskers" connected to the box, as shown in Exhibit 44. The "box" represents the lower bound of the second quartile and the upper bound of the third quartile, with the median or arithmetic average noted as a measure of central tendency of the entire distribution. The whiskers are the lines that run from the box and are bounded by the "fences," which represent the lowest and highest values of the distribution.

Exhibit 44 Box and Whisker Plot



There are several variations for box and whisker displays. For example, for ease in detecting potential outliers, the fences of the whiskers may be a function of the interquartile range instead of the highest and lowest values like that in Exhibit 44.

In Exhibit 44, visually, the interquartile range is the height of the box and the fences are set at extremes. But another form of box and whisker plot typically uses 1.5 times the interquartile range for the fences. Thus, the upper fence is 1.5 times the interquartile range added to the upper bound of Q_3, and the lower fence is 1.5 times the interquartile range subtracted from the lower bound of Q_2. Observations beyond the fences (i.e., outliers) may also be displayed.

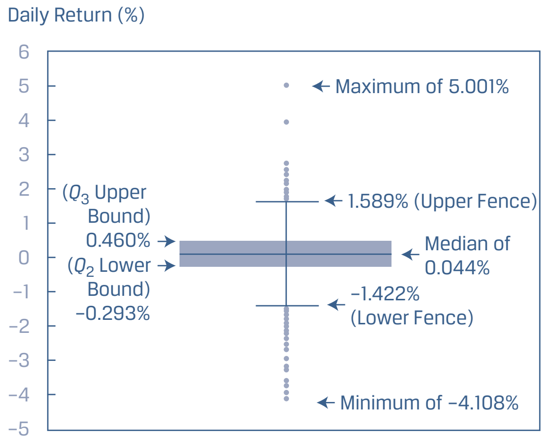
We can see the role of outliers in such a box and whisker plot using the EAA Equity Index daily returns, as shown in Exhibit 45. Referring back to Exhibit 43 (Example 13), we know:

- The maximum and minimum values of the distribution are 5.001 and −4.108, respectively, while the median (50th percentile) value is 0.044.

- The interquartile range is 0.753 [= 0.460 − (−0.293)], and when multiplied by 1.5 and added to the Q_3 upper bound of 0.460 gives an upper fence of 1.589 [= (1.5 × 0.753) + 0.460].
- The lower fence is determined in a similar manner, using the Q_2 lower bound, to be −1.422 [= −(1.5 × 0.753) + (−0.293)].

As noted, any observation above (below) the upper (lower) fence is deemed to be an outlier.

Exhibit 45 Box and Whisker Chart for EAA Equity Index Daily Returns



EXAMPLE 15

Quantiles

Consider the results of an analysis focusing on the market capitalizations of a sample of 100 firms:

Bin	Cumulative Percentage of Sample (%)	Market Capitalization (in billions of €) Lower Bound	Market Capitalization (in billions of €) Upper Bound	Number of Observations
1	5	0.28	15.45	5
2	10	15.45	21.22	5
3	15	21.22	29.37	5
4	20	29.37	32.57	5
5	25	32.57	34.72	5
6	30	34.72	37.58	5
7	35	37.58	39.90	5
8	40	39.90	41.57	5
9	45	41.57	44.86	5
10	50	44.86	46.88	5
11	55	46.88	49.40	5
12	60	49.40	51.27	5
13	65	51.27	53.58	5
14	70	53.58	56.66	5

Bin	Cumulative Percentage of Sample (%)	Market Capitalization (in billions of €) Lower Bound	Market Capitalization (in billions of €) Upper Bound	Number of Observations
15	75	56.66	58.34	5
16	80	58.34	63.10	5
17	85	63.10	67.06	5
18	90	67.06	73.00	5
19	95	73.00	81.62	5
20	100	81.62	96.85	5

Using this information, answer the following five questions.

1 The tenth percentile corresponds to observations in bins:

A 2.

B 1 and 2.

C 19 and 20.

2 The second quintile corresponds to observations in bins:

A 8

B 5, 6, 7, and 8.

C 6, 7, 8, 9, and 10.

3 The fourth quartile corresponds to observations in bins:

A 17.

B 17, 18, 19, and 20.

C 16, 17, 18, 19, and 20.

4 The median is *closest* to:

A 44.86.

B 46.88.

C 49.40.

5 The interquartile range is *closest* to:

A 20.76.

B 23.62.

C 25.52.

Solution to 1

B is correct because the tenth percentile corresponds to the lowest 10% of the observations in the sample, which are in bins 1 and 2.

Solution to 2

B is correct because the second quintile corresponds to the second 20% of observations. The first 20% consists of bins 1 through 4. The second 20% of observations consists of bins 5 through 8.

Solution to 3

C is correct because a quartile consists of 25% of the data, and the last 25% of the 20 bins are 16 through 20.

Solution to 4

B is correct because this is the center of the 20 bins. The market capitalization of 46.88 is the highest value of the 10th bin and the lowest value of the 11th bin.

Solution to 5

B is correct because the interquartile range is the difference between the lowest value in the second quartile and the highest value in the third quartile. The lowest value of the second quartile is 34.72, and the highest value of the third quartile is 58.34. Therefore, the interquartile range is 58.34 − 34.72 = 23.62.

8.2 Quantiles in Investment Practice

In this section, we briefly discuss the use of quantiles in investments. Quantiles are used in portfolio performance evaluation as well as in investment strategy development and research.

Investment analysts use quantiles every day to rank performance—for example, the performance of portfolios. The performance of investment managers is often characterized in terms of the percentile or quartile in which they fall relative to the performance of their peer group of managers. The Morningstar investment fund star rankings, for example, associate the number of stars with percentiles of performance relative to similar-style investment funds.

Another key use of quantiles is in investment research. For example, analysts often refer to the set of companies with returns falling below the 10th percentile cutoff point as the bottom return decile. Dividing data into quantiles based on some characteristic allows analysts to evaluate the impact of that characteristic on a quantity of interest. For instance, empirical finance studies commonly rank companies based on the market value of their equity and then sort them into deciles. The first decile contains the portfolio of those companies with the smallest market values, and the tenth decile contains those companies with the largest market values. Ranking companies by decile allows analysts to compare the performance of small companies with large ones.

9

MEASURES OF DISPERSION

j Calculate and interpret measures of dispersion

Few would disagree with the importance of expected return or mean return in investments: The mean return tells us where returns, and investment results, are centered. To more completely understand an investment, however, we also need to know how returns are dispersed around the mean. **Dispersion** is the variability around the central tendency. If mean return addresses reward, then dispersion addresses risk.

In this section, we examine the most common measures of dispersion: range, mean absolute deviation, variance, and standard deviation. These are all measures of **absolute dispersion**. Absolute dispersion is the amount of variability present without comparison to any reference point or benchmark.

These measures are used throughout investment practice. The variance or standard deviation of return is often used as a measure of risk pioneered by Nobel laureate Harry Markowitz. Other measures of dispersion, mean absolute deviation and range, are also useful in analyzing data.

9.1 The Range

We encountered range earlier when we discussed the construction of frequency distributions. It is the simplest of all the measures of dispersion.

Definition of Range. The **range** is the difference between the maximum and minimum values in a dataset:

$$\text{Range} = \text{Maximum value} - \text{Minimum value}. \tag{8}$$

As an illustration of range, consider Exhibit 35, our example of annual returns for countries' stock indexes. The range of returns for Year 1 is the difference between the returns of Country G's index and Country A's index, or 12.7 − (−15.6) = 28.3%. The range of returns for Year 3 is the difference between the returns for the County D index and the Country B index, or 6.2 − (−1.5) = 7.7%.

An alternative definition of range specifically reports the maximum and minimum values. This alternative definition provides more information than does the range as defined in Equation 8. In other words, in the above-mentioned case for Year 1, the range is reported as "from 12.7% to −15.6%."

One advantage of the range is ease of computation. A disadvantage is that the range uses only two pieces of information from the distribution. It cannot tell us how the data are distributed (that is, the shape of the distribution). Because the range is the difference between the maximum and minimum returns, it can reflect extremely large or small outcomes that may not be representative of the distribution.

9.2 The Mean Absolute Deviation

Measures of dispersion can be computed using all the observations in the distribution rather than just the highest and lowest. But how should we measure dispersion? Our previous discussion on properties of the arithmetic mean introduced the notion of distance or deviation from the mean $\left(X_i - \overline{X}\right)$ as a fundamental piece of information used in statistics. We could compute measures of dispersion as the arithmetic average of the deviations around the mean, but we would encounter a problem: The deviations around the mean always sum to 0. If we computed the mean of the deviations, the result would also equal 0. Therefore, we need to find a way to address the problem of negative deviations canceling out positive deviations.

One solution is to examine the absolute deviations around the mean as in the **mean absolute deviation**. This is also known as the average absolute deviation.

Mean Absolute Deviation Formula. The mean absolute deviation (MAD) for a sample is:

$$\text{MAD} = \frac{\sum_{i=1}^{n}\left|X_i - \overline{X}\right|}{n} \tag{9}$$

where $\overline{X}$ is the sample mean, n is the number of observations in the sample, and the | | indicate the absolute value of what is contained within these bars.

In calculating MAD, we ignore the signs of the deviations around the mean. For example, if $X_i = -11.0$ and $\overline{X} = 4.5$, the absolute value of the difference is $|-11.0 - 4.5| = |-15.5| = 15.5$. The mean absolute deviation uses all of the observations in the sample and is thus superior to the range as a measure of dispersion. One technical drawback of MAD is that it is difficult to manipulate mathematically compared with the next measure we will introduce, sample variance. Example 16 illustrates the use of the range and the mean absolute deviation in evaluating risk.

EXAMPLE 16

Mean Absolute Deviation for Selected Countries' Stock Index Returns

Using the country stock index returns in Exhibit 35, calculate the mean absolute deviation of the index returns for each year. Note the sample mean returns ($\bar{X}$) are 3.5%, 2.5%, and 2.0% for Years 1, 2, and 3, respectively.

Solution

	Absolute Value of Deviation from the Mean $\lvert X_i - \bar{X} \rvert$		
	Year 1	**Year 2**	**Year 3**
Country A	19.1	7.9	4.1
Country B	4.3	3.8	3.5
Country C	1.8	1.3	1.5
Country D	5.9	5.6	4.2
Country E	7.5	5.5	1.0
Country F	1.9	2.7	3.0
Country G	9.2	4.2	3.2
Country H	0.0	1.8	1.4
Country I	2.7	5.3	1.2
Country J	4.6	1.6	2.9
Country K	8.0	0.9	0.8
Sum	65.0	40.6	26.8
MAD	5.91	3.69	2.44

For Year 3, for example, the sum of the absolute deviations from the arithmetic mean ($\bar{X} = 2.0$) is 26.8. We divide this by 11, with the resulting MAD of 2.44.

9.3 Sample Variance and Sample Standard Deviation

The mean absolute deviation addressed the issue that the sum of deviations from the mean equals zero by taking the absolute value of the deviations. A second approach to the treatment of deviations is to square them. The variance and standard deviation, which are based on squared deviations, are the two most widely used measures of dispersion. **Variance** is defined as the average of the squared deviations around the mean. **Standard deviation** is the positive square root of the variance. The following discussion addresses the calculation and use of variance and standard deviation.

9.3.1 *Sample Variance*

In investments, we often do not know the mean of a population of interest, usually because we cannot practically identify or take measurements from each member of the population. We then estimate the population mean using the mean from a sample drawn from the population, and we calculate a sample variance or standard deviation.

Sample Variance Formula. The **sample variance**, s^2, is:

$$s^2 = \frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2}{n-1} \tag{10}$$

where $\bar{X}$ is the sample mean and n is the number of observations in the sample.

Given knowledge of the sample mean, we can use Equation 10 to calculate the sum of the squared differences from the mean, taking account of all n items in the sample, and then to find the mean squared difference by dividing the sum by $n - 1$. Whether a difference from the mean is positive or negative, squaring that difference results in a positive number. Thus, variance takes care of the problem of negative deviations from the mean canceling out positive deviations by the operation of squaring those deviations.

For the sample variance, by dividing by the sample size minus 1 (or $n - 1$) rather than n, we improve the statistical properties of the sample variance. In statistical terms, the sample variance defined in Equation 10 is an unbiased estimator of the population variance (a concept covered later in the curriculum on sampling). The quantity $n - 1$ is also known as the number of degrees of freedom in estimating the population variance. To estimate the population variance with s^2, we must first calculate the sample mean, which itself is an estimated parameter. Therefore, once we have computed the sample mean, there are only $n - 1$ independent pieces of information from the sample; that is, if you know the sample mean and $n - 1$ of the observations, you could calculate the missing sample observation.

9.3.2 *Sample Standard Deviation*

Because the variance is measured in squared units, we need a way to return to the original units. We can solve this problem by using standard deviation, the square root of the variance. Standard deviation is more easily interpreted than the variance because standard deviation is expressed in the same unit of measurement as the observations. By taking the square root, we return the values to the original unit of measurement. Suppose we have a sample with values in euros. Interpreting the standard deviation in euros is easier than interpreting the variance in squared euros.

Sample Standard Deviation Formula. The **sample standard deviation**, s, is:

$$s = \sqrt{\frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2}{n-1}} \tag{11}$$

where $\bar{X}$ is the sample mean and n is the number of observations in the sample.

To calculate the sample standard deviation, we first compute the sample variance. We then take the square root of the sample variance. The steps for computing the sample variance and the standard deviation are provided in Exhibit 46.

Exhibit 46 Steps to Calculate Sample Standard Deviation and Variance

Step	Description	Notation
1	Calculate the sample mean	$\bar{X}$
2	Calculate the deviations from the sample mean	$\left(X_i - \bar{X}\right)$

(continued)

Exhibit 46 (Continued)

Step	Description	Notation
3	Calculate each observation's squared deviation from the sample mean	$\left(X_i - \bar{X}\right)^2$
4	Sum the squared deviations from the mean	$\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2$
5	Divide the sum of squared deviations from the mean by $n - 1$. This is the variance (s^2).	$\frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2}{n-1}$
6	Take the square root of the sum of the squared deviations divided by $n - 1$. This is the standard deviation (s).	$\sqrt{\frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2}{n-1}}$

We illustrate the process of calculating the sample variance and standard deviation in Example 17 using the returns of the selected country stock indexes presented in Exhibit 35.

EXAMPLE 17

Calculating Sample Variance and Standard Deviation for Returns on Selected Country Stock Indexes

Using the sample information on country stock indexes in Exhibit 35, calculate the sample variance and standard deviation of the sample of index returns for Year 3.

Solution

Index	Sample Observation	Deviation from the Sample Mean	Squared Deviation
Country A	6.1	4.1	16.810
Country B	−1.5	−3.5	12.250
Country C	3.5	1.5	2.250
Country D	6.2	4.2	17.640
Country E	3.0	1.0	1.000
Country F	−1.0	−3.0	9.000
Country G	−1.2	−3.2	10.240
Country H	3.4	1.4	1.960
Country I	3.2	1.2	1.440
Country J	−0.9	−2.9	8.410
Country K	1.2	−0.8	0.640
Sum	**22.0**	**0.0**	**81.640**

Sample variance = 81.640/10 = 8.164

Sample standard deviation = $\sqrt{8.164}$ = 2.857

In addition to looking at the cross-sectional standard deviation as we did in Example 17, we could also calculate the standard deviation of a given country's returns across time (that is, the three years). Consider Country F, which has an arithmetic mean return of 3.2%. The sample standard deviation is calculated as:

$$\sqrt{\frac{(0.054-0.032)^2+(0.052-0.032)^2+(-0.01-0.032)^2}{2}}$$

$$=\sqrt{\frac{0.000484+0.000400+0.001764}{2}}$$

$$=\sqrt{0.001324}$$

$$=3.6387\%.$$

Because the standard deviation is a measure of dispersion about the arithmetic mean, we usually present the arithmetic mean and standard deviation together when summarizing data. When we are dealing with data that represent a time series of percentage changes, presenting the geometric mean—representing the compound rate of growth—is also very helpful.

9.3.3 *Dispersion and the Relationship between the Arithmetic and the Geometric Means*

We can use the sample standard deviation to help us understand the gap between the arithmetic mean and the geometric mean. The relation between the arithmetic mean $(\bar{X})$ and geometric mean $(\bar{X}_G)$ is:

$$\bar{X}_G \approx \bar{X}-\frac{s^2}{2}$$

In other words, the larger the variance of the sample, the wider the difference between the geometric mean and the arithmetic mean.

Using the data for Country F from Example 8, the geometric mean return is 3.1566%, the arithmetic mean return is 3.2%, and the factor $s^2/2$ is 0.001324/2 = 0.0662%:

$$3.1566\% \approx 3.2\% - 0.0662\%$$

$$3.1566\% \approx 3.1338\%.$$

This relation informs us that the more disperse or volatile the returns, the larger the gap between the geometric mean return and the arithmetic mean return.

DOWNSIDE DEVIATION AND COEFFICIENT OF VARIATION

10

k Calculate and interpret target downside deviation

An asset's variance or standard deviation of returns is often interpreted as a measure of the asset's risk. Variance and standard deviation of returns take account of returns above and below the mean, or upside and downside risks, respectively. However, investors are typically concerned only with **downside risk**—for example, returns below the mean or below some specified minimum target return. As a result, analysts have developed measures of downside risk.

In practice, we may be concerned with values of return (or another variable) below some level other than the mean. For example, if our return objective is 6.0% annually (our minimum acceptable return), then we may be concerned particularly with returns below 6.0% a year. The 6.0% is the target. The target downside deviation, also referred to as the **target semideviation**, is a measure of dispersion of the observations (here, returns) below the target. To calculate a sample target semideviation, we first specify the target. After identifying observations below the target, we find the sum of the squared negative deviations from the target, divide that sum by the total number of observations in the sample minus 1, and, finally, take the square root.

Sample Target Semideviation Formula. The target semideviation, s_{Target}, is:

$$s_{\text{Target}} = \sqrt{\sum_{\text{for all} X_i \leq B}^{n} \frac{(X_i - B)^2}{n - 1}}, \tag{12}$$

where B is the target and n is the total number of sample observations. We illustrate this in Example 18.

EXAMPLE 18

Calculating Target Downside Deviation

Suppose the monthly returns on a portfolio are as shown:

Monthly Portfolio Returns

Month	Return (%)
January	5
February	3
March	–1
April	–4
May	4
June	2
July	0
August	4
September	3
October	0
November	6
December	5

1 Calculate the target downside deviation when the target return is 3%.

2 If the target return were 4%, would your answer be different from that for question 1? Without using calculations, explain how would it be different?

Solution to 1

Month	Observation	Deviation from the 3% Target	Deviations below the Target	Squared Deviations below the Target
January	5	2	—	—
February	3	0	—	—
March	–1	–4	–4	16
April	–4	–7	–7	49
May	4	1	—	—
June	2	–1	–1	1
July	0	–3	–3	9
August	4	1	—	—
September	3	0	—	—
October	0	–3	–3	9
November	6	3	—	—
December	5	2	—	—
Sum				**84**

$$\textbf{Target semideviation} = \sqrt{\frac{84}{11}} = 2.7634\%$$

Solution to 2

If the target return is higher, then the existing deviations would be larger and there would be several more values in the deviations and squared deviations below the target; so, the target semideviation would be larger.

How does the target downside deviation relate to the sample standard deviation? We illustrate the differences between the target downside deviation and the standard deviation in Example 19, using the data in Example 18.

EXAMPLE 19

Comparing the Target Downside Deviation with the Standard Deviation

1 Given the data in Example 18, calculate the sample standard deviation.

2 Given the data in Example 18, calculate the target downside deviation if the target is 2%.

3 Compare the standard deviation, the target downside deviation if the target is 2%, and the target downside deviation if the target is 3%.

Solution to 1

Month	Observation	Deviation from the mean	Squared deviation
January	5	2.75	7.5625
February	3	0.75	0.5625

(continued)

Month	Observation	Deviation from the mean	Squared deviation
March	−1	−3.25	10.5625
April	−4	−6.25	39.0625
May	4	1.75	3.0625
June	2	−0.25	0.0625
July	0	−2.25	5.0625
August	4	1.75	3.0625
September	3	0.75	0.5625
October	0	−2.25	5.0625
November	6	3.75	14.0625
December	5	2.75	7.5625
Sum	27		**96.2500**

The sample standard deviation is $\sqrt{\frac{96.2500}{11}} = 2.958\%$.

Solution to 2

Month	Observation	Deviation from the 2% Target	Deviations below the Target	Squared Deviations below the Target
January	5	3	—	—
February	3	1	—	—
March	−1	−3	−3	9
April	−4	−6	−6	36
May	4	2	—	—
June	2	0	—	—
July	0	−2	−2	4
August	4	2	—	—
September	3	1	—	—
October	0	−2	−2	4
November	6	4	—	—
December	5	3	—	—
Sum				**53**

The target semideviation with 2% target = $\sqrt{\frac{53}{11}} = 2.195\%$.

Solution to 3

The standard deviation is based on the deviation from the mean, which is 2.25%. The standard deviation includes all deviations from the mean, not just those below it. This results in a sample standard deviation of 2.958%.

Considering just the four observations below the 2% target, the target semideviation is 2.195%. It is less than the sample standard deviation since target semideviation captures only the downside risk (i.e., deviations below the target). Considering target semideviation with a 3% target, there are now five observations below 3%, so the target semideviation is higher, at 2.763%.

10.1 Coefficient of Variation

We noted earlier that the standard deviation is more easily interpreted than variance because standard deviation uses the same units of measurement as the observations. We may sometimes find it difficult to interpret what standard deviation means in terms of the relative degree of variability of different sets of data, however, either because the datasets have markedly different means or because the datasets have different units of measurement. In this section, we explain a measure of relative dispersion, the coefficient of variation that can be useful in such situations. **Relative dispersion** is the amount of dispersion relative to a reference value or benchmark.

The coefficient of variation is helpful in such situations as that just described (i.e., datasets with markedly different means or different units of measurement).

Coefficient of Variation Formula. The **coefficient of variation**, CV, is the ratio of the standard deviation of a set of observations to their mean value:

$$\text{CV} = s/\overline{X} \tag{13}$$

where s is the sample standard deviation and $\overline{X}$ is the sample mean.

When the observations are returns, for example, the coefficient of variation measures the amount of risk (standard deviation) per unit of reward (mean return). An issue that may arise, especially when dealing with returns, is that if $\overline{X}$ is negative, the statistic is meaningless.

The CV may be stated as a multiple (e.g., 2 times) or as a percentage (e.g., 200%). Expressing the magnitude of variation among observations relative to their average size, the coefficient of variation permits direct comparisons of dispersion across different datasets. Reflecting the correction for scale, the coefficient of variation is a scale-free measure (that is, it has no units of measurement).

We illustrate the usefulness of coefficient of variation for comparing datasets with markedly different standard deviations using two hypothetical samples of companies in Example 20.

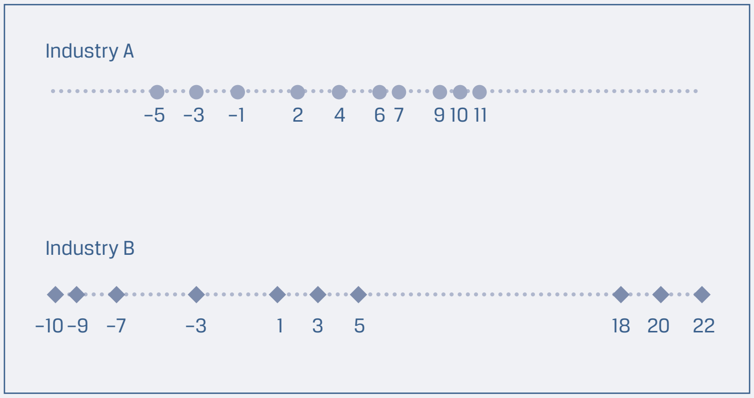
EXAMPLE 20

Coefficient of Variation of Returns on Assets

Suppose an analyst collects the return on assets (in percentage terms) for ten companies for each of two industries:

Company	Industry A	Industry B
1	−5	−10
2	−3	−9
3	−1	−7
4	2	−3
5	4	1
6	6	3
7	7	5
8	9	18
9	10	20
10	11	22

These data can be represented graphically as the following:



1 Calculate the average return on assets (ROA) for each industry.
2 Calculate the standard deviation of ROA for each industry.
3 Calculate the coefficient of variation of ROA for each industry.

Solution to 1

The arithmetic mean for both industries is the sum divided by 10, or 40/10 = 4%.

Solution to 2

The standard deviation using Equation 11 for Industry A is 5.60, and for Industry B the standard deviation is 12.12.

Solution to 3

The coefficient of variation for Industry A = 5.60/4 = 1.40.

The coefficient of variation for Industry B = 12.12/4 = 3.03.

Though the two industries have the same arithmetic mean ROA, the dispersion is different—with Industry B's returns on assets being much more disperse than those of Industry A. The coefficients of variation for these two industries reflects this, with Industry B having a larger coefficient of variation. The interpretation is that the risk per unit of mean return is more than two times (2.16 = 3.03/1.40) greater for Industry B compared to Industry A.

11 THE SHAPE OF THE DISTRIBUTIONS

l. Interpret skewness

Mean and variance may not adequately describe an investment's distribution of returns. In calculations of variance, for example, the deviations around the mean are squared, so we do not know whether large deviations are likely to be positive or negative. We need to go beyond measures of central tendency and dispersion to reveal other important characteristics of the distribution. One important characteristic of interest to analysts is the degree of symmetry in return distributions.

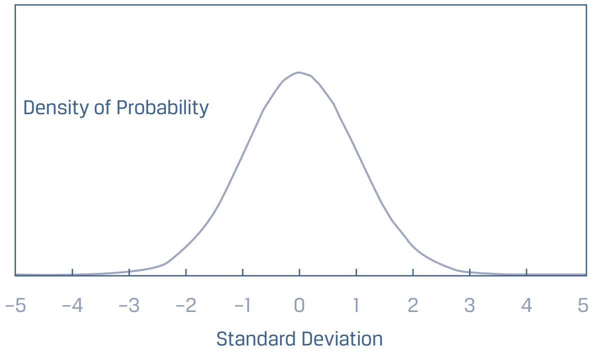
If a return distribution is symmetrical about its mean, each side of the distribution is a mirror image of the other. Thus, equal loss and gain intervals exhibit the same frequencies. If the mean is zero, for example, then losses from −5% to −3% occur with about the same frequency as gains from 3% to 5%.

One of the most important distributions is the normal distribution, depicted in Exhibit 47. This symmetrical, bell-shaped distribution plays a central role in the mean–variance model of portfolio selection; it is also used extensively in financial risk management. The normal distribution has the following characteristics:

- Its mean, median, and mode are equal.
- It is completely described by two parameters—its mean and variance (or standard deviation).

But with any distribution other than a normal distribution, more information than the mean and variance is needed to characterize its shape.

Exhibit 47 The Normal Distribution

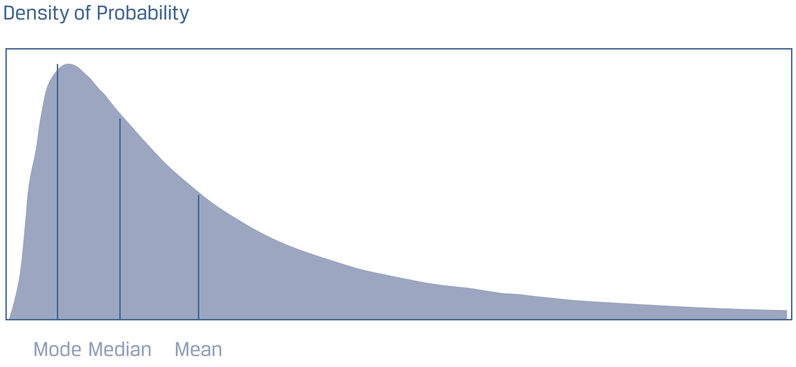


A distribution that is not symmetrical is **skewed**. A return distribution with positive skew has frequent small losses and a few extreme gains. A return distribution with negative skew has frequent small gains and a few extreme losses. Exhibit 48 shows continuous positively and negatively skewed distributions. The continuous positively skewed distribution shown has a long tail on its right side; the continuous negatively skewed distribution shown has a long tail on its left side.

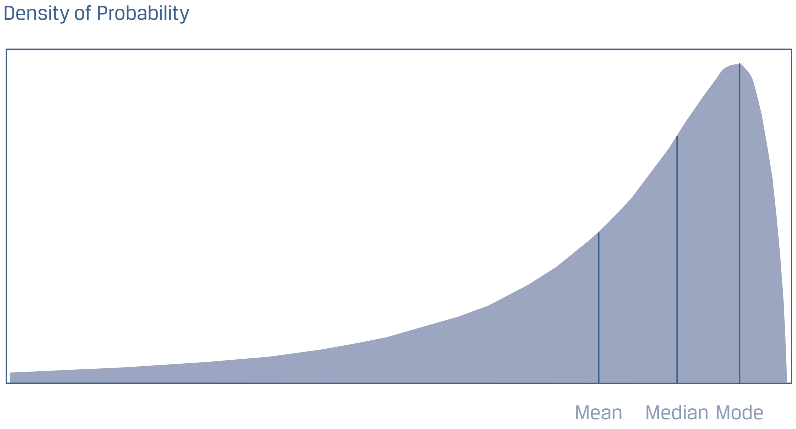
For a continuous positively skewed unimodal distribution, the mode is less than the median, which is less than the mean. For the continuous negatively skewed unimodal distribution, the mean is less than the median, which is less than the mode. For a given expected return and standard deviation, investors should be attracted by a positive skew because the mean return lies above the median. Relative to the mean return, positive skew amounts to limited, though frequent, downside returns compared with somewhat unlimited, but less frequent, upside returns.

Exhibit 48 Properties of Skewed Distributions

A. Positively Skewed



B. Negatively Skewed



Skewness is the name given to a statistical measure of skew. (The word "skewness" is also sometimes used interchangeably for "skew.") Like variance, skewness is computed using each observation's deviation from its mean. **Skewness** (sometimes referred to as relative skewness) is computed as the average cubed deviation from the mean standardized by dividing by the standard deviation cubed to make the measure free of scale. A symmetric distribution has skewness of 0, a positively skewed distribution has positive skewness, and a negatively skewed distribution has negative skewness, as given by this measure.

We can illustrate the principle behind the measure by focusing on the numerator. Cubing, unlike squaring, preserves the sign of the deviations from the mean. If a distribution is positively skewed with a mean greater than its median, then more than half of the deviations from the mean are negative and less than half are positive. However, for the sum of the cubed deviations to be positive, the losses must be small and likely and the gains less likely but more extreme. Therefore, if skewness is positive, the average magnitude of positive deviations is larger than the average magnitude of negative deviations.

The approximation for computing **sample skewness** when n is large (100 or more) is:

$$\text{Skewness} \approx \left(\frac{1}{n}\right)\frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^3}{s^3}$$

A simple example illustrates that a symmetrical distribution has a skewness measure equal to 0. Suppose we have the following data: 1, 2, 3, 4, 5, 6, 7, 8, and 9. The mean outcome is 5, and the deviations are −4, −3, −2, −1, 0, 1, 2, 3, and 4. Cubing the deviations yields −64, −27, −8, −1, 0, 1, 8, 27, and 64, with a sum of 0. The numerator of skewness (and so skewness itself) is thus equal to 0, supporting our claim.

As you will learn as the CFA Program curriculum unfolds, different investment strategies may tend to introduce different types and amounts of skewness into returns.

11.1 The Shape of the Distributions: Kurtosis

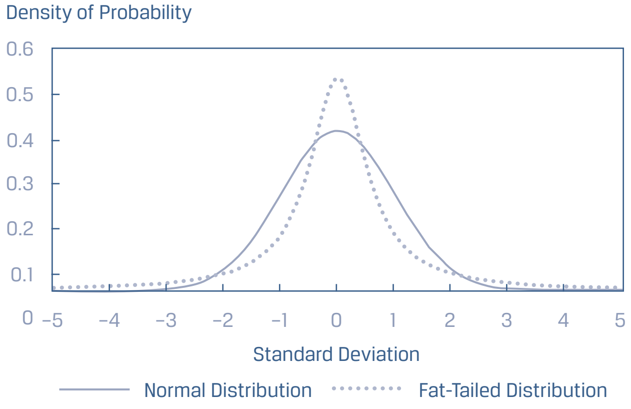
m Interpret kurtosis

In the previous section, we discussed how to determine whether a return distribution deviates from a normal distribution because of skewness. Another way in which a return distribution might differ from a normal distribution is its relative tendency to generate large deviations from the mean. Most investors would perceive a greater chance of extremely large deviations from the mean as increasing risk.

Kurtosis is a measure of the combined weight of the tails of a distribution relative to the rest of the distribution—that is, the proportion of the total probability that is outside of, say, 2.5 standard deviations of the mean. A distribution that has fatter tails than the normal distribution is referred to as **leptokurtic** or **fat-tailed**; a distribution that has thinner tails than the normal distribution is referred to as being **platykurtic** or **thin-tailed**; and a distribution similar to the normal distribution as concerns relative weight in the tails is called **mesokurtic**. A fat-tailed (thin-tailed) distribution tends to generate more-frequent (less-frequent) extremely large deviations from the mean than the normal distribution.

Exhibit 49 illustrates a fat-tailed distribution. It has fatter tails than the normal distribution. By construction, the fat-tailed and normal distributions in this exhibit have the same mean, standard deviation, and skewness. Note that this fat-tailed distribution is more likely than the normal distribution to generate observations in the tail regions defined by the intersection of graphs near a standard deviation of about ±2.5. This fat-tailed distribution is also more likely to generate observations that are near the mean, defined here as the region ±1 standard deviation around the mean. In compensation, to have probabilities sum to 1, this distribution generates fewer observations in the regions between the central region and the two tail regions.

Exhibit 49 Fat-Tailed Distribution Compared to the Normal Distribution



The calculation for kurtosis involves finding the average of deviations from the mean raised to the fourth power and then standardizing that average by dividing by the standard deviation raised to the fourth power. A normal distribution has kurtosis of 3.0, so a fat-tailed distribution has a kurtosis of above 3 and a thin-tailed distribution of below 3.0.

Excess kurtosis is the kurtosis relative to the normal distribution. For a large sample size (n = 100 or more), **sample excess kurtosis** (K_E) is approximately as follows:

$$K_E \approx \left[\left(\frac{1}{n} \right) \frac{\sum_{i=1}^{n} \left(X_i - \bar{X} \right)^4}{s^4} \right] - 3$$

As with skewness, this measure is free of scale. Many statistical packages report estimates of sample **excess kurtosis**, labeling this as simply "kurtosis."

Excess kurtosis thus characterizes kurtosis relative to the normal distribution. A normal distribution has excess kurtosis equal to 0. A fat-tailed distribution has excess kurtosis greater than 0, and a thin-tailed distribution has excess kurtosis less than 0. A return distribution with positive excess kurtosis—a fat-tailed return distribution—has more frequent extremely large deviations from the mean than a normal distribution.

Summarizing:

If kurtosis is …	then excess kurtosis is …	Therefore, the distribution is …	And we refer to the distribution as being …
above 3.0	above 0.	fatter-tailed than the normal distribution.	fat-tailed (leptokurtic).
equal to 3.0	equal to 0.	similar in tails to the normal distribution.	mesokurtic.
less than 3.0	less than 0.	thinner-tailed than the normal distribution.	thin-tailed (platykurtic).

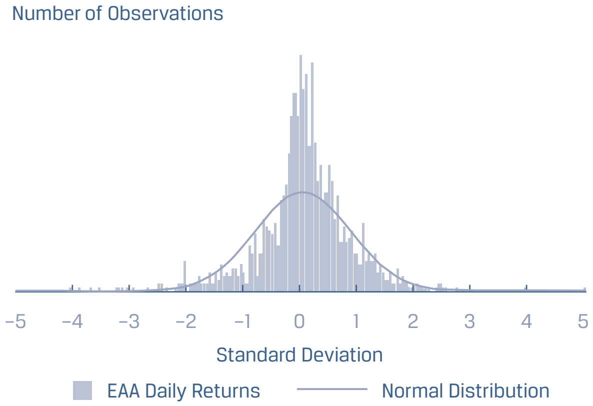
Most equity return series have been found to be fat-tailed. If a return distribution is fat-tailed and we use statistical models that do not account for the distribution, then we will underestimate the likelihood of very bad or very good outcomes. Using the data on the daily returns of the fictitious EAA Equity Index, we see the skewness and kurtosis of these returns in Exhibit 50.

Exhibit 50 Skewness and Kurtosis of EAA Equity Index Daily Returns

	Daily Return (%)
Arithmetic mean	0.0347
Standard deviation	0.8341
	Measure of Symmetry
Skewness	−0.4260
Excess kurtosis	3.7962

We can see this graphically, comparing the distribution of the daily returns with a normal distribution with the same mean and standard deviation:

Exhibit 50 (Continued)



Using both the statistics and the graph, we see the following:

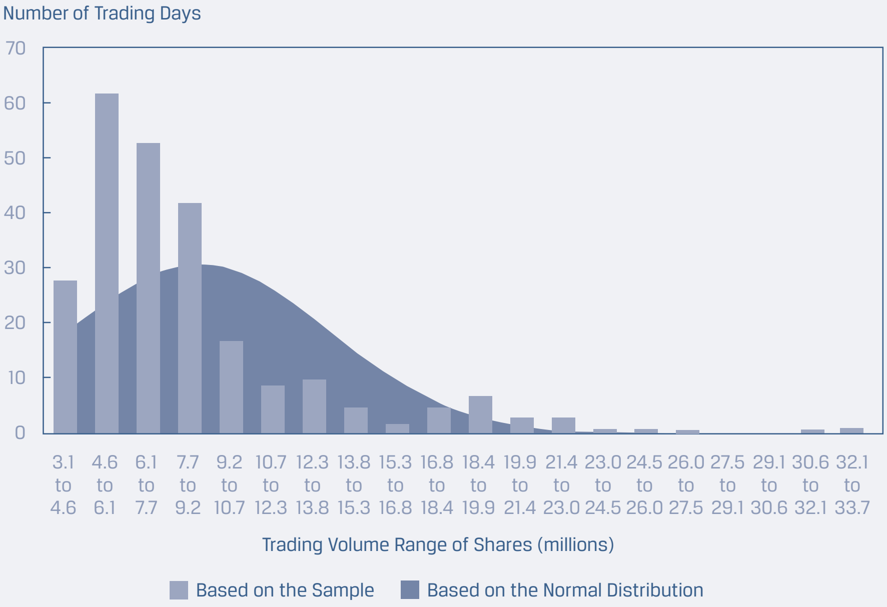
- The distribution is negatively skewed, as indicated by the negative calculated skewness of −0.4260 and the influence of observations below the mean of 0.0347%.
- The highest frequency of returns occurs within the −0.5 to 0.0 standard deviations from the mean (i.e., negatively skewed).
- The distribution is fat-tailed, as indicated by the positive excess kurtosis of 3.7962. We can see fat tails, a concentration of returns around the mean, and fewer observations in the regions between the central region and the two-tail regions.

EXAMPLE 21

Interpreting Skewness and Kurtosis

Consider the daily trading volume for a stock for one year, as shown in the graph below. In addition to the count of observations within each bin or interval, the number of observations anticipated based on a normal distribution (given the sample arithmetic average and standard deviation) is provided in the chart as well. The average trading volume per day for this stock in this year is 8.6 million shares, and the standard deviation is 4.9 million shares.

Histogram of Daily Trading Volume for a Stock for One Year



1. Describe whether or not this distribution is skewed. If so, what could account for this situation?
2. Describe whether or not this distribution displays kurtosis. How would you make this determination?

Solution to 1

The distribution appears to be skewed to the right, or positively skewed. This is likely due to: (1) no possible negative trading volume on a given trading day, so the distribution is truncated at zero; and (2) greater-than-typical trading occurring relatively infrequently, such as when there are company-specific announcements.

The actual skewness for this distribution is 2.1090, which supports this interpretation.

Solution to 2

The distribution appears to have excess kurtosis, with a right-side fat tail and with maximum shares traded in the 4.6 to 6.1 million range, exceeding what is expected if the distribution was normally distributed. There are also fewer observations than expected between the central region and the tail.

The actual excess kurtosis for this distribution is 5.2151, which supports this interpretation.

12 CORRELATION BETWEEN TWO VARIABLES

- **Interpret correlation between two variables**

Now that we have some understanding of sample variance and standard deviation, we can more formally consider the concept of correlation between two random variables that we previously explored visually in the scatter plots in Section 6. **Correlation** is a measure of the linear relationship between two random variables.

The first step is to consider how two variables vary together, their covariance.

Definition of Sample Covariance. The **sample covariance** (s_{XY}) is a measure of how two variables in a sample move together:

$$s_{XY} = \frac{\sum_{i=1}^{n}\left(X_i - \overline{X}\right)\left(Y_i - \overline{Y}\right)}{n-1} \tag{14}$$

Equation 14 indicates that the sample covariance is the average value of the product of the deviations of observations on two random variables (X_i and Yi) from their sample means. If the random variables are returns, the units would be returns squared. Also, note the use of $n - 1$ in the denominator, which ensures that the sample covariance is an unbiased estimate of population covariance.

Stated simply, covariance is a measure of the joint variability of two random variables. If the random variables vary in the same direction—for example, X tends to be above its mean when Y is above its mean, and X tends to be below its mean when Y is below its mean—then their covariance is positive. If the variables vary in the opposite direction relative to their respective means, then their covariance is negative.

By itself, the size of the covariance measure is difficult to interpret as it is not normalized and so depends on the magnitude of the variables. This brings us to the normalized version of covariance, which is the correlation coefficient.

Definition of Sample Correlation Coefficient. The **sample correlation coefficient** is a standardized measure of how two variables in a sample move together. The sample correlation coefficient (r_{XY}) is the ratio of the sample covariance to the product of the two variables' standard deviations:

$$r_{XY} = \frac{s_{XY}}{s_X s_Y} \tag{15}$$

Importantly, the correlation coefficient expresses the strength of the linear relationship between the two random variables.

12.1 Properties of Correlation

We now discuss the correlation coefficient, or simply correlation, and its properties in more detail, as follows:

1. Correlation ranges from −1 and +1 for two random variables, X and Y:

   $-1 \le r_{XY} \le +1.$

2. A correlation of 0 (uncorrelated variables) indicates an absence of any linear (that is, straight-line) relationship between the variables.
3. A positive correlation close to +1 indicates a strong positive linear relationship. A correlation of 1 indicates a perfect linear relationship.
4. A negative correlation close to −1 indicates a strong negative (that is, inverse) linear relationship. A correlation of −1 indicates a perfect inverse linear relationship.

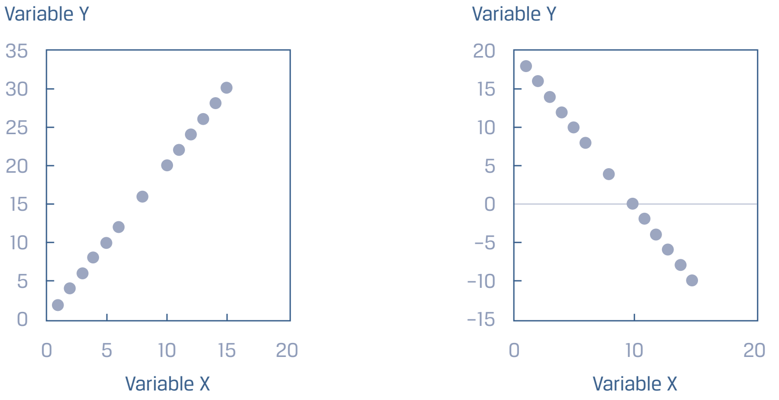
We will make use of scatter plots, similar to those used previously in our discussion of data visualization, to illustrate correlation. In contrast to the correlation coefficient, which expresses the relationship between two data series using a single number, a scatter plot depicts the relationship graphically. Therefore, scatter plots are a very useful tool for the sensible interpretation of a correlation coefficient.

Exhibit 51 shows examples of scatter plots. Panel A shows the scatter plot of two variables with a correlation of +1. Note that all the points on the scatter plot in Panel A lie on a straight line with a positive slope. Whenever variable *X* increases by one unit, variable *Y* increases by two units. Because all of the points in the graph lie on a straight line, an increase of one unit in *X* is associated with exactly a two-unit increase in *Y*, regardless of the level of *X*. Even if the slope of the line were different (but positive), the correlation between the two variables would still be +1 as long as all the points lie on that straight line. Panel B shows a scatter plot for two variables with a correlation coefficient of −1. Once again, the plotted observations all fall on a straight line. In this graph, however, the line has a negative slope. As *X* increases by one unit, *Y* decreases by two units, regardless of the initial value of *X*.

Exhibit 51 Scatter Plots Showing Various Degrees of Correlation

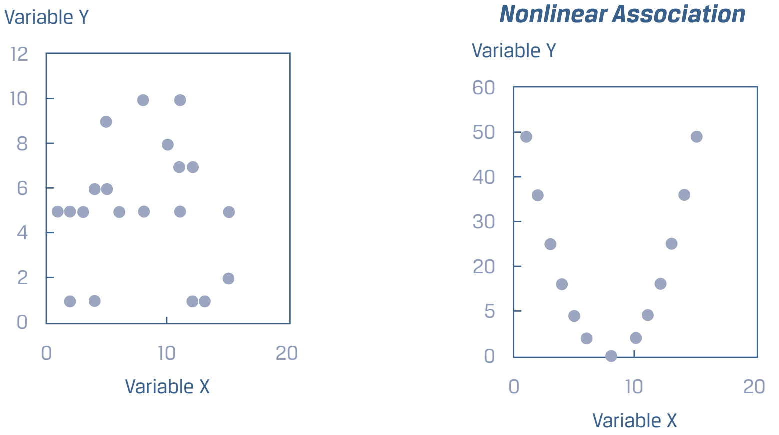
A. Variables With a Correlation of +1

B. Variables With a Correlation of −1



C. Variables With a Correlation of 0

D. Variables With a Strong Nonlinear Association



Panel C shows a scatter plot of two variables with a correlation of 0; they have no linear relation. This graph shows that the value of variable *X* tells us nothing about the value of variable *Y*. Panel D shows a scatter plot of two variables that have a non-linear relationship. Because the correlation coefficient is a measure of the linear association between two variables, it would not be appropriate to use the correlation coefficient in this case.

Example 22 is meant to reinforce your understanding of how to interpret covariance and correlation.

EXAMPLE 22

Interpreting the Correlation Coefficient

Consider the statistics for the returns over twelve months for three funds, A, B, and C, shown in Exhibit 52.

Exhibit 52

	Fund A	Fund B	Fund C
Arithmetic average	2.9333	3.2250	2.6250
Standard deviation	2.4945	2.4091	3.6668

The covariances are represented in the upper-triangle (shaded area) of the matrix shown in Exhibit 53.

Exhibit 53

	Fund A	Fund B	Fund C
Fund A	6.2224	5.7318	−3.6682
Fund B		5.8039	−2.3125
Fund C			13.4457

The covariance of Fund A and Fund B returns, for example, is 5.7318.

Why show just the upper-triangle of this matrix? Because the covariance of Fund A and Fund B returns is the same as the covariance of Fund B and Fund A returns.

The diagonal of the matrix in Exhibit 53 is the variance of each fund's return. For example, the variance of Fund A returns is 6.2224, but the covariance of Fund A and Fund B returns is 5.7138.

The correlations among the funds' returns are given in Exhibit 54, where the correlations are reported in the upper-triangle (shaded area) of the matrix. Note that the correlation of a fund's returns with itself is +1, so the diagonal in the correlation matrix consists of 1.000.

Exhibit 54

	Fund A	Fund B	Fund C
Fund A	1.0000	0.9538	−0.4010
Fund B		1.0000	−0.2618
Fund C			1.0000

1 Interpret the correlation between Fund A's returns and Fund B's returns.

2 Interpret the correlation between Fund A's returns and Fund C's returns.

3 Describe the relationship of the covariance of these returns and the correlation of returns.

Solutions

1 The correlation of Fund A and Fund B returns is 0.9538, which is positive and close to 1.0. This means that when returns of Fund A tend to be above their mean, Fund B's returns also tend to be above their mean. Graphically, we would observe a positive, but not perfect, linear relationship between the returns for the two funds.

2 The correlation of Fund A's returns and Fund C's returns is −0.4010, which indicates that when Fund A's returns are above their mean, Fund B's returns tend to be below their mean. This implies a negative slope when graphing the returns of these two funds, but it would not be a perfect inverse relationship.

3 There are two negative correlations: Fund A returns with Fund C returns, and Fund B returns with Fund C returns. What determines the sign of the correlation is the sign of the covariance, which in each of these cases is negative. When the covariance between fund returns is positive, such as between Fund A and Fund B returns, the correlation is positive. This follows from the fact that the correlation coefficient is the ratio of the covariance of the two funds' returns to the product of their standard deviations.

12.2 Limitations of Correlation Analysis

Exhibit 51 illustrates that correlation measures the linear association between two variables, but it may not always be reliable. Two variables can have a strong *nonlinear* relation and still have a very low correlation. For example, the relation $Y = (X - 4)^2$ is a nonlinear relation contrasted to the linear relation $Y = 2X - 4$. The nonlinear relation between variables X and Y is shown in Panel D. Below a level of 4 for X, Y increases with decreasing values of X. When X is 4 or greater, however, Y increases whenever X increases. Even though these two variables are perfectly associated, there is no linear association between them (hence, no meaningful correlation).

Correlation may also be an unreliable measure when outliers are present in one or both of the variables. As we have seen, outliers are small numbers of observations at either extreme (small or large) of a sample. The correlation may be quite sensitive to outliers. In such a situation, we should consider whether it makes sense to exclude those outlier observations and whether they are noise or news. As a general rule, we must determine whether a computed sample correlation changes greatly by removing outliers. We must also use judgment to determine whether those outliers contain information about the two variables' relationship (and should thus be included in the correlation analysis) or contain no information (and should thus be excluded). If they are to be excluded from the correlation analysis, as we have seen previously, outlier observations can be handled by trimming or winsorizing the dataset.

Importantly, keep in mind that correlation does not imply causation. Even if two variables are highly correlated, one does not necessarily cause the other in the sense that certain values of one variable bring about the occurrence of certain values of the other.

Moreover, with visualizations too, including scatter plots, we must be on guard against unconsciously making judgments about causal relationships that may or may not be supported by the data.

The term **spurious correlation** has been used to refer to: 1) correlation between two variables that reflects chance relationships in a particular dataset; 2) correlation induced by a calculation that mixes each of two variables with a third variable; and 3) correlation between two variables arising not from a direct relation between them but from their relation to a third variable.

As an example of the chance relationship, consider the monthly US retail sales of beer, wine, and liquor and the atmospheric carbon dioxide levels from 2000–2018. The correlation is 0.824, indicating that there is a positive relation between the two. However, there is no reason to suspect that the levels of atmospheric carbon dioxide are related to the retail sales of beer, wine, and liquor.

As an example of the second kind of spurious correlation, two variables that are uncorrelated may be correlated if divided by a third variable. For example, consider a cross-sectional sample of companies' dividends and total assets. While there may be a low correlation between these two variables, dividing each by market capitalization may increase the correlation.

As an example of the third kind of spurious correlation, height may be positively correlated with the extent of a person's vocabulary, but the underlying relationships are between age and height and between age and vocabulary.

Investment professionals must be cautious in basing investment strategies on high correlations. Spurious correlations may suggest investment strategies that appear profitable but actually would not be, if implemented.

A further issue is that correlation does not tell the whole story about the data. Consider Anscombe's Quartet, discussed in Exhibit 55, where very dissimilar graphs can be developed with variables that have the same mean, same standard deviation, and same correlation.

Exhibit 55 Anscombe's Quartet

Francis Anscombe, a British statistician, developed datasets that illustrate why just looking at summary statistics (that is, mean, standard deviation, and correlation) does not fully describe the data. He created four datasets (designated I, II, III, and IV), each with two variables, X and Y, such that:

- The Xs in each dataset have the same mean and standard deviation, 9.00 and 3.32, respectively.
- The Ys in each dataset have the same mean and standard deviation, 7.50 and 2.03, respectively.
- The Xs and Ys in each dataset have the same correlation of 0.82.

(continued)

Exhibit 55 (Continued)

	I		II		III		IV	
Observation	***X***	***Y***	***X***	***Y***	***X***	***Y***	***X***	***Y***
1	10	8.04	10	9.14	10	7.46	8	6.6
2	8	6.95	8	8.14	8	6.77	8	5.8
3	13	7.58	13	8.74	13	12.74	8	7.7
4	9	8.81	9	8.77	9	7.11	8	8.8
5	11	8.33	11	9.26	11	7.81	8	8.5
6	14	9.96	14	8.1	14	8.84	8	7
7	6	7.24	6	6.13	6	6.08	8	5.3
8	4	4.26	4	3.1	4	5.39	19	13
9	12	10.8	12	9.13	12	8.15	8	5.6
10	7	4.82	7	7.26	7	6.42	8	7.9
11	5	5.68	5	4.74	5	5.73	8	6.9
N	11	11	11	11	11	11	11	11
Mean	9.00	7.50	9.00	7.50	9.00	7.50	9.00	7.50
Standard deviation	3.32	2.03	3.32	2.03	3.32	2.03	3.32	2.03
Correlation	0.82		0.82		0.82		0.82	

While the X variable has the same values for I, II, and III in the quartet of datasets, the Y variables are quite different, creating different relationships. The four datasets are:

I An approximate linear relationship between X and Y.

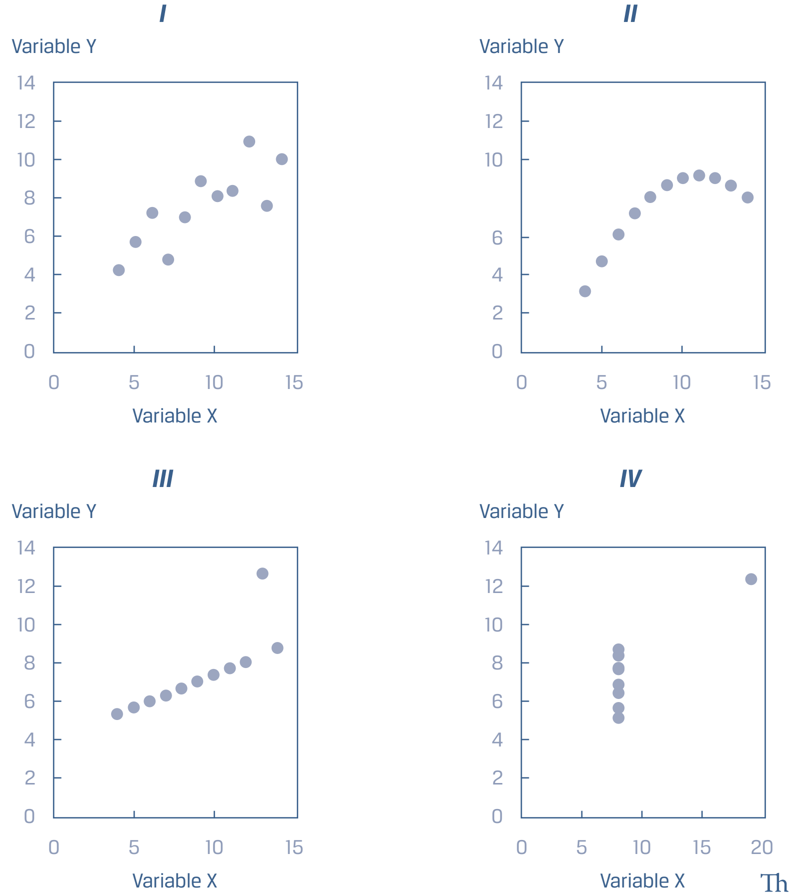
II A curvilinear relationship between X and Y.

III A linear relationship except for one outlier.

IV A constant X with the exception of one outlier.

Depicting the quartet visually,

Exhibit 55 (Continued)



The bottom line? Knowing the means and standard deviations of the two variables, as well as the correlation between them, does not tell the entire story.

SUMMARY

In this reading, we have presented tools and techniques for organizing, visualizing, and describing data that permit us to convert raw data into useful information for investment analysis.

- Data can be defined as a collection of numbers, characters, words, and text—as well as images, audio, and video—in a raw or organized format to represent facts or information.
- From a statistical perspective, data can be classified as numerical data and categorical data. Numerical data (also called quantitative data) are values that represent measured or counted quantities as a number. Categorical data (also called qualitative data) are values that describe a quality or characteristic of a group of observations and usually take only a limited number of values that are mutually exclusive.

- Numerical data can be further split into two types: continuous data and discrete data. Continuous data can be measured and can take on any numerical value in a specified range of values. Discrete data are numerical values that result from a counting process and therefore are limited to a finite number of values.
- Categorical data can be further classified into two types: nominal data and ordinal data. Nominal data are categorical values that are not amenable to being organized in a logical order, while ordinal data are categorical values that can be logically ordered or ranked.
- Based on how they are collected, data can be categorized into three types: cross-sectional, time series, and panel. Time-series data are a sequence of observations for a single observational unit on a specific variable collected over time and at discrete and typically equally spaced intervals of time. Cross-sectional data are a list of the observations of a specific variable from multiple observational units at a given point in time. Panel data are a mix of time-series and cross-sectional data that consists of observations through time on one or more variables for multiple observational units.
- Based on whether or not data are in a highly organized form, they can be classified into structured and unstructured types. Structured data are highly organized in a pre-defined manner, usually with repeating patterns. Unstructured data do not follow any conventionally organized forms; they are typically alternative data as they are usually collected from unconventional sources.
- Raw data are typically organized into either a one-dimensional array or a two-dimensional rectangular array (also called a data table) for quantitative analysis.
- A frequency distribution is a tabular display of data constructed either by counting the observations of a variable by distinct values or groups or by tallying the values of a numerical variable into a set of numerically ordered bins. Frequency distributions permit us to evaluate how data are distributed.
- The relative frequency of observations in a bin (interval or bucket) is the number of observations in the bin divided by the total number of observations. The cumulative relative frequency cumulates (adds up) the relative frequencies as we move from the first bin to the last, thus giving the fraction of the observations that are less than the upper limit of each bin.
- A contingency table is a tabular format that displays the frequency distributions of two or more categorical variables simultaneously. One application of contingency tables is for evaluating the performance of a classification model (using a confusion matrix). Another application of contingency tables is to investigate a potential association between two categorical variables by performing a chi-square test of independence.
- Visualization is the presentation of data in a pictorial or graphical format for the purpose of increasing understanding and for gaining insights into the data.
- A histogram is a bar chart of data that have been grouped into a frequency distribution. A frequency polygon is a graph of frequency distributions obtained by drawing straight lines joining successive midpoints of bars representing the class frequencies.
- A bar chart is used to plot the frequency distribution of categorical data, with each bar representing a distinct category and the bar's height (or length) proportional to the frequency of the corresponding category. Grouped bar charts or stacked bar charts can present the frequency distribution of multiple categorical variables simultaneously.

- A tree-map is a graphical tool to display categorical data. It consists of a set of colored rectangles to represent distinct groups, and the area of each rectangle is proportional to the value of the corresponding group. Additional dimensions of categorical data can be displayed by nested rectangles.
- A word cloud is a visual device for representing textual data, with the size of each distinct word being proportional to the frequency with which it appears in the given text.
- A line chart is a type of graph used to visualize ordered observations and often to display the change of data series over time. A bubble line chart is a special type of line chart that uses varying-sized bubbles as data points to represent an additional dimension of data.
- A scatter plot is a type of graph for visualizing the joint variation in two numerical variables. It is constructed by drawing dots to indicate the values of the two variables plotted against the corresponding axes. A scatter plot matrix organizes scatter plots between pairs of variables into a matrix format to inspect all pairwise relationships between more than two variables in one combined visual.
- A heat map is a type of graphic that organizes and summarizes data in a tabular format and represents it using a color spectrum. It is often used in displaying frequency distributions or visualizing the degree of correlation among different variables.
- The key consideration when selecting among chart types is the intended purpose of visualizing data (i.e., whether it is for exploring/presenting distributions or relationships or for making comparisons).
- A population is defined as all members of a specified group. A sample is a subset of a population.
- A parameter is any descriptive measure of a population. A sample statistic (statistic, for short) is a quantity computed from or used to describe a sample.
- Sample statistics—such as measures of central tendency, measures of dispersion, skewness, and kurtosis—help with investment analysis, particularly in making probabilistic statements about returns.
- Measures of central tendency specify where data are centered and include the mean, median, and mode (i.e., the most frequently occurring value).
- The arithmetic mean is the sum of the observations divided by the number of observations. It is the most frequently used measure of central tendency.
- The median is the value of the middle item (or the mean of the values of the two middle items) when the items in a set are sorted into ascending or descending order. The median is not influenced by extreme values and is most useful in the case of skewed distributions.
- The mode is the most frequently observed value and is the only measure of central tendency that can be used with nominal data. A distribution may be unimodal (one mode), bimodal (two modes), trimodal (three modes), or have even more modes.
- A portfolio's return is a weighted mean return computed from the returns on the individual assets, where the weight applied to each asset's return is the fraction of the portfolio invested in that asset.
- The geometric mean, $\bar{X}_G$, of a set of observations $X_1, X_2, \ldots, X_n$, is $\bar{X}_G = \sqrt[n]{X_1 X_2 X_3 \ldots X_n}$, with $X_i \geq 0$ for $i = 1, 2, \ldots, n$. The geometric mean is especially important in reporting compound growth rates for time-series data. The geometric mean will always be less than an arithmetic mean whenever there is variance in the observations.

- The harmonic mean, $\bar{X}_H$, is a type of weighted mean in which an observation's weight is inversely proportional to its magnitude.
- Quantiles—such as the median, quartiles, quintiles, deciles, and percentiles—are location parameters that divide a distribution into halves, quarters, fifths, tenths, and hundredths, respectively.
- A box and whiskers plot illustrates the interquartile range (the "box") as well as a range outside of the box that is based on the interquartile range, indicated by the "whiskers."
- Dispersion measures—such as the range, mean absolute deviation (MAD), variance, standard deviation, target downside deviation, and coefficient of variation—describe the variability of outcomes around the arithmetic mean.
- The range is the difference between the maximum value and the minimum value of the dataset. The range has only a limited usefulness because it uses information from only two observations.
- The MAD for a sample is the average of the absolute deviations of observations from the mean, $\frac{\sum_{i=1}^{n}\left|X_i - \bar{X}\right|}{n}$, where $\bar{X}$ is the sample mean and n is the number of observations in the sample.
- The variance is the average of the squared deviations around the mean, and the standard deviation is the positive square root of variance. In computing sample variance (s^2) and sample standard deviation (s), the average squared deviation is computed using a divisor equal to the sample size minus 1.
- The target downside deviation, or target semideviation, is a measure of the risk of being below a given target. It is calculated as the square root of the average squared deviations from the target, but it includes only those observations below the target (B), or $\sqrt{\sum_{\text{for all} X_i \le B}^{n} \frac{\left(X_i - B\right)^2}{n - 1}}$.
- The coefficient of variation, CV, is the ratio of the standard deviation of a set of observations to their mean value. By expressing the magnitude of variation among observations relative to their average size, the CV permits direct comparisons of dispersion across different datasets. Reflecting the correction for scale, the CV is a scale-free measure (i.e., it has no units of measurement).
- Skew or skewness describes the degree to which a distribution is asymmetric about its mean. A return distribution with positive skewness has frequent small losses and a few extreme gains compared to a normal distribution. A return distribution with negative skewness has frequent small gains and a few extreme losses compared to a normal distribution. Zero skewness indicates a symmetric distribution of returns.
- Kurtosis measures the combined weight of the tails of a distribution relative to the rest of the distribution. A distribution with fatter tails than the normal distribution is referred to as fat-tailed (leptokurtic); a distribution with thinner tails than the normal distribution is referred to as thin-tailed (platykurtic). Excess kurtosis is kurtosis minus 3, since 3 is the value of kurtosis for all normal distributions.
- The correlation coefficient is a statistic that measures the association between two variables. It is the ratio of covariance to the product of the two variables' standard deviations. A positive correlation coefficient indicates that the two variables tend to move together, whereas a negative coefficient indicates that

the two variables tend to move in opposite directions. Correlation does not imply causation, simply association. Issues that arise in evaluating correlation include the presence of outliers and spurious correlation.

PRACTICE PROBLEMS

1 Published ratings on stocks ranging from 1 (strong sell) to 5 (strong buy) are examples of which measurement scale?

- **A** Ordinal
- **B** Continuous
- **C** Nominal

2 Data values that are categorical and not amenable to being organized in a logical order are *most likely* to be characterized as:

- **A** ordinal data.
- **B** discrete data.
- **C** nominal data.

3 Which of the following data types would be classified as being categorical?

- **A** Discrete
- **B** Nominal
- **C** Continuous

4 A fixed-income analyst uses a proprietary model to estimate bankruptcy probabilities for a group of firms. The model generates probabilities that can take any value between 0 and 1. The resulting set of estimated probabilities would *most likely* be characterized as:

- **A** ordinal data.
- **B** discrete data.
- **C** continuous data.

5 An analyst uses a software program to analyze unstructured data—specifically, management's earnings call transcript for one of the companies in her research coverage. The program scans the words in each sentence of the transcript and then classifies the sentences as having negative, neutral, or positive sentiment. The resulting set of sentiment data would *most likely* be characterized as:

- **A** ordinal data.
- **B** discrete data.
- **C** nominal data.

Use the following information to answer Questions 6 and 7

An equity analyst gathers total returns for three country equity indexes over the past four years. The data are presented below.

© 2020 CFA Institute. All rights reserved.

Time Period	Index A	Index B	Index C
Year *t*–3	15.56%	11.84%	–4.34%
Year t–2	–4.12%	–6.96%	9.32%
Year *t*–1	11.19%	10.29%	–12.72%
Year *t*	8.98%	6.32%	21.44%

6 Each individual column of data in the table can be *best* characterized as:

A panel data.

B time-series data.

C cross-sectional data.

7 Each individual row of data in the table can be *best* characterized as:

A panel data.

B time-series data.

C cross-sectional data.

---

8 A two-dimensional rectangular array would be most suitable for organizing a collection of raw:

A panel data.

B time-series data.

C cross-sectional data.

9 In a frequency distribution, the absolute frequency measure:

A represents the percentages of each unique value of the variable.

B represents the actual number of observations counted for each unique value of the variable.

C allows for comparisons between datasets with different numbers of total observations.

10 An investment fund has the return frequency distribution shown in the following exhibit.

Return Interval (%)	Absolute Frequency
–10.0 to –7.0	3
–7.0 to –4.0	7
–4.0 to –1.0	10
–1.0 to +2.0	12
+2.0 to +5.0	23
+5.0 to +8.0	5

Which of the following statements is correct?

A The relative frequency of the bin "–1.0 to +2.0" is 20%.

B The relative frequency of the bin "+2.0 to +5.0" is 23%.

C The cumulative relative frequency of the bin "+5.0 to +8.0" is 91.7%.

11 An analyst is using the data in the following exhibit to prepare a statistical report.

Portfolio's Deviations from Benchmark Return for a 12-Year Period (%)			
Year 1	2.48	Year 7	–9.19
Year 2	–2.59	Year 8	–5.11
Year 3	9.47	Year 9	1.33
Year 4	–0.55	Year 10	6.84
Year 5	–1.69	Year 11	3.04
Year 6	–0.89	Year 12	4.72

The cumulative relative frequency for the bin $-1.71\% \le x < 2.03\%$ is *closest* to:

- **A** 0.250.
- **B** 0.333.
- **C** 0.583.

Use the following information to answer questions 12 and 13

A fixed-income portfolio manager creates a contingency table of the number of bonds held in her portfolio by sector and bond rating. The contingency table is presented here:

	Bond Rating		
Sector	**A**	**AA**	**AAA**
Communication Services	25	32	27
Consumer Staples	30	25	25
Energy	100	85	30
Health Care	200	100	63
Utilities	22	28	14

12 The marginal frequency of energy sector bonds is *closest* to:

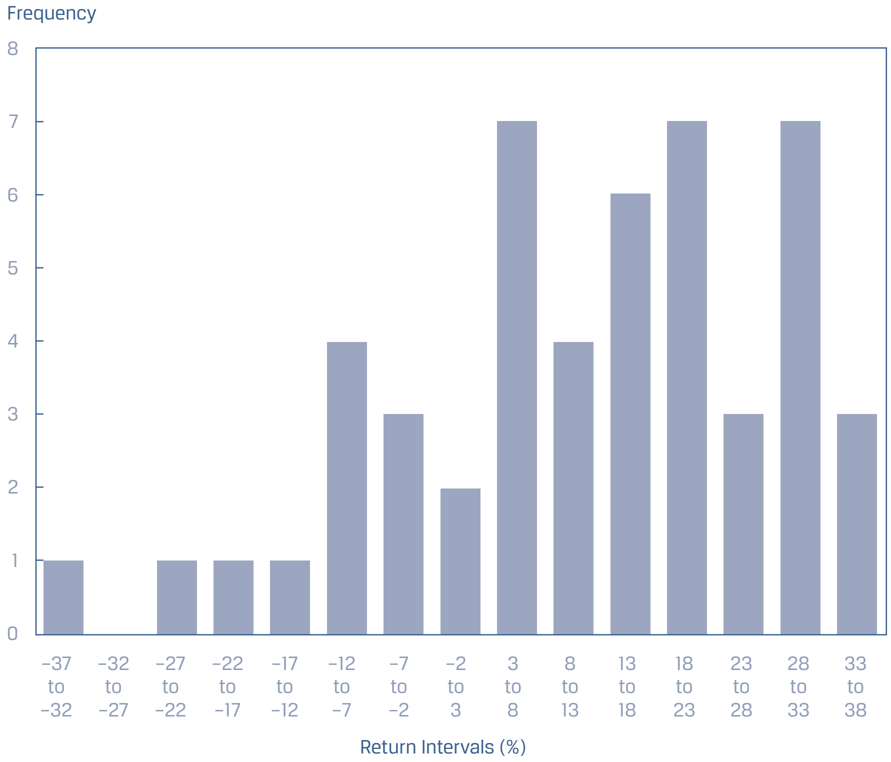
- **A** 27.
- **B** 85.
- **C** 215.

13 The relative frequency of AA rated energy bonds, based on the total count, is *closest* to:

- **A** 10.5%.
- **B** 31.5%.
- **C** 39.5%.

The following information relates to Questions 14–15

The following histogram shows a distribution of the S&P 500 Index annual returns for a 50-year period:



14 The bin containing the median return is:

A 3% to 8%.

B 8% to 13%.

C 13% to 18%.

15 Based on the previous histogram, the distribution is *best* described as being:

A unimodal.

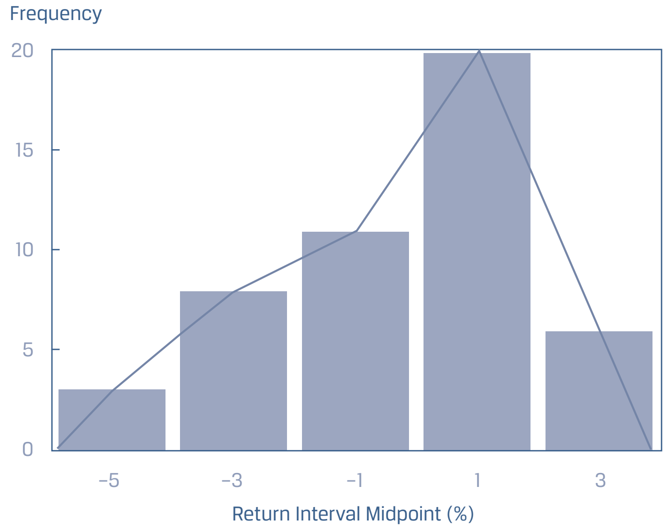
B bimodal.

C trimodal.

---

16 The following is a frequency polygon of monthly exchange rate changes in the US dollar/Japanese yen spot exchange rate for a four-year period. A positive change represents yen appreciation (the yen buys more dollars), and a negative change represents yen depreciation (the yen buys fewer dollars).

Monthly Changes in the US Dollar/Japanese Yen Spot Exchange Rate



Based on the chart, yen appreciation:

A occurred more than 50% of the time.

B was less frequent than yen depreciation.

C in the 0.0 to 2.0 interval occurred 20% of the time.

17 A bar chart that orders categories by frequency in descending order and includes a line displaying cumulative relative frequency is referred to as a:

A Pareto Chart.

B grouped bar chart.

C frequency polygon.

18 Which visualization tool works *best* to represent unstructured, textual data?

A Tree-Map

B Scatter plot

C Word cloud

19 A tree-map is best suited to illustrate:

A underlying trends over time.

B joint variations in two variables.

C value differences of categorical groups.

20 A line chart with two variables—for example, revenues and earnings per share—is best suited for visualizing:

A the joint variation in the variables.

B underlying trends in the variables over time.

C the degree of correlation between the variables.

21 A heat map is best suited for visualizing the:

A frequency of textual data.

B degree of correlation between different variables.

C shape, center, and spread of the distribution of numerical data.

22 Which valuation tool is recommended to be used if the goal is to make comparisons of three or more variables over time?

A Heat map

B Bubble line chart

C Scatter plot matrix

23 The annual returns for three portfolios are shown in the following exhibit. Portfolios P and R were created in Year 1, Portfolio Q in Year 2.

	Annual Portfolio Returns (%)				
	Year 1	**Year 2**	**Year 3**	**Year 4**	**Year 5**
Portfolio P	−3.0	4.0	5.0	3.0	7.0
Portfolio Q		−3.0	6.0	4.0	8.0
Portfolio R	1.0	−1.0	4.0	4.0	3.0

The median annual return from portfolio creation to Year 5 for:

A Portfolio P is 4.5%.

B Portfolio Q is 4.0%.

C Portfolio R is higher than its arithmetic mean annual return.

24 At the beginning of Year X, an investor allocated his retirement savings in the asset classes shown in the following exhibit and earned a return for Year X as also shown.

Asset Class	**Asset Allocation (%)**	**Asset Class Return for Year X (%)**
Large-cap US equities	20.0	8.0
Small-cap US equities	40.0	12.0
Emerging market equities	25.0	−3.0
High-yield bonds	15.0	4.0

The portfolio return for Year X is *closest to*:

A 5.1%.

B 5.3%.

C 6.3%.

25 The following exhibit shows the annual returns for Fund Y.

	Fund Y (%)
Year 1	19.5
Year 2	−1.9
Year 3	19.7
Year 4	35.0
Year 5	5.7

The geometric mean return for Fund Y is *closest* to:

A 14.9%.

B 15.6%.

C 19.5%.

26 A portfolio manager invests €5,000 annually in a security for four years at the prices shown in the following exhibit.

	Purchase Price of Security (€ per unit)
Year 1	62.00
Year 2	76.00
Year 3	84.00
Year 4	90.00

The average price is *best* represented as the:

A harmonic mean of €76.48.

B geometric mean of €77.26.

C arithmetic average of €78.00.

The following information relates to Questions 27–28

The following exhibit shows the annual MSCI World Index total returns for a 10-year period.

Year 1	15.25%	Year 6	30.79%
Year 2	10.02%	Year 7	12.34%
Year 3	20.65%	Year 8	–5.02%
Year 4	9.57%	Year 9	16.54%
Year 5	–40.33%	Year 10	27.37%

27 The fourth quintile return for the MSCI World Index is *closest* to:

A 20.65%.

B 26.03%.

C 27.37%.

28 For Year 6–Year 10, the mean absolute deviation of the MSCI World Index total returns is *closest* to:

A 10.20%.

B 12.74%.

C 16.40%.

---

29 Annual returns and summary statistics for three funds are listed in the following exhibit:

	Annual Returns (%)		
Year	**Fund ABC**	**Fund XYZ**	**Fund PQR**
Year 1	–20.0	–33.0	–14.0
Year 2	23.0	–12.0	–18.0
Year 3	–14.0	–12.0	6.0
Year 4	5.0	–8.0	–2.0
Year 5	–14.0	11.0	3.0

Year	Annual Returns (%) Fund ABC	Fund XYZ	Fund PQR
Mean	−4.0	−10.8	−5.0
Standard deviation	17.8	15.6	10.5

The fund with the highest absolute dispersion is:

A Fund PQR if the measure of dispersion is the range.

B Fund XYZ if the measure of dispersion is the variance.

C Fund ABC if the measure of dispersion is the mean absolute deviation.

30 The mean monthly return and the standard deviation for three industry sectors are shown in the following exhibit.

Sector	Mean Monthly Return (%)	Standard Deviation of Return (%)
Utilities (UTIL)	2.10	1.23
Materials (MATR)	1.25	1.35
Industrials (INDU)	3.01	1.52

Based on the coefficient of variation, the riskiest sector is:

A utilities.

B materials.

C industrials.

31 The average return for Portfolio A over the past twelve months is 3%, with a standard deviation of 4%. The average return for Portfolio B over this same period is also 3%, but with a standard deviation of 6%. The geometric mean return of Portfolio A is 2.85%. The geometric mean return of Portfolio B is:

A less than 2.85%.

B equal to 2.85%.

C greater than 2.85%.

32 An analyst calculated the excess kurtosis of a stock's returns as −0.75. From this information, we conclude that the distribution of returns is:

A normally distributed.

B thin-tailed compared to the normal distribution.

C fat-tailed compared to the normal distribution.

33 When analyzing investment returns, which of the following statements is correct?

A The geometric mean will exceed the arithmetic mean for a series with non-zero variance.

B The geometric mean measures an investment's compound rate of growth over multiple periods.

C The arithmetic mean measures an investment's terminal value over multiple periods.

The following information relates to Questions 34–38

A fund had the following experience over the past 10 years:

Year	Return
1	4.5%
2	6.0%
3	1.5%
4	−2.0%
5	0.0%
6	4.5%
7	3.5%
8	2.5%
9	5.5%
10	4.0%

34 The arithmetic mean return over the 10 years is *closest* to:

A 2.97%.

B 3.00%.

C 3.33%.

35 The geometric mean return over the 10 years is *closest* to:

A 2.94%.

B 2.97%.

C 3.00%.

36 The harmonic mean return over the 10 years is *closest* to:

A 2.94%.

B 2.97%.

C 3.00%.

37 The standard deviation of the 10 years of returns is *closest* to:

A 2.40%.

B 2.53%.

C 7.58%.

38 The target semideviation of the returns over the 10 years if the target is 2% is *closest* to:

A 1.42%.

B 1.50%.

C 2.01%.

---

39 A correlation of 0.34 between two variables, X and Y, is *best* described as:

A changes in X causing changes in Y.

B a positive association between X and Y.

C a curvilinear relationship between X and Y.

40 Which of the following is a potential problem with interpreting a correlation coefficient?

A Outliers

B Spurious correlation

C Both outliers and spurious correlation

The following relates to questions 41 and 42

An analyst is evaluating the tendency of returns on the portfolio of stocks she manages to move along with bond and real estate indexes. She gathered monthly data on returns and the indexes:

	Returns (%)		
	Portfolio Returns	Bond Index Returns	Real Estate Index Returns
Arithmetic average	5.5	3.2	7.8
Standard deviation	8.2	3.4	10.3

	Portfolio Returns and Bond Index Returns	Portfolio Returns and Real Estate Index Returns
Covariance	**18.9**	**–55.9**

41 Without calculating the correlation coefficient, the correlation of the portfolio returns and the bond index returns is:

A negative.

B zero.

C positive.

42 Without calculating the correlation coefficient, the correlation of the portfolio returns and the real estate index returns is:

A negative.

B zero.

C positive.

---

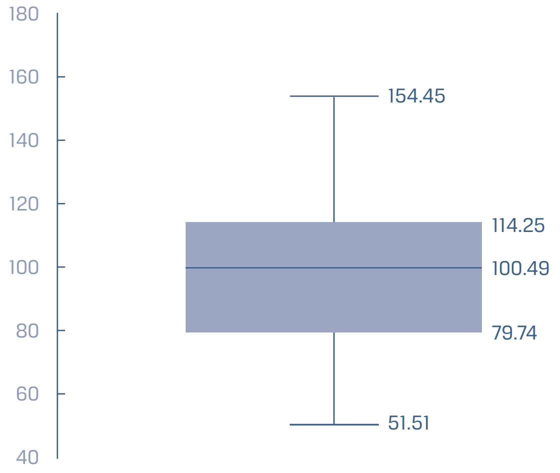
43 Consider two variables, A and B. If variable A has a mean of –0.56, variable B has a mean of 0.23, and the covariance between the two variables is positive, the correlation between these two variables is:

A negative.

B zero.

C positive.

The following information relates to Questions 44–45



44 The median is *closest* to:

- **A** 34.51.
- **B** 100.49.
- **C** 102.98.

45 The interquartile range is *closest* to:

- **A** 13.76.
- **B** 25.74.
- **C** 34.51.

The following information relates to Questions 46–48

An analyst examined a cross-section of annual returns for 252 stocks and calculated the following statistics:

Arithmetic Average	9.986%
Geometric Mean	9.909%
Variance	0.001723
Skewness	0.704
Excess Kurtosis	0.503

46 The coefficient of variation is closest to:

- **A** 0.02.
- **B** 0.42.
- **C** 2.41.

47 This distribution is best described as:

- **A** negatively skewed.
- **B** having no skewness.
- **C** positively skewed.

48 Compared to the normal distribution, this sample's distribution is best described as having tails of the distribution with:

- **A** less probability than the normal distribution.
- **B** the same probability as the normal distribution.
- **C** more probability than the normal distribution.

SOLUTIONS

1 A is correct. Ordinal scales sort data into categories that are ordered with respect to some characteristic and may involve numbers to identify categories but do not assure that the differences between scale values are equal. The buy rating scale indicates that a stock ranked 5 is expected to perform better than a stock ranked 4, but it tells us nothing about the performance difference between stocks ranked 4 and 5 compared with the performance difference between stocks ranked 1 and 2, and so on.

2 C is correct. Nominal data are categorical values that are not amenable to being organized in a logical order. A is incorrect because ordinal data are categorical data that can be logically ordered or ranked. B is incorrect because discrete data are numerical values that result from a counting process; thus, they can be ordered in various ways, such as from highest to lowest value.

3 B is correct. Categorical data (or qualitative data) are values that describe a quality or characteristic of a group of observations and therefore can be used as labels to divide a dataset into groups to summarize and visualize. The two types of categorical data are nominal data and ordinal data. Nominal data are categorical values that are not amenable to being organized in a logical order, while ordinal data are categorical values that can be logically ordered or ranked. A is incorrect because discrete data would be classified as numerical data (not categorical data). C is incorrect because continuous data would be classified as numerical data (not categorical data).

4 C is correct. Continuous data are data that can be measured and can take on any numerical value in a specified range of values. In this case, the analyst is estimating bankruptcy probabilities, which can take on any value between 0 and 1. Therefore, the set of bankruptcy probabilities estimated by the analyst would likely be characterized as continuous data. A is incorrect because ordinal data are categorical values that can be logically ordered or ranked. Therefore, the set of bankruptcy probabilities would not be characterized as ordinal data. B is incorrect because discrete data are numerical values that result from a counting process, and therefore the data are limited to a finite number of values. The proprietary model used can generate probabilities that can take any value between 0 and 1; therefore, the set of bankruptcy probabilities would not be characterized as discrete data.

5 A is correct. Ordinal data are categorical values that can be logically ordered or ranked. In this case, the classification of sentences in the earnings call transcript into three categories (negative, neutral, or positive) describes ordinal data, as the data can be logically ordered from positive to negative. B is incorrect because discrete data are numerical values that result from a counting process. In this case, the analyst is categorizing sentences (i.e., unstructured data) from the earnings call transcript as having negative, neutral, or positive sentiment. Thus, these categorical data do not represent discrete data. C is incorrect because nominal data are categorical values that are not amenable to being organized in a logical order. In this case, the classification of unstructured data (i.e., sentences from the earnings call transcript) into three categories (negative, neutral, or positive) describes ordinal (not nominal) data, as the data can be logically ordered from positive to negative.

6 B is correct. Time-series data are a sequence of observations of a specific variable collected over time and at discrete and typically equally spaced intervals of time, such as daily, weekly, monthly, annually, and quarterly. In this case, each

column is a time series of data that represents annual total return (the specific variable) for a given country index, and it is measured annually (the discrete interval of time). A is incorrect because panel data consist of observations through time on one or more variables for multiple observational units. The entire table of data is an example of panel data showing annual total returns (the variable) for three country indexes (the observational units) by year. C is incorrect because cross-sectional data are a list of the observations of a specific variable from multiple observational units at a given point in time. Each row (not column) of data in the table represents cross-sectional data.

7 C is correct. Cross-sectional data are observations of a specific variable from multiple observational units at a given point in time. Each row of data in the table represents cross-sectional data. The specific variable is annual total return, the multiple observational units are the three countries' indexes, and the given point in time is the time period indicated by the particular row. A is incorrect because panel data consist of observations through time on one or more variables for multiple observational units. The entire table of data is an example of panel data showing annual total returns (the variable) for three country indexes (the observational units) by year. B is incorrect because time-series data are a sequence of observations of a specific variable collected over time and at discrete and typically equally spaced intervals of time, such as daily, weekly, monthly, annually, and quarterly. In this case, each column (not row) is a time series of data that represents annual total return (the specific variable) for a given country index, and it is measured annually (the discrete interval of time).

8 A is correct. Panel data consist of observations through time on one or more variables for multiple observational units. A two-dimensional rectangular array, or data table, would be suitable here as it is comprised of columns to hold the variable(s) for the observational units and rows to hold the observations through time. B is incorrect because a one-dimensional (not a two-dimensional rectangular) array would be most suitable for organizing a collection of data of the same data type, such as the time-series data from a single variable. C is incorrect because a one-dimensional (not a two-dimensional rectangular) array would be most suitable for organizing a collection of data of the same data type, such as the same variable for multiple observational units at a given point in time (cross-sectional data).

9 B is correct. In a frequency distribution, the absolute frequency, or simply the raw frequency, is the actual number of observations counted for each unique value of the variable. A is incorrect because the relative frequency, which is calculated as the absolute frequency of each unique value of the variable divided by the total number of observations, presents the absolute frequencies in terms of percentages. C is incorrect because the relative (not absolute) frequency provides a normalized measure of the distribution of the data, allowing comparisons between datasets with different numbers of total observations.

10 A is correct. The relative frequency is the absolute frequency of each bin divided by the total number of observations. Here, the relative frequency is calculated as: (12/60) × 100 = 20%. B is incorrect because the relative frequency of this bin is (23/60) × 100 = 38.33%. C is incorrect because the cumulative relative frequency of the last bin must equal 100%.

11 C is correct. The cumulative relative frequency of a bin identifies the fraction of observations that are less than the upper limit of the given bin. It is determined by summing the relative frequencies from the lowest bin up to and including the given bin. The following exhibit shows the relative frequencies for all the bins of the data from the previous exhibit:

Lower Limit (%)	Upper Limit (%)	Absolute Frequency	Relative Frequency	Cumulative Relative Frequency
−9.19 ≤	< −5.45	1	0.083	0.083
−5.45 ≤	< −1.71	2	0.167	0.250
−1.71 ≤	< 2.03	4	0.333	0.583
2.03 ≤	< 5.77	3	0.250	0.833
5.77 ≤	≤ 9.47	2	0.167	1.000

The bin −1.71% ≤ x < 2.03% has a cumulative relative frequency of 0.583.

12 C is correct. The marginal frequency of energy sector bonds in the portfolio is the sum of the joint frequencies across all three levels of bond rating, so 100 + 85 + 30 = 215. A is incorrect because 27 is the relative frequency for energy sector bonds based on the total count of 806 bonds, so 215/806 = 26.7%, not the marginal frequency. B is incorrect because 85 is the joint frequency for AA rated energy sector bonds, not the marginal frequency.

13 A is correct. The relative frequency for any value in the table based on the total count is calculated by dividing that value by the total count. Therefore, the relative frequency for AA rated energy bonds is calculated as 85/806 = 10.5%.

B is incorrect because 31.5% is the relative frequency for AA rated energy bonds, calculated based on the marginal frequency for all AA rated bonds, so 85/(32 + 25 + 85 + 100 + 28), not based on total bond counts. C is incorrect because 39.5% is the relative frequency for AA rated energy bonds, calculated based on the marginal frequency for all energy bonds, so 85/(100 + 85 + 30), not based on total bond counts.

14 C is correct. Because 50 data points are in the histogram, the median return would be the mean of the 50/2 = 25th and (50 + 2)/2 = 26th positions. The sum of the return bin frequencies to the left of the 13% to 18% interval is 24. As a result, the 25th and 26th returns will fall in the 13% to 18% interval.

15 C is correct. The mode of a distribution with data grouped in intervals is the interval with the highest frequency. The three intervals of 3% to 8%, 18% to 23%, and 28% to 33% all have a high frequency of 7.

16 A is correct. Twenty observations lie in the interval "0.0 to 2.0," and six observations lie in the "2.0 to 4.0" interval. Together, they represent 26/48, or 54.17%, of all observations, which is more than 50%.

17 A is correct. A bar chart that orders categories by frequency in descending order and includes a line displaying cumulative relative frequency is called a Pareto Chart. A Pareto Chart is used to highlight dominant categories or the most important groups. B is incorrect because a grouped bar chart or clustered bar chart is used to present the frequency distribution of two categorical variables. C is incorrect because a frequency polygon is used to display frequency distributions.

18 C is correct. A word cloud, or tag cloud, is a visual device for representing unstructured, textual data. It consists of words extracted from text with the size of each word being proportional to the frequency with which it appears in the given text. A is incorrect because a tree-map is a graphical tool for displaying and comparing categorical data, not for visualizing unstructured, textual data. B is incorrect because a scatter plot is used to visualize the joint variation in two numerical variables, not for visualizing unstructured, textual data.

19 C is correct. A tree-map is a graphical tool used to display and compare categorical data. It consists of a set of colored rectangles to represent distinct groups, and the area of each rectangle is proportional to the value of the corresponding group. A is incorrect because a line chart, not a tree-map, is used to display the change in a data series over time. B is incorrect because a scatter plot, not a tree-map, is used to visualize the joint variation in two numerical variables.

20 B is correct. An important benefit of a line chart is that it facilitates showing changes in the data and underlying trends in a clear and concise way. Often a line chart is used to display the changes in data series over time. A is incorrect because a scatter plot, not a line chart, is used to visualize the joint variation in two numerical variables. C is incorrect because a heat map, not a line chart, is used to visualize the values of joint frequencies among categorical variables.

21 B is correct. A heat map is commonly used for visualizing the degree of correlation between different variables. A is incorrect because a word cloud, or tag cloud, not a heat map, is a visual device for representing textual data with the size of each distinct word being proportional to the frequency with which it appears in the given text. C is incorrect because a histogram, not a heat map, depicts the shape, center, and spread of the distribution of numerical data.

22 B is correct. A bubble line chart is a version of a line chart where data points are replaced with varying-sized bubbles to represent a third dimension of the data. A line chart is very effective at visualizing trends in three or more variables over time. A is incorrect because a heat map differentiates high values from low values and reflects the correlation between variables but does not help in making comparisons of variables over time. C is incorrect because a scatterplot matrix is a useful tool for organizing scatterplots between pairs of variables, making it easy to inspect all pairwise relationships in one combined visual. However, it does not help in making comparisons of these variables over time.

23 C is correct. The median of Portfolio R is 0.8% higher than the mean for Portfolio R.

24 C is correct. The portfolio return must be calculated as the weighted mean return, where the weights are the allocations in each asset class:

$$(0.20 \times 8\%) + (0.40 \times 12\%) + (0.25 \times -3\%) + (0.15 \times 4\%) = 6.25\%, \text{ or } \approx 6.3\%.$$

25 A is correct. The geometric mean return for Fund Y is found as follows:

$$\begin{aligned}\text{Fund Y} &= [(1 + 0.195) \times (1 - 0.019) \times (1 + 0.197) \times (1 + 0.350) \times (1 + 0.057)]^{(1/5)} - 1\\ &= 14.9\%.\end{aligned}$$

26 A is correct. The harmonic mean is appropriate for determining the average price per unit. It is calculated by summing the reciprocals of the prices, then averaging that sum by dividing by the number of prices, then taking the reciprocal of the average:

$$4/[(1/62.00) + (1/76.00) + (1/84.00) + (1/90.00)] = €76.48.$$

27 B is correct. Quintiles divide a distribution into fifths, with the fourth quintile occurring at the point at which 80% of the observations lie below it. The fourth quintile is equivalent to the 80th percentile. To find the yth percentile (P_y), we first must determine its location. The formula for the location (L_y) of a yth percentile in an array with n entries sorted in ascending order is $L_y = (n + 1) \times (y/100)$. In this case, $n = 10$ and $y = 80\%$, so

$$L_{80} = (10 + 1) \times (80/100) = 11 \times 0.8 = 8.8.$$

With the data arranged in ascending order (−40.33%, −5.02%, 9.57%, 10.02%, 12.34%, 15.25%, 16.54%, 20.65%, 27.37%, and 30.79%), the 8.8th position would be between the 8th and 9th entries, 20.65% and 27.37%, respectively. Using linear interpolation, $P_{80} = X_8 + (L_y - 8) \times (X_9 - X_8)$,

$$\begin{aligned} P_{80} &= 20.65 + (8.8 - 8) \times (27.37 - 20.65) \\ &= 20.65 + (0.8 \times 6.72) = 20.65 + 5.38 \\ &= 26.03\%. \end{aligned}$$

28 A is correct. The formula for mean absolute deviation (MAD) is

$$\text{MAD} = \frac{\sum_{i=1}^{n} \left| X_i - \bar{X} \right|}{n}$$

Column 1: Sum annual returns and divide by n to find the arithmetic mean $\left(\bar{X}\right)$ of 16.40%.

Column 2: Calculate the absolute value of the difference between each year's return and the mean from Column 1. Sum the results and divide by n to find the MAD.

These calculations are shown in the following exhibit:

	Column 1		Column 2
Year	**Return**		$\left\|X_i - \bar{X}\right\|$
Year 6	30.79%		14.39%
Year 7	12.34%		4.06%
Year 8	−5.02%		21.42%
Year 9	16.54%		0.14%
Year 10	27.37%		10.97%
Sum:	82.02%	Sum:	50.98%
n:	5	n:	5
$\bar{X}$:	16.40%	MAD:	10.20%

29 C is correct. The mean absolute deviation (MAD) of Fund ABC's returns is greater than the MAD of both of the other funds.

$$\text{MAD} = \frac{\sum_{i=1}^{n} \left| X_i - \bar{X} \right|}{n}, \text{ where } \bar{X} \text{ is the arithmetic mean of the series.}$$

MAD for Fund ABC =

$$\frac{\left|-20-(-4)\right| + \left|23-(-4)\right| + \left|-14-(-4)\right| + \left|5-(-4)\right| + \left|-14-(-4)\right|}{5} = 14.4\%$$

MAD for Fund XYZ =

$$\frac{|-33-(-10.8)|+|-12-(-10.8)|+|-12-(-10.8)|+|-8-(-10.8)|+|11-(-10.8)|}{5}=9.8\%$$

MAD for Fund PQR =

$$\frac{|-14-(-5)|+|-18-(-5)|+|6-(-5)|+|-2-(-5)|+|3-(-5)|}{5}=8.8\%$$

A and B are incorrect because the range and variance of the three funds are as follows:

	Fund ABC	Fund XYZ	Fund PQR
Range	43%	44%	24%
Variance	317	243	110

The numbers shown for variance are understood to be in "percent squared" terms so that when taking the square root, the result is standard deviation in percentage terms. Alternatively, by expressing standard deviation and variance in decimal form, one can avoid the issue of units. In decimal form, the variances for Fund ABC, Fund XYZ, and Fund PQR are 0.0317, 0.0243, and 0.0110, respectively.

30 B is correct. The coefficient of variation (CV) is the ratio of the standard deviation to the mean, where a higher CV implies greater risk per unit of return.

$$CV_{UTIL}=\frac{s}{\overline{X}}=\frac{1.23\%}{2.10\%}=0.59$$

$$CV_{MATR}=\frac{s}{\overline{X}}=\frac{1.35\%}{1.25\%}=1.08$$

$$CV_{INDU}=\frac{s}{\overline{X}}=\frac{1.52\%}{3.01\%}=0.51$$

31 A is correct. The more disperse a distribution, the greater the difference between the arithmetic mean and the geometric mean.

32 B is correct. The distribution is thin-tailed relative to the normal distribution because the excess kurtosis is less than zero.

33 B is correct. The geometric mean compounds the periodic returns of every period, giving the investor a more accurate measure of the terminal value of an investment.

34 B is correct. The sum of the returns is 30.0%, so the arithmetic mean is 30.0%/10 = 3.0%.

35 B is correct.

Year	Return	1+ Return
1	4.5%	1.045
2	6.0%	1.060
3	1.5%	1.015
4	−2.0%	0.980
5	0.0%	1.000
6	4.5%	1.045

(continued)

Year	Return	1+ Return
7	3.5%	1.035
8	2.5%	1.025
9	5.5%	1.055
10	4.0%	1.040

The product of the 1 + Return is 1.3402338.

Therefore, $\bar{X}_G = \sqrt[10]{1.3402338} - 1 = 2.9717\%$.

36 A is correct.

Year	Return	1+ Return	1/(1+Return)
1	4.5%	1.045	0.957
2	6.0%	1.060	0.943
3	1.5%	1.015	0.985
4	−2.0%	0.980	1.020
5	0.0%	1.000	1.000
6	4.5%	1.045	0.957
7	3.5%	1.035	0.966
8	2.5%	1.025	0.976
9	5.5%	1.055	0.948
10	4.0%	1.040	0.962
Sum			**9.714**

The harmonic mean return = (n/Sum of reciprocals) − 1 = (10 / 9.714) − 1.

The harmonic mean return = 2.9442%.

37 B is correct.

Year	Return	Deviation	Deviation Squared
1	4.5%	0.0150	0.000225
2	6.0%	0.0300	0.000900
3	1.5%	−0.0150	0.000225
4	−2.0%	−0.0500	0.002500
5	0.0%	−0.0300	0.000900
6	4.5%	0.0150	0.000225
7	3.5%	0.0050	0.000025
8	2.5%	−0.0050	0.000025
9	5.5%	0.0250	0.000625
10	4.0%	0.0100	0.000100
Sum		0.0000	**0.005750**

The standard deviation is the square root of the sum of the squared deviations divided by $n - 1$:

$$s = \sqrt{\frac{0.005750}{9}} = 2.5276\%.$$

38 B is correct.

Year	Return	Deviation Squared below Target of 2%
1	4.5%	
2	6.0%	
3	1.5%	0.000025
4	−2.0%	0.001600
5	0.0%	0.000400
6	4.5%	
7	3.5%	
8	2.5%	
9	5.5%	
10	4.0%	
Sum		0.002025

The target semi-deviation is the square root of the sum of the squared deviations from the target, divided by $n - 1$:

$$s_{\text{Target}} = \sqrt{\frac{0.002025}{9}} = 1.5\%.$$

39 B is correct. The correlation coefficient is positive, indicating that the two series move together.

40 C is correct. Both outliers and spurious correlation are potential problems with interpreting correlation coefficients.

41 C is correct. The correlation coefficient is positive because the covariation is positive.

42 A is correct. The correlation coefficient is negative because the covariation is negative.

43 C is correct. The correlation coefficient is positive because the covariance is positive. The fact that one or both variables have a negative mean does not affect the sign of the correlation coefficient.

44 B is correct. The median is indicated within the box, which is the 100.49 in this diagram.

45 C is correct. The interquartile range is the difference between 114.25 and 79.74, which is 34.51.

46 B is correct. The coefficient of variation is the ratio of the standard deviation to the arithmetic average, or $\sqrt{0.001723}/0.09986 = 0.416$.

47 C is correct. The skewness is positive, so it is right-skewed (positively skewed).

48 C is correct. The excess kurtosis is positive, indicating that the distribution is “fat-tailed”; therefore, there is more probability in the tails of the distribution relative to the normal distribution.

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** define a random variable, an outcome, and an event;
☐	**b.** identify the two defining properties of probability, including mutually exclusive and exhaustive events, and compare and contrast empirical, subjective, and a priori probabilities;
☐	**c.** describe the probability of an event in terms of odds for and against the event;
☐	**d.** calculate and interpret conditional probabilities;
☐	**e.** demonstrate the application of the multiplication and addition rules for probability;
☐	**f.** compare and contrast dependent and independent events;
☐	**g.** calculate and interpret an unconditional probability using the total probability rule;
☐	**h.** calculate and interpret the expected value, variance, and standard deviation of random variables;
☐	**i.** explain the use of conditional expectation in investment applications;
☐	**j.** interpret a probability tree and demonstrate its application to investment problems;
☐	**k.** calculate and interpret the expected value, variance, standard deviation, covariances, and correlations of portfolio returns;

(continued)

CFA Institute would like to thank John Stowe, PhD, CFA, for his significant contributions in revising this reading.

LEARNING OUTCOMES

Mastery	The candidate should be able to:
☐	**l.** calculate and interpret the covariances of portfolio returns using the joint probability function;
☐	**m.** calculate and interpret an updated probability using Bayes' formula;
☐	**n.** identify the most appropriate method to solve a particular counting problem and analyze counting problems using factorial, combination, and permutation concepts.

1 INTRODUCTION, PROBABILITY CONCEPTS, AND ODDS RATIOS

a define a random variable, an outcome, and an event

Investment decisions are made in a risky environment. The tools that allow us to make decisions with consistency and logic in this setting are based on probability concepts. This reading presents the essential probability tools needed to frame and address many real-world problems involving risk. These tools apply to a variety of issues, such as predicting investment manager performance, forecasting financial variables, and pricing bonds so that they fairly compensate bondholders for default risk. Our focus is practical. We explore the concepts that are most important to investment research and practice. Among these are independence, as it relates to the predictability of returns and financial variables; expectation, as analysts continually look to the future in their analyses and decisions; and variability, variance or dispersion around expectation, as a risk concept important in investments. The reader will acquire specific skills and competencies in using these probability concepts to understand risks and returns on investments.

1.1 Probability, Expected Value, and Variance

The probability concepts and tools necessary for most of an analyst's work are relatively few and straightforward but require thought to apply. This section presents the essentials for working with probability, expectation, and variance, drawing on examples from equity and fixed income analysis.

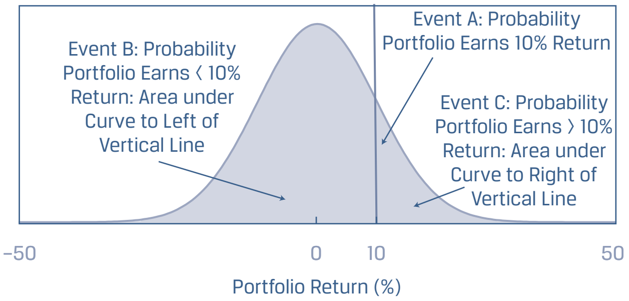
An investor's concerns center on returns. The return on a risky asset is an example of a random variable.

- Definition of Random Variable. A **random variable** is a quantity whose future outcomes are uncertain.
- Definition of Outcome. An **outcome** is a possible value of a random variable.

Using Exhibit 1 as an example, a portfolio manager may have a return objective of 10% a year. The portfolio manager's focus at the moment may be on the likelihood of earning a return that is less than 10% over the next year. Ten percent is a particular value or outcome of the random variable "portfolio return." Although we may be concerned about a single outcome, frequently our interest may be in a set of outcomes. The concept of "event" covers both.

- Definition of Event. An **event** is a specified set of outcomes.

Exhibit 1 Visualizing Probability



An event can be a single outcome—for example, the portfolio earns a return of (exactly) 10%. We can capture the portfolio manager's concerns by defining another event as the portfolio earns a return below 10%. This second event, referring as it does to all possible returns greater than or equal to –100% (the worst possible return, losing all the money in the portfolio) but less than 10%, contains an infinite number of outcomes. To save words, it is common to use a capital letter in italics to represent a defined event. We could define A = *the portfolio earns a return of 10%* and B = *the portfolio earns a return below 10%.*

To return to the portfolio manager's concern, how likely is it that the portfolio will earn a return below 10%? The answer to this question is a **probability**: a number between 0 and 1 that measures the chance that a stated event will occur. If the probability is 0.65 that the portfolio earns a return below 10%, there is a 65% chance of that event happening. If an event is impossible, it has a probability of 0. If an event is certain to happen, it has a probability of 1. If an event is impossible or a sure thing, it is not random at all. So, 0 and 1 bracket all the possible values of a probability.

To reiterate, a probability can be thought of as the likelihood that something will happen. If it has a probability of 1, it is likely to happen 100% of the time, and if it has a probably of 0, it is likely to never happen. Some people think of probabilities as akin to relative frequencies. If something is expected to happen 30 times out of 100, the probability is 0.30. The probability is the number of ways that an (equally likely) event can happen divided by the total number of possible outcomes.

b identify the two defining properties of probability, including mutually exclusive and exhaustive events, and compare and contrast empirical, subjective, and a priori probabilities

Probability has two properties, which together constitute its definition.

- Definition of Probability. The two defining properties of a probability are:
  1. The probability of any event E is a number between 0 and 1: $0 \le P(E) \le 1$.
  2. The sum of the probabilities of any set of mutually exclusive and exhaustive events equals 1.

P followed by parentheses stands for "the probability of (the event in parentheses)," as in $P(E)$ for "the probability of event E." We can also think of P as a rule or function that assigns numerical values to events consistent with Properties 1 and 2.

In the above definition, the term **mutually exclusive** means that only one event can occur at a time; **exhaustive** means that the events cover all possible outcomes. Referring back to Exhibit 1, the events A = *the portfolio earns a return of 10%* and B = *the portfolio earns a return below 10%* are mutually exclusive because A and B cannot both occur at the same time. For example, a return of 8.1% means that B has occurred and A has not occurred. Although events A and B are mutually exclusive, they are not exhaustive because they do not cover outcomes such as a return of 11%.

Suppose we define a third event: C = *the portfolio earns a return above 10%.* Clearly, A, B, and C are mutually exclusive and exhaustive events. Each of $P(A)$, $P(B)$, and $P(C)$ is a number between 0 and 1, and $P(A) + P(B) + P(C) = 1$.

Earlier, to illustrate a concept, we assumed a probability of 0.65 for a portfolio earning less than 10%, without justifying the particular assumption. We also talked about using assigned probabilities of outcomes to calculate the probability of events, without explaining how such a probability distribution might be estimated. Making actual financial decisions using inaccurate probabilities could have grave consequences. How, in practice, do we estimate probabilities? This topic is a field of study in itself, but there are three broad approaches to estimating probabilities. In investments, we often estimate the probability of an event as a relative frequency of occurrence based on historical data. This method produces an **empirical probability**. For example, suppose you noted that 51 of the 60 stocks in a particular large-cap equity index pay dividends. The empirical probability of the stocks in the index paying a dividend is $P(\textit{stock is dividend paying}) = 51 / 60 = 0.85$.

Relationships must be stable through time for empirical probabilities to be accurate. We cannot calculate an empirical probability of an event not in the historical record or a reliable empirical probability for a very rare event. In some cases, then, we may adjust an empirical probability to account for perceptions of changing relationships. In other cases, we have no empirical probability to use at all. We may also make a personal assessment of probability without reference to any particular data. Another type of probability is a **subjective probability**, one drawing on personal or subjective judgment. Subjective probabilities are of great importance in investments. Investors, in making buy and sell decisions that determine asset prices, often draw on subjective probabilities.

For many well-defined problems, we can deduce probabilities by reasoning about the problem. The resulting probability is an **a priori probability**, one based on logical analysis rather than on observation or personal judgment. Because a priori and empirical probabilities generally do not vary from person to person, they are often grouped as **objective probabilities**.

For examples of the three types of probabilities, suppose you want to estimate the probability of flipping a coin and getting exactly two heads out of five flips. For the empirical probability, you do the experiment 100 times (five flips each time) and find that you get two heads 33 times. The empirical probability would be 33/100 = 0.33. For a subjective judgement, you think the probability is somewhere between 0.25 and 0.50, so you split the difference and choose 0.375. For the a priori probability, you assume that the binomial probability function (discussed later in the curriculum) applies, and the mathematical probability of two heads out of five flips is 0.3125.

c describe the probability of an event in terms of odds for and against the event

Another way of stating probabilities often encountered in investments is in terms of odds—for instance, "the odds for *E*" or the "odds against *E*." A probability is the fraction of the time you expect an event to occur, and the odds for an event is the probability that an event will occur divided by the probability that the event will not occur. Consider a football team that has a 0.25 probability of winning the World Cup, and a 0.75 probability of losing. The odds for winning are 0.25/0.75 = 0.33 (and the odds for losing are 0.75/0.25 = 3.0). If another team has a 0.80 probability of winning, the odds for winning would be 0.80/0.20 = 4.0. If, for a third team, the probability of winning was 0.50, the odds are even: odds = 0.50/0.50 = 1. If the probability is low, the odds are very close to the probability. For example, if the probability of winning is 0.05, the odds for winning are 0.05/0.95 = 0.0526.

EXAMPLE 1

Odds of Passing a Quantitative Methods Investment Course

Two of your colleagues are taking a quantitative methods investment course.

1. If your first colleague has a 0.40 probability of passing, what are his odds for passing?
2. If your second colleague has odds of passing of 4 to 1, what is the probability of her passing?

Solution for 1:

The odds are the probability of passing divided by the probability of not passing. The odds are 0.40 / 0.60 = 2/3 ≈ 0.667.

Solution for 2:

The odds = *Probability* (*passing*) / *Probability* (*not passing*). If Y = Probability of passing, then 4 = Y / (1 − Y). Solving for Y, we get 0.80 as the probability of passing.

We interpret probabilities stated in terms of odds as follows:

- Probability Stated as Odds. Given a probability $P(E)$,
  1. **Odds for *E*** = $P(E)/[1 - P(E)]$. The odds for E are the probability of E divided by 1 minus the probability of E. Given odds for E of "a to b," the implied probability of E is $a/(a + b)$.

  In the example, the statement that your second colleague's odds of passing the exam are 4 to 1 means that the probability of the event is 4/(4 + 1) = 4/5 = 0.80.

  2. **Odds against *E*** = $[1 - P(E)]/P(E)$, the reciprocal of odds for E. Given odds against E of "a to b," the implied probability of E is $b/(a + b)$.

  In the example, if the odds against your second colleague passing the exam are 1 to 4, this means that the probability of the event is 1/(4 + 1) = 1/5 = 0.20.

To further explain odds for an event, if $P(E) = 1/8$, the odds for E are $(1/8)/(7/8) = (1/8)(8/7) = 1/7$, or "1 to 7." For each occurrence of E, we expect seven cases of nonoccurrence; out of eight cases in total, therefore, we expect E to happen once, and the probability of E is 1/8. In wagering, it is common to speak in terms of the odds against something, as in Statement 2. For odds of "15 to 1" against E (an implied probability of E of 1/16), a $1 wager on E, if successful, returns $15 in profits plus the $1 staked in the wager. We can calculate the bet's anticipated profit as follows:

Win:	Probability = 1/16; Profit =$15
Loss:	Probability = 15/16; Profit = −$1

Anticipated profit = (1/16)($15) + (15/16)(−$1) = $0

Weighting each of the wager's two outcomes by the respective probability of the outcome, if the odds (probabilities) are accurate, the anticipated profit of the bet is $0.

EXAMPLE 2

Profiting from Inconsistent Probabilities

You are examining the common stock of two companies in the same industry in which an important antitrust decision will be announced next week. The first company, SmithCo Corporation, will benefit from a governmental decision that there is no antitrust obstacle related to a merger in which it is involved. You believe that SmithCo's share price reflects a 0.85 probability of such a decision. A second company, Selbert Corporation, will equally benefit from a "go ahead" ruling. Surprisingly, you believe Selbert stock reflects only a 0.50 probability of a favorable decision. Assuming your analysis is correct, what investment strategy would profit from this pricing discrepancy?

Consider the logical possibilities. One is that the probability of 0.50 reflected in Selbert's share price is accurate. In that case, Selbert is fairly valued, but SmithCo is overvalued, because its current share price overestimates the probability of a "go ahead" decision. The second possibility is that the probability of 0.85 is accurate. In that case, SmithCo shares are fairly valued, but Selbert shares, which build in a lower probability of a favorable decision, are undervalued. You diagram the situation as shown in Exhibit 2.

Exhibit 2 Worksheet for Investment Problem

	True Probability of a "Go Ahead" Decision	
	0.50	**0.85**
SmithCo	Shares Overvalued	Shares Fairly Valued
Selbert	Shares Fairly Valued	Shares Undervalued
Strategy	Short-Sell Smith / Buy Selbert	Sell Smith / Buy Selbert

The 0.50 probability column shows that Selbert shares are a better value than SmithCo shares. Selbert shares are also a better value if a 0.85 probability is accurate. Thus, SmithCo shares are overvalued relative to Selbert shares.

Your investment actions depend on your confidence in your analysis and on any investment constraints you face (such as constraints on selling stock short). Selling short or shorting stock means selling borrowed shares in the hope of repurchasing them later at a lower price. A conservative strategy would be to buy Selbert shares and reduce or eliminate any current position in SmithCo. The most aggressive strategy is to short SmithCo stock (relatively overvalued) and simultaneously buy the stock of Selbert (relatively undervalued). The prices of SmithCo and Selbert shares reflect probabilities that are not consistent. According to one of the most important probability results for investments, the **Dutch Book Theorem**, inconsistent probabilities create profit opportunities. In our example, investors' buy and sell decisions exploit the inconsistent probabilities to eliminate the profit opportunity and inconsistency.

CONDITIONAL AND JOINT PROBABILITY

2

d calculate and interpret conditional probabilities

To understand the meaning of a probability in investment contexts, we need to distinguish between two types of probability: unconditional and conditional. Both unconditional and conditional probabilities satisfy the definition of probability stated earlier, but they are calculated or estimated differently and have different interpretations. They provide answers to different questions.

The probability in answer to the straightforward question "What is the probability of this event *A*?" is an **unconditional probability**, denoted $P(A)$. Suppose the question is "What is the probability that *the stock earns a return above the risk-free rate* (event *A*)?" The answer is an unconditional probability that can be viewed as the ratio of two quantities. The numerator is the sum of the probabilities of stock returns above the risk-free rate. Suppose that sum is 0.70. The denominator is 1, the sum of the probabilities of all possible returns. The answer to the question is $P(A) = 0.70$.

Contrast the question "What is the probability of *A*?" with the question "What is the probability of *A*, given that *B* has occurred?" The probability in answer to this last question is a **conditional probability**, denoted $P(A \mid B)$ (read: "the probability of *A* given *B*").

Suppose we want to know the probability that *the stock earns a return above the risk-free rate* (event *A*), given that *the stock earns a positive return* (event *B*). With the words "given that," we are restricting returns to those larger than 0%—a new element in contrast to the question that brought forth an unconditional probability. The conditional probability is calculated as the ratio of two quantities. The numerator is the sum of the probabilities of stock returns above the risk-free rate; in this particular case, the numerator is the same as it was in the unconditional case, which we gave as 0.70. The denominator, however, changes from 1 to the sum of the probabilities for all outcomes (returns) above 0%. Suppose that number is 0.80, a larger number than 0.70 because returns between 0 and the risk-free rate have some positive probability of occurring. Then $P(A \mid B) = 0.70/0.80 = 0.875$. If we observe that the stock earns a positive return, the probability of a return above the risk-free rate is greater than the unconditional probability, which is the probability of the event given no other information. To review, an unconditional probability is the probability of an event without any restriction (i.e., a standalone probability). A conditional probability, in contrast, is a probability of an event given that another event has occurred.

To state an exact definition of conditional probability, we first need to introduce the concept of joint probability. Suppose we ask the question "What is the probability of both *A* and *B* happening?" The answer to this question is a **joint probability**, denoted $P(AB)$ (read: "the probability of *A* and *B*"). If we think of the probability of *A* and the probability of *B* as sets built of the outcomes of one or more random variables, the joint probability of *A* and *B* is the sum of the probabilities of the outcomes they have in common. For example, consider two events: *the stock earns a return above the risk-free rate* (*A*) and *the stock earns a positive return* (*B*). The outcomes of *A* are contained within (a subset of) the outcomes of *B*, so $P(AB)$ equals $P(A)$. We can now state a formal definition of conditional probability that provides a formula for calculating it.

- Definition of Conditional Probability. The conditional probability of *A* given that *B* has occurred is equal to the joint probability of *A* and *B* divided by the probability of *B* (assumed not to equal 0).

$$P(A \mid B) = P(AB)/P(B),\ P(B) \neq 0 \tag{1}$$

For example, suppose B happens half the time, $P(B) = 0.50$, and A and B both happen 10% of the time, $P(AB) = 0.10$. What is the probability that A happens, given that B happens? That is $P(A \mid B) = P(AB)/P(B) = 0.10 / 0.50 = 0.20$.

e demonstrate the application of the multiplication and addition rules for probability

Sometimes we know the conditional probability $P(A \mid B)$ and we want to know the joint probability $P(AB)$. We can obtain the joint probability from the following multiplication rule for probabilities, Equation 1 rearranged.

- **Multiplication Rule for Probability**. The joint probability of A and B can be expressed as

$$P(AB) = P(A \mid B)P(B) \tag{2}$$

With the same numbers above, if B happens 50% of the time, and the probability of A given that B happens is 20%, the joint probability of A and B happening is $P(AB) = P(A \mid B)P(B) = 0.20 \times 0.50 = 0.10$.

EXAMPLE 3

Conditional Probabilities and Predictability of Mutual Fund Performance (1)

An analyst conducts a study of the returns of 200 mutual funds over a two-year period. For each year, the total returns for the funds were ranked, and the top 50% of funds were labeled winners; the bottom 50% were labeled losers. Exhibit 3 shows the percentage of those funds that were winners in two consecutive years, winners in one year and then losers in the next year, losers then winners, and finally losers in both years. The winner–winner entry, for example, shows that 66% of the first-year winner funds were also winners in the second year. The four entries in the table can be viewed as conditional probabilities.

Exhibit 3 Persistence of Returns: Conditional Probability for Year 2 Performance Given Year 1 Performance

	Year 2 Winner	Year 2 Loser
Year 1 Winner	66%	34%
Year 1 Loser	34%	66%

Based on the data in Exhibit 3, answer the following questions:

1 State the four events needed to define the four conditional probabilities.

2 State the four entries of the table as conditional probabilities using the form $P(\textit{this event} \mid \textit{that event})$ = number.

3 Are the conditional probabilities in Question 2 empirical, a priori, or subjective probabilities?

4 Using information in the table, calculate the probability of the event a *fund is a loser in both Year 1 and Year 2.* (Note that because 50% of funds are categorized as losers in each year, the unconditional probability that a fund is labeled a loser in either year is 0.5.)

Solution to 1:

The four events needed to define the conditional probabilities are as follows:

Fund is a Year 1 winner

Fund is a Year 1 loser

Fund is a Year 2 loser

Fund is a Year 2 winner

Solution to 2:

From Row 1:

$P(\text{fund is a Year 2 winner} \mid \text{fund is a Year 1 winner}) = 0.66$

$P(\text{fund is a Year 2 loser} \mid \text{fund is a Year 1 winner}) = 0.34$

From Row 2:

$P(\text{fund is a Year 2 winner} \mid \text{fund is a Year 1 loser}) = 0.34$

$P(\text{fund is a Year 2 loser} \mid \text{fund is a Year 1 loser}) = 0.66$

Solution to 3:

These probabilities are calculated from data, so they are empirical probabilities.

Solution to 4:

The estimated probability is 0.33. Let A represent the event that a *fund is a Year 2 loser*, and let B represent the event that the *fund is a Year 1 loser*. Therefore, the event AB is the event that a *fund is a loser in both Year 1 and Year 2.* From Exhibit 3, $P(A \mid B) = 0.66$ and $P(B) = 0.50$. Thus, using Equation 2, we find that

$$P(AB) = P(A \mid B)P(B) = 0.66(0.50) = 0.33$$

or a probability of 0.33. Note that Equation 2 states that the joint probability of A and B equals the probability of A given B times the probability of B. Because $P(AB) = P(BA)$, the expression $P(AB) = P(BA) = P(B \mid A)P(A)$ is equivalent to Equation 2.

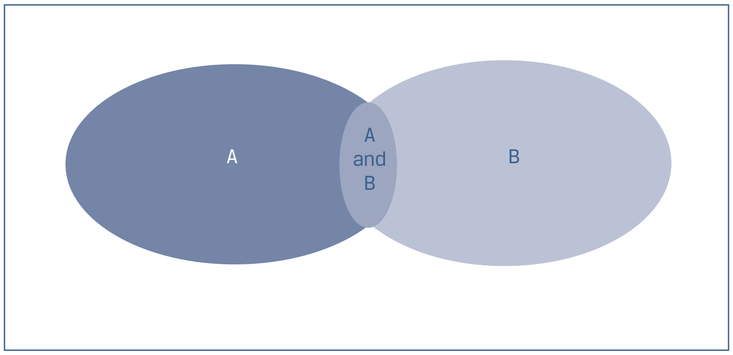
When we have two events, A and B, that we are interested in, we often want to know the probability that either A or B occurs. Here the word "or" is inclusive, meaning that either A or B occurs or that both A and B occur. Put another way, the probability of A or B is the probability that at least one of the two events occurs. Such probabilities are calculated using the **addition rule for probabilities**.

- **Addition Rule for Probabilities.** Given events A and B, the probability that A or B occurs, or both occur, is equal to the probability that A occurs, plus the probability that B occurs, minus the probability that both A and B occur.

$$P(A \text{ or } B) = P(A) + P(B) - P(AB) \quad (3)$$

If we think of the individual probabilities of A and B as sets built of outcomes of one or more random variables, the first step in calculating the probability of A or B is to sum the probabilities of the outcomes in A to obtain $P(A)$. If A and B share any outcomes, then if we now added $P(B)$ to $P(A)$, we would count twice the probabilities of those shared outcomes. So we add to $P(A)$ the quantity $[P(B) - P(AB)]$, which is the probability of outcomes in B net of the probability of any outcomes already counted when we computed $P(A)$. Exhibit 4 illustrates this process; we avoid double-counting the outcomes in the intersection of A and B by subtracting $P(AB)$. As an example of the calculation, if $P(A) = 0.50$, $P(B) = 0.40$, and $P(AB) = 0.20$, then $P(A \text{ or } B) = 0.50 + 0.40 - 0.20 = 0.70$. Only if the two events A and B were mutually exclusive, so that $P(AB) = 0$, would it be correct to state that $P(A \text{ or } B) = P(A) + P(B)$.

Exhibit 4 Addition Rule for Probabilities



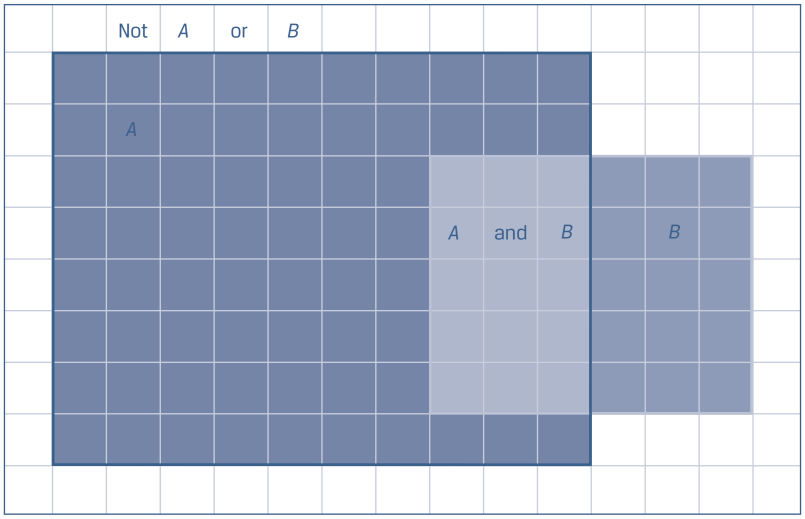
Example 4 illustrates the relation between empirical frequencies and unconditional, conditional, and joint probabilities as well as the multiplication and addition rules for probability.

EXAMPLE 4

Frequencies and Probability Concepts

Analysts often discuss the frequencies of events as well as their probabilities. In Exhibit 5, there are 150 cells, each representing one trading day. Outcome A, one of the 80 trading days when the stock market index increased, is represented by the dark-shaded rectangle with 80 cells. Outcome B, one the 30 trading days when interest rates decreased, is represented by the light -bordered rectangle with 30 cells. The overlap between these two rectangles, when both events A and B occurred—the stock market index increased, and interest rates decreased—happened 15 times and is represented by the intermediate-shaded rectangle.

Exhibit 5 Frequencies for Two Events



- The frequency of *A* (stock market index increased) is 80 and has an unconditional probability *P*(*A*) = 80/150 = 0.533.
- The frequency of *B* (interest rates decreased) is 30 and has an unconditional probability *P*(*B*) = 30/150 = 0.20.
- The frequency of *A* and *B* (stock market index increased, and interest rates decreased) is 15 and has a joint probability, *P*(*AB*) = 15/150 = 0.10.

The frequency of *A* or *B* (stock market index increased or interest rates decreased is 95, and *P*(*A* or *B*) is 95/150 = 0.633. Using the addition rule for probabilities, the probability of *A* or *B* is *P*(*A* or *B*) = *P*(*A*) + *P*(*B*) – *P*(*AB*) = 80/150 + 30/150 – 15/150 = 95/150 = 0.633. The probability of not *A* or *B* (stock market index did not increase or interest rates did not decrease) = 1 – 95/150 = 55/150 = 0.367.

The conditional probability of *A* given *B*, *P*(*A*|*B*), stock market index increased given that interest rates decreased, was 15/30 = 0.50, which is also *P*(*A*|*B*) = *P*(*AB*) / *P*(*B*) = (15/150) / (30/150) = 0.10 / 0.20 = 0.50

The next example shows how much useful information can be obtained using the probability rules presented to this point.

EXAMPLE 5

Probability of a Limit Order Executing

You have two buy limit orders outstanding on the same stock. A limit order to buy stock at a stated price is an order to buy at that price or lower. A number of vendors, including an internet service that you use, supply the estimated probability that a limit order will be filled within a stated time horizon, given the current stock price and the price limit. One buy order (Order 1) was placed at a price limit of \$10. The probability that it will execute within one hour is 0.35. The second buy order (Order 2) was placed at a price limit of \$9.75; it has a 0.25 probability of executing within the same one-hour time frame.

1 What is the probability that either Order 1 or Order 2 will execute?
2 What is the probability that Order 2 executes, given that Order 1 executes?

Solution to 1:

The probability is 0.35. The two probabilities that are given are $P(\textit{Order 1 executes}) = 0.35$ and $P(\textit{Order 2 executes}) = 0.25$. Note that if Order 2 executes, it is certain that Order 1 also executes because the price must pass through \$10 to reach \$9.75. Thus,

$$P(\textit{Order 1 executes} \mid \textit{Order 2 executes}) = 1$$

and using the multiplication rule for probabilities,

$$P(\textit{Order 1 executes} \text{ and } \textit{Order 2 executes}) = P(\textit{Order 1 executes} \mid \textit{Order 2 executes})P(\textit{Order 2 executes}) = 1(0.25) = 0.25$$

To answer the question, we use the addition rule for probabilities:

$$\begin{aligned}&P(\textit{Order 1 executes} \text{ or } \textit{Order 2 executes}) = P(\textit{Order 1 executes})\\&+ P(\textit{Order 2 executes}) - P(\textit{Order 1 executes} \text{ and } \textit{Order 2 executes})\\&= 0.35 + 0.25 - 0.25 = 0.35\end{aligned}$$

Note that the outcomes for which Order 2 executes are a subset of the outcomes for which Order 1 executes. After you count the probability that Order 1 executes, you have counted the probability of the outcomes for which Order 2 also executes. Therefore, the answer to the question is the probability that Order 1 executes, 0.35.

Solution to 2:

If the first order executes, the probability that the second order executes is 0.714. In the solution to Part 1, you found that $P(\textit{Order 1 executes} \text{ and } \textit{Order 2 executes}) = P(\textit{Order 1 executes} \mid \textit{Order 2 executes})P(\textit{Order 2 executes}) = 1(0.25) = 0.25$. An equivalent way to state this joint probability is useful here:

$$\begin{aligned}&P(\textit{Order 1 executes} \text{ and } \textit{Order 2 executes}) = 0.25\\&= P(\textit{Order 2 executes} \mid \textit{Order 1 executes})P(\textit{Order 1 executes})\end{aligned}$$

Because $P(\textit{Order 1 executes}) = 0.35$ was a given, you have one equation with one unknown:

$$0.25 = P(\textit{Order 2 executes} \mid \textit{Order 1 executes})(0.35)$$

You conclude that $P(\textit{Order 2 executes} \mid \textit{Order 1 executes}) = 0.25/0.35 = 0.714$. You can also use Equation 1 to obtain this answer.

f compare and contrast dependent and independent events

The concepts of independence and dependence are of great interest to investment analysts. These concepts bear on such basic investment questions as which financial variables are useful for investment analysis, whether asset returns can be predicted, and whether superior investment managers can be selected based on their past records.

Two events are independent if the occurrence of one event does not affect the probability of occurrence of the other event.

- Definition of Independent Events. Two events A and B are **independent** if and only if $P(A \mid B) = P(A)$ or, equivalently, $P(B \mid A) = P(B)$.

The logic of independence is clear: A and B are independent if the conditional probability of A given B, $P(A \mid B)$, is the same as the unconditional probability of A, $P(A)$. Independence means that knowing B tells you nothing about A.

For an example of independent events, suppose that event A is the bankruptcy of Company A, and event B is the bankruptcy of Company B. If the probability of bankruptcy of Company A is $P(A) = 0.20$, and the probability of bankruptcy of Company A given that Company B goes bankrupt is the same, $P(A \mid B) = 0.20$, then event A is independent of event B.

When two events are not independent, they are **dependent**: The probability of occurrence of one is related to the occurrence of the other. If we are trying to forecast one event, information about a dependent event may be useful, but information about an independent event will not be useful. For example, suppose an announcement is released that a biotech company will be acquired at an attractive price by another company. If the prices of pharmaceutical companies increase as a result of this news, the companies' stock prices are not independent of the biotech takeover announcement event. For a different example, if two events are mutually exclusive, then knowledge that one event has occurred gives us information that the other (mutually exclusive) event cannot occur.

When two events are independent, the multiplication rule for probabilities, Equation 2, simplifies because $P(A \mid B)$ in that equation then equals $P(A)$.

- **Multiplication Rule for Independent Events**. When two events are independent, the joint probability of A and B equals the product of the individual probabilities of A and B.

$$P(AB) = P(A)P(B) \tag{4}$$

Therefore, if we are interested in two independent events with probabilities of 0.75 and 0.50, respectively, the probability that both will occur is $0.375 = 0.75(0.50)$. The multiplication rule for independent events generalizes to more than two events; for example, if A, B, and C are independent events, then $P(ABC) = P(A)P(B)P(C)$.

EXAMPLE 6

BankCorp's Earnings per Share (1)

As part of your work as a banking industry analyst, you build models for forecasting earnings per share of the banks you cover. Today you are studying BankCorp. The historical record shows that in 55% of recent quarters, BankCorp's EPS has increased sequentially, and in 45% of quarters, EPS has decreased or remained unchanged sequentially. At this point in your analysis, you are assuming that changes in sequential EPS are independent.

Earnings per share for 2Q:Year 1 (that is, EPS for the second quarter of Year 1) were larger than EPS for 1Q:Year 1.

1 What is the probability that *3Q:Year 1 EPS will be larger than 2Q:Year 1 EPS* (a positive change in sequential EPS)?

2 What is the probability that EPS decreases or remains unchanged in the next two quarters?

Solution to 1:

Under the assumption of independence, the probability that *3Q:Year 1 EPS will be larger than 2Q:Year 1 EPS* is the unconditional probability of positive change, 0.55. The fact that 2Q:Year 1 EPS was larger than 1Q:Year 1 EPS is not useful information, because the next change in EPS is independent of the prior change.

Solution to 2:

Assuming independence, the probability is 0.2025 = 0.45(0.45).

The following example illustrates how difficult it is to satisfy a set of independent criteria even when each criterion by itself is not necessarily stringent.

EXAMPLE 7

Screening Stocks for Investment

You have developed a stock screen—a set of criteria for selecting stocks. Your investment universe (the set of securities from which you make your choices) is 905 large- and medium-cap US equities, specifically all stocks that are members of the S&P 500 and S&P 400 Indexes. Your criteria capture different aspects of the stock selection problem; you believe that the criteria are independent of each other, to a close approximation.

Criterion	Number of stocks meeting criterion	Fraction of stocks meeting criterion
First valuation criterion	556	0.614
Second valuation criterion	489	0.540
Analyst coverage criterion	600	0.663
Profitability criterion	490	0.541
Financial strength criterion	313	0.346

How many stocks do you expect to pass your screen?

Only 37 stocks out of 905 should pass through your screen. If you define five events—*the stock passes the first valuation criterion, the stock passes the second valuation criterion, the stock passes the analyst coverage criterion, the company passes the profitability criterion, the company passes the financial strength criterion* (say events A, B, C, D, and E, respectively)—then the probability that a stock will pass all five criteria, under independence, is

$$P(ABCDE) = P(A)P(B)P(C)P(D)P(E) = (0.614)(0.540)(0.663)(0.541)(0.346) = 0.0411$$

Although only one of the five criteria is even moderately strict (the strictest lets 34.6% of stocks through), the probability that a stock can pass all five criteria is only 0.0411, or about 4%. If the criteria are independent, the size of the list of candidate investments is expected to be 0.0411(905) = 37 stocks.

An area of intense interest to investment managers and their clients is whether records of past performance are useful in identifying repeat winners and losers. The following example shows how this issue relates to the concept of independence.

EXAMPLE 8

Conditional Probabilities and Predictability of Mutual Fund Performance (2)

The purpose of the mutual fund study introduced in Example 3 was to address the question of repeat mutual fund winners and losers. If the status of a fund as a winner or a loser in one year is independent of whether it is a winner in the next year, the practical value of performance ranking is questionable. Using the four events defined in Example 3 as building blocks, we can define the following events to address the issue of predictability of mutual fund performance:

Fund is a Year 1 winner and *fund is a Year 2 winner*

Fund is a Year 1 winner and *fund is a Year 2 loser*

Fund is a Year 1 loser and *fund is a Year 2 winner*

Fund is a Year 1 loser and *fund is a Year 2 loser*

In Part 4 of Example 3, you calculated that

P(*fund is a Year 2 loser* and *fund is a Year 1 loser*) = 0.33

If the ranking in one year is independent of the ranking in the next year, what will you expect P(*fund is a Year 2 loser* and *fund is a Year 1 loser*) to be? Interpret the empirical probability 0.33.

By the multiplication rule for independent events, P(*fund is a Year 2 loser* and *fund is a Year 1 loser*) = P(*fund is a Year 2 loser*)P(*fund is a Year 1 loser*). Because 50% of funds are categorized as losers in each year, the unconditional probability that a fund is labeled a loser in either year is 0.50. Thus P(*fund is a Year 2 loser*)P(*fund is a Year 1 loser*) = 0.50(0.50) = 0.25. If the status of a fund as a loser in one year is independent of whether it is a loser in the prior year, we conclude that P(*fund is a Year 2 loser* and *fund is a Year 1 loser*) = 0.25. This probability is a priori because it is obtained from reasoning about the problem. You could also reason that the four events described above define categories and that if funds are randomly assigned to the four categories, there is a 1/4 probability of *fund is a Year 1 loser* and *fund is a Year 2 loser.* If the classifications in Year 1 and Year 2 were dependent, then the assignment of funds to categories would not be random. The empirical probability of 0.33 is above 0.25. Is this apparent predictability the result of chance? Further analysis would be necessary to determine whether these results would allow you to reject the hypothesis that investment returns are independent between Year 1 and Year 2.

g calculate and interpret an unconditional probability using the total probability rule

In many practical problems, we logically analyze a problem as follows: We formulate scenarios that we think affect the likelihood of an event that interests us. We then estimate the probability of the event, given the scenario. When the scenarios (conditioning events) are mutually exclusive and exhaustive, no possible outcomes are left out. We can then analyze the event using the **total probability rule**. This rule explains the unconditional probability of the event in terms of probabilities conditional on the scenarios.

The total probability rule is stated below for two cases. Equation 5 gives the simplest case, in which we have two scenarios. One new notation is introduced: If we have an event or scenario S, the event not-S, called the **complement** of S, is written S^C. Note that $P(S) + P(S^C) = 1$, as either S or not-S must occur. Equation 6 states the rule for the general case of n mutually exclusive and exhaustive events or scenarios.

- **Total Probability Rule.**

$$\begin{aligned} P(A) &= P(AS) + P\left(AS^C\right) \\ &= P(A \mid S)P(S) + P\left(A \mid S^C\right)P\left(S^C\right) \end{aligned} \tag{5}$$

$$\begin{aligned} P(A) &= P(AS_1) + P(AS_2) + \ldots + P(AS_n) \\ &= P(A \mid S_1)P(S_1) + P(A \mid S_2)P(S_2) + \ldots + P(A \mid S_n)P(S_n) \end{aligned} \tag{6}$$

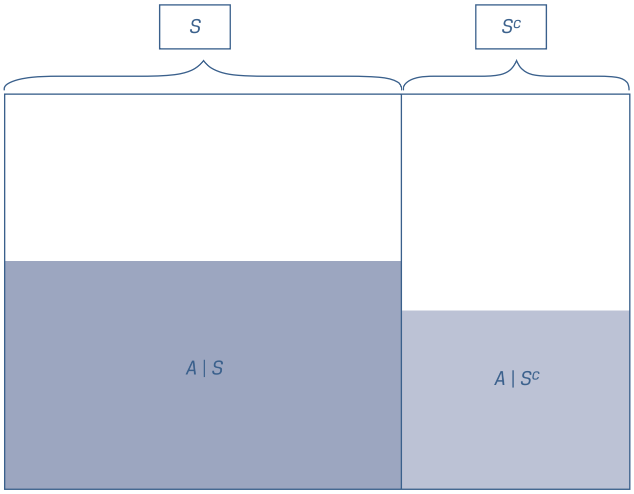
where S_1, S_2, …, S_n are mutually exclusive and exhaustive scenarios or events.

Equation 6 states the following: The probability of any event [$P(A)$] can be expressed as a weighted average of the probabilities of the event, given scenarios [terms such $P(A \mid S_1)$]; the weights applied to these conditional probabilities are the respective probabilities of the scenarios [terms such as $P(S_1)$ multiplying $P(A \mid S_1)$], and the scenarios must be mutually exclusive and exhaustive. Among other applications, this rule is needed to understand Bayes' formula, which we discuss later.

Exhibit 6 is a visual representation of the total probability rule. Panel A illustrates Equation 5 for the total probability rule when there are two scenarios (S and its complement S^C). For two scenarios, the probabilities of S and S^C sum to 1, and the probability of A is a weighted average where the probability of A in each scenario is weighted by the probability of each scenario. Panel B of Exhibit 6 illustrates Equation 6 for the total probability rule when there are n scenarios. The scenarios are mutually exclusive and exhaustive, and the sum of the probabilities for the scenarios is 1. Like the two-scenario case, the probability of A given the n-scenarios is a weighted average of the conditional probabilities of A in each scenario, using as weights the probability of each scenario.

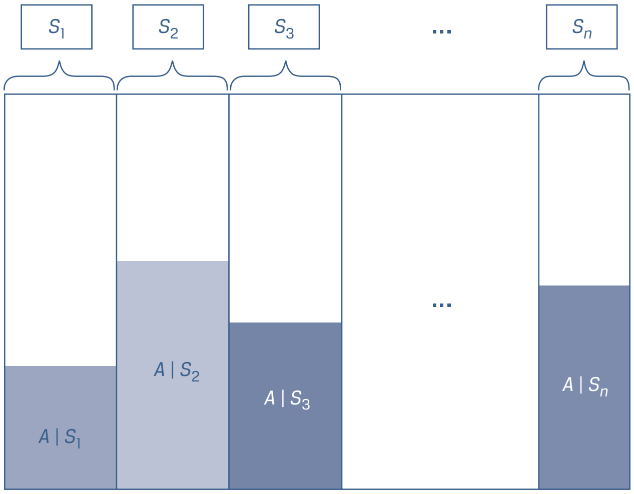
Exhibit 6 The Total Probability Rule for Two Scenarios and for *n* Scenarios

A. Total Probability Rule for Two Scenarios (S and S^C)



$P(S) + P(S^C) = 1\,;\ \ P(A) = P(AS) + P(AS^C) = P(A \mid S)\,P(S) + P(A \mid S^C)\,P(S^C)$

B. Total Probability Rule for n Scenarios



$S_1, S_2, \ldots S_n$, are mutually exclusive and exhaustive scenarios, such that

$$\sum_{i=1}^{n} P(S_i) = 1$$

$$\begin{aligned} P(A) &= P(AS_1) + P(AS_2) + \ldots + P(AS_n) \\ &= P(A \mid S_1)\,P(S_1) + P(A \mid S_2)\,P(S_2) + \ldots + P(A \mid S_n)\,P(S_n) \end{aligned}$$

In the next example, we use the total probability rule to develop a consistent set of views about BankCorp's earnings per share.

EXAMPLE 9

BankCorp's Earnings per Share (2)

You are continuing your investigation into whether you can predict the direction of changes in BankCorp's quarterly EPS. You define four events:

Event	Probability
A = *Change in sequential EPS is positive next quarter*	0.55
A^C = *Change in sequential EPS is 0 or negative next quarter*	0.45
S = *Change in sequential EPS is positive in the prior quarter*	0.55
S^C = *Change in sequential EPS is 0 or negative in the prior quarter*	0.45

On inspecting the data, you observe some persistence in EPS changes: Increases tend to be followed by increases, and decreases by decreases. The first probability estimate you develop is P(*change in sequential EPS is positive next quarter* | *change in sequential EPS is 0 or negative in the prior quarter*) = $P(A \mid S^C)$ = 0.40. The most recent quarter's EPS (2Q:Year 1) is announced, and the change is a positive sequential change (the event S). You are interested in forecasting EPS for 3Q:Year 1.

1 Write this statement in probability notation: "the probability that the change in sequential EPS is positive next quarter, given that the change in sequential EPS is positive the prior quarter."

2 Calculate the probability in Part 1. (Calculate the probability that is consistent with your other probabilities or beliefs.)

Solution to 1:

In probability notation, this statement is written $P(A \mid S)$.

Solution to 2:

The probability is 0.673 that the change in sequential EPS is positive for 3Q:Year 1, given the positive change in sequential EPS for 2Q:Year 1, as shown below.

According to Equation 5, $P(A) = P(A \mid S)P(S) + P(A \mid S^C)P(S^C)$. The values of the probabilities needed to calculate $P(A \mid S)$ are already known: $P(A) = 0.55$, $P(S) = 0.55$, $P(S^C) = 0.45$, and $P(A \mid S^C) = 0.40$. Substituting into Equation 5,

$$0.55 = P(A \mid S)(0.55) + 0.40(0.45)$$

Solving for the unknown, $P(A \mid S) = [0.55 - 0.40(0.45)]/0.55 = 0.672727$, or 0.673.

You conclude that P(*change in sequential EPS is positive next quarter* | *change in sequential EPS is positive the prior quarter*) = 0.673. Any other probability is not consistent with your other estimated probabilities. Reflecting the persistence in EPS changes, this conditional probability of a positive EPS change, 0.673, is greater than the unconditional probability of an EPS increase, 0.55.

3 EXPECTED VALUE (MEAN), VARIANCE, AND CONDITIONAL MEASURES OF EXPECTED VALUE AND VARIANCE

h calculate and interpret the expected value, variance, and standard deviation of random variables

The expected value of a random variable is an essential quantitative concept in investments. Investors continually make use of expected values—in estimating the rewards of alternative investments, in forecasting EPS and other corporate financial variables and ratios, and in assessing any other factor that may affect their financial position. The expected value of a random variable is defined as follows:

- Definition of Expected Value. The **expected value** of a random variable is the probability-weighted average of the possible outcomes of the random variable. For a random variable X, the expected value of X is denoted $E(X)$.

Expected value (for example, expected stock return) looks either to the future, as a forecast, or to the "true" value of the mean (the population mean). We should distinguish expected value from the concepts of historical or sample mean. The sample mean also summarizes in a single number a central value. However, the sample mean presents a central value for a particular set of observations as an equally weighted average of those observations. In sum, the contrast is forecast versus historical, or population versus sample.

EXAMPLE 10

BankCorp's Earnings per Share (3)

You continue with your analysis of BankCorp's EPS. In Exhibit 7, you have recorded a probability distribution for BankCorp's EPS for the current fiscal year.

Exhibit 7 Probability Distribution for BankCorp's EPS

Probability	EPS ($)
0.15	2.60
0.45	2.45
0.24	2.20
0.16	2.00
1.00	

What is the expected value of BankCorp's EPS for the current fiscal year?

Following the definition of expected value, list each outcome, weight it by its probability, and sum the terms.

$$E(\text{EPS}) = 0.15(\$2.60) + 0.45(\$2.45) + 0.24(\$2.20) + 0.16(\$2.00) = \$2.3405$$

The expected value of EPS is $2.34.

An equation that summarizes your calculation in Example 10 is

$$E(X) = P(X_1)X_1 + P(X_2)X_2 + \ldots + P(X_n)X_n = \sum_{i=1}^{n} P(X_i)X_i \quad (7)$$

where X_i is one of n possible outcomes of the random variable X.

The expected value is our forecast. Because we are discussing random quantities, we cannot count on an individual forecast being realized (although we hope that, on average, forecasts will be accurate). It is important, as a result, to measure the risk we face. Variance and standard deviation measure the dispersion of outcomes around the expected value or forecast.

- Definition of Variance. The **variance** of a random variable is the expected value (the probability-weighted average) of squared deviations from the random variable's expected value:

  $$\sigma^2(X) = E\left\{\left[X - E(X)\right]^2\right\} \tag{8}$$

  The two notations for variance are $\sigma^2(X)$ and $\mathrm{Var}(X)$.

Variance is a number greater than or equal to 0 because it is the sum of squared terms. If variance is 0, there is no dispersion or risk. The outcome is certain, and the quantity X is not random at all. Variance greater than 0 indicates dispersion of outcomes. Increasing variance indicates increasing dispersion, all else equal. Variance of X is a quantity in the squared units of X. For example, if the random variable is return in percent, variance of return is in units of percent squared. Standard deviation is easier to interpret than variance because it is in the same units as the random variable. If the random variable is return in percent, standard deviation of return is also in units of percent. In the following example, when the variance of returns is stated as a percent or amount of money, to conserve space, we may suppress showing the unit squared.

- Definition of Standard Deviation. **Standard deviation** is the positive square root of variance.

The best way to become familiar with these concepts is to work examples.

EXAMPLE 11

BankCorp's Earnings per Share (4)

In Example 10, you calculated the expected value of BankCorp's EPS as \$2.34, which is your forecast. Using the probability distribution of EPS from Exhibit 6, you want to measure the dispersion around your forecast. What are the variance and standard deviation of BankCorp's EPS for the current fiscal year?

The order of calculation is always expected value, then variance, then standard deviation. Expected value has already been calculated. Following the definition of variance above, calculate the deviation of each outcome from the mean or expected value, square each deviation, weight (multiply) each squared deviation by its probability of occurrence, and then sum these terms.

$$\begin{aligned}\sigma^2(\text{EPS}) &= P(\$2.60)\left[\$2.60 - E(\text{EPS})\right]^2 + P(\$2.45)\left[\$2.45 - E(\text{EPS})\right]^2\\ &\quad + P(\$2.20)\left[\$2.20 - E(\text{EPS})\right]^2 + P(\$2.00)\left[\$2.00 - E(\text{EPS})\right]^2\\ &= 0.15(2.60 - 2.34)^2 + 0.45(2.45 - 2.34)^2\\ &\quad + 0.24(2.20 - 2.34)^2 + 0.16(2.00 - 2.34)^2\\ &= 0.01014 + 0.005445 + 0.004704 + 0.018496 = 0.038785\end{aligned}$$

Standard deviation is the positive square root of 0.038785:

$$\sigma(\text{EPS}) = 0.038785^{1/2} = 0.196939, \text{ or approximately } 0.20.$$

An equation that summarizes your calculation of variance in Example 11 is

$$\sigma^2(X) = P(X_1)[X_1 - E(X)]^2 + P(X_2)[X_2 - E(X)]^2 + \ldots + P(X_n)[X_n - E(X)]^2 = \sum_{i=1}^{n} P(X_i)[X_i - E(X)]^2 \quad (9)$$

where X_i is one of n possible outcomes of the random variable X.

i. explain the use of conditional expectation in investment applications

In investments, we make use of any relevant information available in making our forecasts. When we refine our expectations or forecasts, we are typically making adjustments based on new information or events; in these cases, we are using **conditional expected values**. The expected value of a random variable X given an event or scenario S is denoted $E(X \mid S)$. Suppose the random variable X can take on any one of n distinct outcomes $X_1, X_2, \ldots, X_n$ (these outcomes form a set of mutually exclusive and exhaustive events). The expected value of X conditional on S is the first outcome, X_1, times the probability of the first outcome given S, $P(X_1 \mid S)$, plus the second outcome, X_2, times the probability of the second outcome given S, $P(X_2 \mid S)$, and so forth.

$$E(X \mid S) = P(X_1 \mid S)X_1 + P(X_2 \mid S)X_2 + \ldots + P(X_n \mid S)X_n \quad (10)$$

We will illustrate this equation shortly.

Parallel to the total probability rule for stating unconditional probabilities in terms of conditional probabilities, there is a principle for stating (unconditional) expected values in terms of conditional expected values. This principle is the **total probability rule for expected value**.

- **Total Probability Rule for Expected Value.**

$$E(X) = E(X \mid S)P(S) + E(X \mid S^C)P(S^C) \quad (11)$$

$$E(X) = E(X \mid S_1)P(S_1) + E(X \mid S_2)P(S_2) + \ldots + E(X \mid S_n)P(S_n) \quad (12)$$

where $S_1, S_2, \ldots, S_n$ are mutually exclusive and exhaustive scenarios or events.

The general case, Equation 12, states that the expected value of X equals the expected value of X given Scenario 1, $E(X \mid S_1)$, times the probability of Scenario 1, $P(S_1)$, plus the expected value of X given Scenario 2, $E(X \mid S_2)$, times the probability of Scenario 2, $P(S_2)$, and so forth.

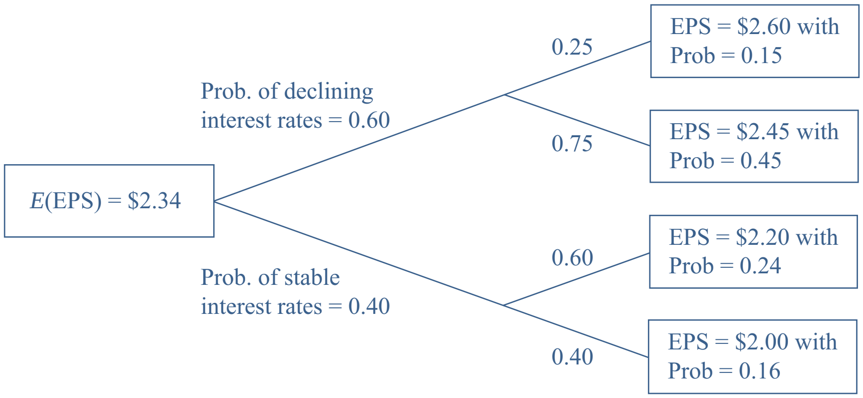
To use this principle, we formulate mutually exclusive and exhaustive scenarios that are useful for understanding the outcomes of the random variable. This approach was employed in developing the probability distribution of BankCorp's EPS in Examples 10 and 11, as we now discuss.

j interpret a probability tree and demonstrate its application to investment problems

The earnings of BankCorp are interest rate sensitive, benefiting from a declining interest rate environment. Suppose there is a 0.60 probability that BankCorp will operate in a *declining interest rate environment* in the current fiscal year and a 0.40 probability that it will operate in a *stable interest rate environment* (assessing the chance of an increasing interest rate environment as negligible). If a *declining interest rate environment* occurs, the probability that EPS will be \$2.60 is estimated at 0.25, and the probability that EPS will be \$2.45 is estimated at 0.75. Note that 0.60, the probability of *declining interest rate environment,* times 0.25, the probability of \$2.60 EPS given a *declining interest rate environment,* equals 0.15, the (unconditional) probability of

$2.60 given in the table in Exhibit 7. The probabilities are consistent. Also, 0.60(0.75) = 0.45, the probability of $2.45 EPS given in Exhibit 7. The **probability tree diagram** in Exhibit 8 shows the rest of the analysis.

Exhibit 8 BankCorp's Forecasted EPS



E(EPS) = $2.34
Prob. of declining interest rates = 0.60
Prob. of stable interest rates = 0.40
0.25
0.75
0.60
0.40
EPS = $2.60 with Prob = 0.15
EPS = $2.45 with Prob = 0.45
EPS = $2.20 with Prob = 0.24
EPS = $2.00 with Prob = 0.16

A declining interest rate environment points us to the **node** of the tree that branches off into outcomes of $2.60 and $2.45. We can find expected EPS given a declining interest rate environment as follows, using Equation 10:

$$\begin{aligned} E(\text{EPS} \mid \textit{declining interest rate environment}) &= 0.25(\$2.60) + 0.75(\$2.45) \\ &= \$2.4875 \end{aligned}$$

If interest rates are stable,

$$\begin{aligned} E(\text{EPS} \mid \textit{stable interest rate environment}) &= 0.60(\$2.20) + 0.40(\$2.00) \\ &= \$2.12 \end{aligned}$$

Once we have the new piece of information that interest rates are stable, for example, we revise our original expectation of EPS from $2.34 downward to $2.12. Now using the total probability rule for expected value,

$$\begin{aligned} &\text{E}(\text{EPS}) \\ &= \text{E}(\text{EPS} \mid \text{declining interest rate environment})\text{P}(\text{declining interest rateenvironment}) \\ &+ \text{E}(\text{EPS} \mid \text{stable interest rate environment})\text{P}(\text{stable interest rateenvironment}) \end{aligned}$$

So, E(EPS) = $2.4875(0.60) + $2.12(0.40) = $2.3405 or about $2.34.

This amount is identical to the estimate of the expected value of EPS calculated directly from the probability distribution in Example 10. Just as our probabilities must be consistent, so must our expected values, unconditional and conditional; otherwise our investment actions may create profit opportunities for other investors at our expense.

To review, we first developed the factors or scenarios that influence the outcome of the event of interest. After assigning probabilities to these scenarios, we formed expectations conditioned on the different scenarios. Then we worked backward to formulate an expected value as of today. In the problem just worked, EPS was the event of interest, and the interest rate environment was the factor influencing EPS.

We can also calculate the variance of EPS given each scenario:

$$\begin{aligned}&\sigma^2(\text{EPS} \mid \textit{declining interest rate environment})\\&\quad= P(\$2.60 \mid \textit{declining interest rate environment})\\&\quad\times\left[\$2.60 - E(\text{EPS} \mid \textit{declining interest rate environment})\right]^2\\&\quad+P(\$2.45 \mid \textit{declining interest rate environment})\\&\quad\times\left[\$2.45 - E(\text{EPS} \mid \textit{declining interest rate environment})\right]^2\\&\quad= 0.25(\$2.60 - \$2.4875)^2 + 0.75(\$2.45 - \$2.4875)^2\\&\quad= 0.004219\end{aligned}$$

Similarly, σ^2(EPS | *stable interest rate environment*) is found to be equal to

$$= 0.60(\$2.20 - \$2.12)^2 + 0.40(\$2.00 - \$2.12)^2 = 0.0096$$

These are **conditional variances**, the variance of EPS given a *declining interest rate environment* and the variance of EPS given a *stable interest rate environment*. The relationship between unconditional variance and conditional variance is a relatively advanced topic. The main points are 1) that variance, like expected value, has a conditional counterpart to the unconditional concept and 2) that we can use conditional variance to assess risk given a particular scenario.

EXAMPLE 12

BankCorp's Earnings per Share (5)

Continuing with BankCorp, you focus now on BankCorp's cost structure. One model, a simple linear regression model, you are researching for BankCorp's operating costs is

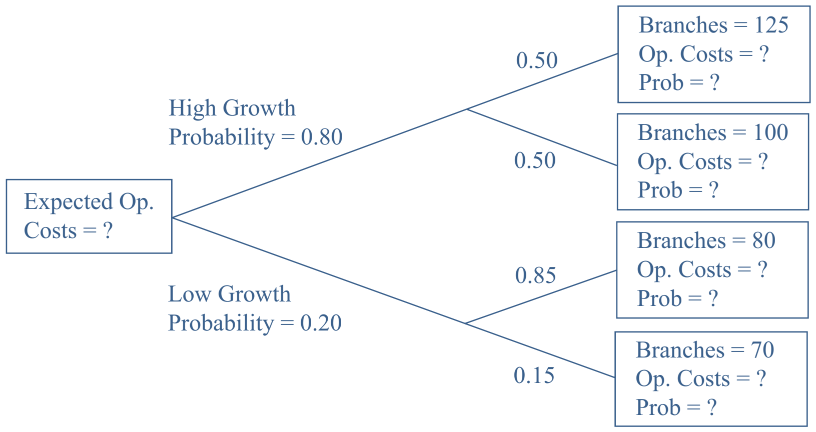
$$\hat{Y} = a + bX$$

where $\hat{Y}$ is a forecast of operating costs in millions of dollars and X is the number of branch offices. $\hat{Y}$ represents the expected value of Y given X, or $E(Y \mid X)$. You interpret the intercept a as fixed costs and b as variable costs. You estimate the equation as

$$\hat{Y} = 12.5 + 0.65X$$

BankCorp currently has 66 branch offices, and the equation estimates operating costs as 12.5 + 0.65(66) = \$55.4 million. You have two scenarios for growth, pictured in the tree diagram in Exhibit 9.

Exhibit 9 BankCorp's Forecasted Operating Costs



Expected Op. Costs = ?
High Growth Probability = 0.80
Low Growth Probability = 0.20
0.50
0.50
0.85
0.15
Branches = 125 Op. Costs = ? Prob = ?
Branches = 100 Op. Costs = ? Prob = ?
Branches = 80 Op. Costs = ? Prob = ?
Branches = 70 Op. Costs = ? Prob = ?

1. Compute the forecasted operating costs given the different levels of operating costs, using $\hat{Y} = 12.5 + 0.65X$. State the probability of each level of the number of branch offices. These are the answers to the questions in the terminal boxes of the tree diagram.
2. Compute the expected value of operating costs under the high growth scenario. Also calculate the expected value of operating costs under the low growth scenario.
3. Answer the question in the initial box of the tree: What are BankCorp's expected operating costs?

Solution to 1:

Using $\hat{Y} = 12.5 + 0.65X$, from top to bottom, we have

Operating Costs	Probability
$\hat{Y} = 12.5 + 0.65(125) = \$93.75$ million	$0.80(0.50) = 0.40$
$\hat{Y} = 12.5 + 0.65(100) = \$77.50$ million	$0.80(0.50) = 0.40$
$\hat{Y} = 12.5 + 0.65(80) = \$64.50$ million	$0.20(0.85) = 0.17$
$\hat{Y} = 12.5 + 0.65(70) = \$58.00$ million	$0.20(0.15) = 0.03$
	Sum = 1.00

Solution to 2:

Dollar amounts are in millions.

$$E(\text{operating costs} \mid \textit{high growth}) = 0.50(\$93.75) + 0.50(\$77.50)$$
$$= \$85.625$$

$$E(\text{operating costs} \mid \textit{low growth}) = 0.85(\$64.50) + 0.15(\$58.00)$$
$$= \$63.525$$

Solution to 3:

Dollar amounts are in millions.

$$\begin{aligned} E(\text{operating costs}) &= E(\text{operating costs} \mid \textit{high growth})P(\textit{high growth}) \\ &\quad + E(\text{operating costs} \mid \textit{low growth})P(\textit{low growth}) \\ &= \$85.625(0.80) + \$63.525(0.20) = \$81.205 \end{aligned}$$

BankCorp's expected operating costs are $81.205 million.

In this section, we have treated random variables such as EPS as standalone quantities. We have not explored how descriptors such as expected value and variance of EPS may be functions of other random variables. Portfolio return is one random variable that is clearly a function of other random variables, the random returns on the individual securities in the portfolio. To analyze a portfolio's expected return and variance of return, we must understand these quantities are a function of characteristics of the individual securities' returns. Looking at the variance of portfolio return, we see that the way individual security returns move together or covary is key. So, next we cover portfolio expected return, variance of return, and importantly, covariance and correlation.

EXPECTED VALUE, VARIANCE, STANDARD DEVIATION, COVARIANCES, AND CORRELATIONS OF PORTFOLIO RETURNS

4

k calculate and interpret the expected value, variance, standard deviation, covariances, and correlations of portfolio returns

Modern portfolio theory makes frequent use of the idea that investment opportunities can be evaluated using expected return as a measure of reward and variance of return as a measure of risk. In this section, we will develop an understanding of portfolio expected return and variance of return, which are functions of the returns on the individual portfolio holdings. To begin, the expected return on a portfolio is a weighted average of the expected returns on the securities in the portfolio, using exactly the same weights. When we have estimated the expected returns on the individual securities, we immediately have portfolio expected return.

- **Calculation of Portfolio Expected Return.** Given a portfolio with n securities, the **expected return on the portfolio** ($E(Rp)$) is a weighted average of the expected returns (R_1 to R_n) on the component securities using their respective weights (w_1 to w_n):

$$\begin{aligned} E(R_p) &= E(w_1R_1 + w_2R_2 + \ldots + w_nR_n) \\ &= w_1E(R_1) + w_2E(R_2) + \ldots + w_nE(R_n) \end{aligned} \quad (13)$$

Suppose we have estimated expected returns on assets in the three-asset portfolio shown in Exhibit 10.

Exhibit 10 Weights and Expected Returns

Asset Class	Weight	Expected Return (%)
S&P 500	0.50	13
US long-term corporate bonds	0.25	6
MSCI EAFE	0.25	15

We calculate the expected return on the portfolio as 11.75%:

$$\begin{aligned} E\left(R_p\right) &= w_1 E\left(R_1\right) + w_2 E\left(R_2\right) + w_3 E\left(R_3\right) \\ &= 0.50\left(13\%\right) + 0.25\left(6\%\right) + 0.25\left(15\%\right) = 11.75\% \end{aligned}$$

Here we are interested in portfolio variance of return as a measure of investment risk. Accordingly, portfolio variance is $\sigma^2(R_p) = E\{[R_p - E(R_p)]^2\}$, which is variance in a forward-looking sense. To implement this definition of portfolio variance, we use information about the individual assets in the portfolio, but we also need the concept of covariance. To avoid notational clutter, we write ER_p for $E(R_p)$.

- Definition of Covariance. Given two random variables R_i and R_j, the **covariance** between R_i and R_j is

$$\mathrm{Cov}\left(R_i, R_j\right) = E\left[\left(R_i - ER_i\right)\left(R_j - ER_j\right)\right] \tag{14}$$

Alternative notations are $\sigma(R_i,R_j)$ and σ_{ij}. Equation 14 states that the covariance between two random variables is the probability-weighted average of the cross-products of each random variable's deviation from its own expected value. The above measure is the population covariance and is forward-looking. The sample covariance between two random variables R_i and R_j, based on a sample of past data of size n is

$$\mathrm{Cov}\left(R_i, R_j\right) = \sum_{n=1}^{n}\left(R_{i,t} - \bar{R}_i\right)\left(R_{j,t} - \bar{R}_j\right)\Big/\left(n-1\right) \tag{15}$$

Start with the definition of variance for a three-asset portfolio and see how it decomposes into three variance terms and six covariance terms. Dispensing with the derivation, the result is Equation 16:

$$\begin{aligned} \sigma^2\left(R_p\right) &= E\left[\left(R_p - ER_p\right)^2\right] \\ &= E\left\{\left[w_1R_1 + w_2R_2 + w_3R_3 - E\left(w_1R_1 + w_2R_2 + w_3R_3\right)\right]^2\right\} \\ &= E\left\{\left[w_1R_1 + w_2R_2 + w_3R_3 - w_1ER_1 - w_2ER_2 - w_3ER_3\right]^2\right\} \\ &\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\left(\text{using Equation 13}\right) \end{aligned}$$

$$\begin{aligned} &= w_1^2\sigma^2\left(R_1\right) + w_1w_2\mathrm{Cov}\left(R_1,R_2\right) + w_1w_3\mathrm{Cov}\left(R_1,R_3\right) \\ &\quad + w_1w_2Cov\left(R_1,R_2\right) + w_2^2\sigma^2\left(R_2\right) + w_2w_3\mathrm{Cov}\left(R_2,R_3\right) \\ &\quad + w_1w_3Cov\left(R_1,R_3\right) + w_2w_3Cov\left(R_2,R_3\right) + w_3^2\sigma^2\left(R_3\right) \end{aligned} \tag{16}$$

Noting that the order of variables in covariance does not matter, for example, $\text{Cov}(R_2,R_1) = \text{Cov}(R_1,R_2)$, and that diagonal variance terms $\sigma^2(R_1)$, $\sigma^2(R_2)$, and $\sigma^2(R_3)$ can be expressed as $\text{Cov}(R_1,R_1)$, $\text{Cov}(R_2,R_2)$, and $\text{Cov}(R_3,R_3)$, respectively, the most compact way to state Equation 16 is $\sigma^2\left(R_p\right) = \sum_{i=1}^{3}\sum_{j=1}^{3} w_i w_j \text{Cov}\left(R_i, R_j\right)$. Moreover, this expression generalizes for a portfolio of any size n to

$$\sigma^2\left(R_p\right) = \sum_{i=1}^{n}\sum_{j=1}^{n} w_i w_j \text{Cov}\left(R_i, R_j\right) \tag{17}$$

We see from Equation 16 that individual variances of return constitute part, but not all, of portfolio variance. The three variances are actually outnumbered by the six covariance terms off the diagonal. If there are 20 assets, there are 20 variance terms and 20(20) − 20 = 380 off-diagonal covariance terms. A first observation is that as the number of holdings increases, covariance becomes increasingly important, all else equal.

The covariance terms capture how the co-movements of returns affect portfolio variance. From the definition of covariance, we can establish two essential observations about covariance.

1. We can interpret the sign of covariance as follows:

   Covariance of returns is negative if, when the return on one asset is above its expected value, the return on the other asset tends to be below its expected value (an average inverse relationship between returns).

   Covariance of returns is 0 if returns on the assets are unrelated.

   Covariance of returns is positive when the returns on both assets tend to be on the same side (above or below) their expected values at the same time (an average positive relationship between returns).

2. The covariance of a random variable with itself (*own covariance*) is its own variance: $\text{Cov}(R,R) = E\{[R - E(R)][R - E(R)]\} = E\{[R - E(R)]^2\} = \sigma^2(R)$.

Exhibit 11 summarizes the inputs for portfolio expected return and variance of return. A complete list of the covariances constitutes all the statistical data needed to compute portfolio variance of return as shown in the **covariance matrix** in Panel B.

Exhibit 11 Inputs to Portfolio Expected Return and Variance

A. Inputs to Portfolio Expected Return

Asset	A	B	C
	$E(R_A)$	$E(R_B)$	$E(R_C)$

B. Covariance Matrix: The Inputs to Portfolio Variance of Return

Asset	A	B	C
A	**$\text{Cov}(R_A,R_A)$**	$\text{Cov}(R_A,R_B)$	$\text{Cov}(R_A,R_C)$
B	$\text{Cov}(R_B,R_A)$	**$\text{Cov}(R_B,R_B)$**	$\text{Cov}(R_B,R_C)$
C	$\text{Cov}(R_C,R_A)$	$\text{Cov}(R_C,R_B)$	**$\text{Cov}(R_C,R_C)$**

With three assets, the covariance matrix has $3^2 = 3 \times 3 = 9$ entries, but the diagonal terms, the variances (bolded in Exhibit 11), are treated separately from the off-diagonal terms. So there are 9 − 3 = 6 covariances, excluding variances. But $\text{Cov}(R_B,R_A) =$

$\text{Cov}(R_A,R_B)$, $\text{Cov}(R_C,R_A) = \text{Cov}(R_A,R_C)$, and $\text{Cov}(R_C,R_B) = \text{Cov}(R_B,R_C)$. The covariance matrix below the diagonal is the mirror image of the covariance matrix above the diagonal, so you only need to use one (i.e., either below or above the diagonal). As a result, there are only 6/2 = 3 distinct covariance terms to estimate. In general, for n securities, there are $n(n - 1)/2$ distinct covariances and n variances to estimate.

Suppose we have the covariance matrix shown in Exhibit 12. We will be working in returns stated as percents, and the table entries are in units of percent squared ($\%^2$). The terms $38\%^2$ and $400\%^2$ are 0.0038 and 0.0400, respectively, stated as decimals; correctly working in percents and decimals leads to identical answers.

Exhibit 12 Covariance Matrix

	S&P 500	US Long-Term Corporate Bonds	MSCI EAFE
S&P 500	400	45	189
US long-term corporate bonds	45	81	38
MSCI EAFE	189	38	441

Taking Equation 16 and grouping variance terms together produces the following:

$$\begin{aligned}\sigma^2\left(R_p\right) &= w_1^2\sigma^2\left(R_1\right) + w_2^2\sigma^2\left(R_2\right) + w_3^2\sigma^2\left(R_3\right) + 2w_1w_2\text{Cov}\left(R_1,R_2\right)\\ &\quad + 2w_1w_3\text{Cov}\left(R_1,R_3\right) + 2w_2w_3\text{Cov}\left(R_2,R_3\right)\\ &= \left(0.50\right)^2\left(400\right) + \left(0.25\right)^2\left(81\right) + \left(0.25\right)^2\left(441\right)\\ &\quad + 2\left(0.50\right)\left(0.25\right)\left(45\right) + 2\left(0.50\right)\left(0.25\right)\left(189\right)\\ &\quad + 2\left(0.25\right)\left(0.25\right)\left(38\right)\\ &= 100 + 5.0625 + 27.5625 + 11.25 + 47.25 + 4.75 = 195.875\end{aligned} \tag{18}$$

The variance is 195.875. Standard deviation of return is $195.875^{1/2}$ = 14%. To summarize, the portfolio has an expected annual return of 11.75% and a standard deviation of return of 14%.

Looking at the first three terms in the calculation above, their sum (100 + 5.0625 + 27.5625) is 132.625, the contribution of the individual variances to portfolio variance. If the returns on the three assets were independent, covariances would be 0 and the standard deviation of portfolio return would be $132.625^{1/2}$ = 11.52% as compared to 14% before, so a less risky portfolio. If the covariance terms were negative, then a negative number would be added to 132.625, so portfolio variance and risk would be even smaller, while expected return would not change. For the same expected portfolio return, the portfolio has less risk. This risk reduction is a diversification benefit, meaning a risk-reduction benefit from holding a portfolio of assets. The diversification benefit increases with decreasing covariance. This observation is a key insight of modern portfolio theory. This insight is even more intuitively stated when we can use the concept of correlation.

- Definition of Correlation. The **correlation** between two random variables, R_i and R_j, is defined as $\rho(R_i,R_j) = \text{Cov}(R_i,R_j)/[\sigma(R_i)\sigma(R_j)]$. Alternative notations are $\text{Corr}(R_i,R_j)$ and ρ_{ij}.

The above definition of correlation is forward-looking because it involves dividing the forward-looking covariance by the product of forward-looking standard deviations. Frequently, covariance is substituted out using the relationship $\text{Cov}(R_i,R_j) = \rho(R_i,R_j)\sigma(R_i)\sigma(R_j)$. Like covariance, the correlation coefficient is a measure of linear association.

However, the division in the definition makes correlation a pure number (without a unit of measurement) and places bounds on its largest and smallest possible values, which are +1 and −1, respectively.

If two variables have a strong positive linear relation, then their correlation will be close to +1. If two variables have a strong negative linear relation, then their correlation will be close to −1. If two variables have a weak linear relation, then their correlation will be close to 0. Using the above definition, we can state a correlation matrix from data in the covariance matrix alone. Exhibit 13 shows the correlation matrix.

Exhibit 13 Correlation Matrix of Returns

	S&P 500	US Long-Term Corporate Bonds	MSCI EAFE
S&P 500	1.00	0.25	0.45
US long-term corporate bonds	0.25	1.00	0.20
MSCI EAFE	0.45	0.20	1.00

For example, the covariance between long-term bonds and MSCI EAFE is 38, from Exhibit 12. The standard deviation of long-term bond returns is $81^{1/2}$ = 9%, that of MSCI EAFE returns is $441^{1/2}$ = 21%, from diagonal terms in Exhibit 12. The correlation $\rho(R_{\text{long-term bonds}}, R_{\text{EAFE}})$ is 38/[(9%)(21%)] = 0.201, rounded to 0.20. The correlation of the S&P 500 with itself equals 1: The calculation is its own covariance divided by its standard deviation squared.

EXAMPLE 13

Portfolio Expected Return and Variance of Return with Varying Portfolio Weights

Anna Cintara is constructing different portfolios from the following two stocks:

Exhibit 14 Description of Two-Stock Portfolio

	Stock 1	Stock 2
Expected return	4%	8%
Standard deviation	6%	15%
Current portfolio weights	0.40	0.60
Correlation between returns	0.30	

1 Calculate the covariance between the returns on the two stocks.

2 What is the portfolio expected return and standard deviation if Cintara puts 100% of her investment in Stock 1 (w_1 = 1.00 and w_2 = 0.00)? What is the portfolio expected return and standard deviation if Cintara puts 100% of her investment in Stock 2 (w_1 = 0.00 and w_2 = 1.00)?

3 What are the portfolio expected return and standard deviation using the current portfolio weights?

4 Calculate the expected return and standard deviation of the portfolios when w_1 goes from 0.00 to 1.00 in 0.10 increments (and $w_2 = 1 - w_1$). Place the results (stock weights, portfolio expected return, and portfolio standard deviation) in a table, and then sketch a graph of the results with the standard deviation on the horizontal axis and expected return on the vertical axis.

Solution to 1:

The correlation between two stock returns is $\rho(R_i,R_j) = \text{Cov}(R_i,R_j)/[\sigma(R_i)\ \sigma(R_j)]$, so the covariance is $\text{Cov}(R_i,R_j) = \rho(R_i,R_j)\ \sigma(R_i)\ \sigma(R_j)$. For these two stocks, the covariance is $\text{Cov}(R_1,R_2) = \rho(R_1,R_2)\ \sigma(R_1)\ \sigma(R_2) = 0.30\ (6)\ (15) = 27$.

Solution to 2:

If the portfolio is 100% invested in Stock 1, the portfolio has an expected return of 4% and a standard deviation of 6%. If the portfolio is 100% invested in Stock 2, the portfolio has an expected return of 8% and a standard deviation of 15%.

Solution to 3:

For the current 40/60 portfolio, the expected return is

$$E(R_p) = w_1 E(R_1) + (1 - w_1)E(R_2) = 0.40(4\%) + 0.60(8\%) = 6.4\%$$

The portfolio variance and standard deviation are

$$\begin{aligned}\sigma^2(R_p) &= w_1^2\sigma^2(R_1) + w_2^2\sigma^2(R_2) + 2w_1w_2\text{Cov}(R_1,R_2)\\ &= (0.40)^2(36) + (0.60)^2(225) + 2(0.40)(0.60)(27)\\ &= 5.76 + 81 + 12.94 = 99.72\end{aligned}$$

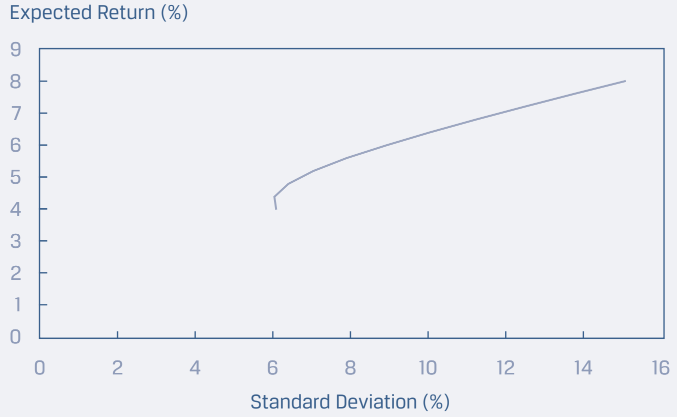
$$\sigma(R_p) = 99.72^{1/2} = 9.99\%$$

Solution to 4:

The portfolio expected returns, variances, and standard deviations for the different sets of portfolio weights are given in the following table. Three of the rows are already computed in the Solutions to 2 and 3, and the other rows are computed using the same expected return, variance, and standard deviation formulas as in the Solution to 3:

Stock 1 weight	Stock 2 weight	Expected return (%)	Variance (%^{2})	Standard deviation (%)
1.00	0.00	4.00	36.00	6.00
0.90	0.10	4.40	36.27	6.02
0.80	0.20	4.80	40.68	6.38
0.70	0.30	5.20	49.23	7.02
0.60	0.40	5.60	61.92	7.87
0.50	0.50	6.00	78.75	8.87
0.40	0.60	6.40	99.72	9.99
0.30	0.70	6.80	124.83	11.17
0.20	0.80	7.20	154.08	12.41
0.10	0.90	7.60	187.47	13.69
0.00	1.00	8.00	225.00	15.00

The graph of the expected return and standard deviation is



COVARIANCE GIVEN A JOINT PROBABILITY FUNCTION

5

l. calculate and interpret the covariances of portfolio returns using the joint probability function

How do we estimate return covariance and correlation? Frequently, we make forecasts on the basis of historical covariance or use other methods such as a market model regression based on historical return data. We can also calculate covariance using the **joint probability function** of the random variables, if that can be estimated. The joint probability function of two random variables X and Y, denoted $P(X,Y)$, gives the probability of joint occurrences of values of X and Y. For example, $P(X=3, Y=2)$, is the probability that X equals 3 and Y equals 2.

Suppose that the joint probability function of the returns on BankCorp stock (R_A) and the returns on NewBank stock (R_B) has the simple structure given in Exhibit 15.

Exhibit 15 Joint Probability Function of BankCorp and NewBank Returns (Entries Are Joint Probabilities)

	R_B = 20%	R_B = 16%	R_B = 10%
R_A = 25%	0.20	0	0
R_A = 12%	0	0.50	0
R_A = 10%	0	0	0.30

The expected return on BankCorp stock is 0.20(25%) + 0.50(12%) + 0.30(10%) = 14%. The expected return on NewBank stock is 0.20(20%) + 0.50(16%) + 0.30(10%) = 15%. The joint probability function above might reflect an analysis based on whether banking industry conditions are good, average, or poor. Exhibit 16 presents the calculation of covariance.

Exhibit 16 Covariance Calculations

Banking Industry Condition	Deviations BankCorp	Deviations NewBank	Product of Deviations	Probability of Condition	Probability-Weighted Product
Good	25–14	20–15	55	0.20	11
Average	12–14	16–15	−2	0.50	−1
Poor	10–14	10–15	20	0.30	6
					$\text{Cov}(R_A,R_B) = 16$

Note: Expected return for BankCorp is 14% and for NewBank, 15%.

The first and second columns of numbers show, respectively, the deviations of BankCorp and NewBank returns from their mean or expected value. The next column shows the product of the deviations. For example, for good industry conditions, (25 − 14)(20 − 15) = 11(5) = 55. Then, 55 is multiplied or weighted by 0.20, the probability that banking industry conditions are good: 55(0.20) = 11. The calculations for average and poor banking conditions follow the same pattern. Summing up these probability-weighted products, we find $\text{Cov}(R_A,R_B) = 16$.

A formula for computing the covariance between random variables R_A and R_B is

$$\text{Cov}\left(R_A,R_B\right) = \sum_i \sum_j P\left(R_{A,i},R_{B,j}\right)\left(R_{A,i} - ER_A\right)\left(R_{B,j} - ER_B\right) \tag{19}$$

The formula tells us to sum all possible deviation cross-products weighted by the appropriate joint probability.

Next, we take note of the fact that when two random variables are independent, their joint probability function simplifies.

- Definition of Independence for Random Variables. Two random variables X and Y are **independent** if and only if $P(X,Y) = P(X)P(Y)$.

For example, given independence, $P(3,2) = P(3)P(2)$. We multiply the individual probabilities to get the joint probabilities. *Independence* is a stronger property than *uncorrelatedness* because correlation addresses only linear relationships. The following condition holds for independent random variables and, therefore, also holds for uncorrelated random variables.

- **Multiplication Rule for Expected Value of the Product of Uncorrelated Random Variables**. The expected value of the product of uncorrelated random variables is the product of their expected values.

  $E(XY) = E(X)E(Y)$ if X and Y are uncorrelated.

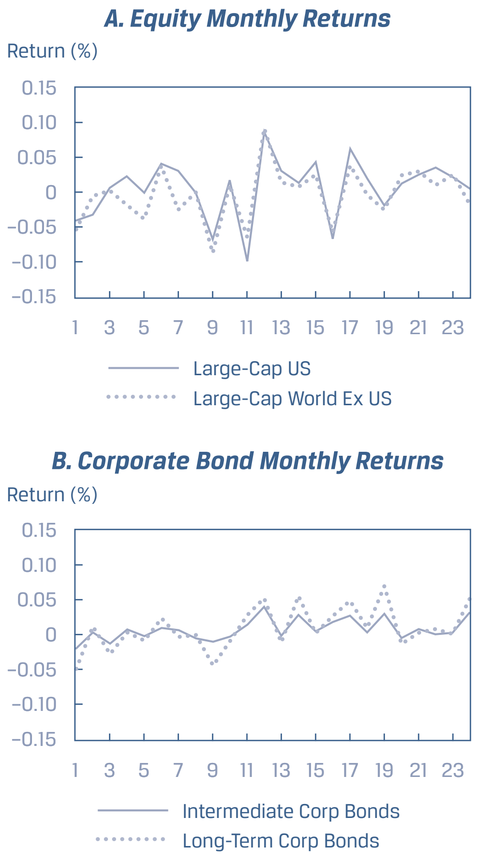
Many financial variables, such as revenue (price times quantity), are the product of random quantities. When applicable, the above rule simplifies calculating expected value of a product of random variables.

EXAMPLE 14

Covariances and Correlations of Security Returns

Isabel Vasquez is reviewing the correlations between four of the asset classes in her company portfolio. In Exhibit 17, she plots 24 recent monthly returns for large-cap US stocks versus for large-cap world ex-US stocks (Panel 1) and the 24 monthly returns for intermediate-term corporate bonds versus long-term corporate bonds (Panel 2). Vasquez presents the returns, variances, and covariances in decimal form instead of percentage form. Note the different ranges of their vertical axes (Return %).

Exhibit 17 Monthly Returns for Four Asset Classes



Selected data for the four asset classes are shown in Exhibit 18.

Exhibit 18 Selected Data for Four Asset Classes

Asset Classes	Large-Cap US Equities	World (ex US) Equities	Intermediate Corp Bonds	Long-Term Corp Bonds
Variance	0.001736	0.001488	0.000174	0.000699
Standard deviation	0.041668	0.038571	0.013180	0.026433
Covariance	0.001349		0.000318	
Correlation	0.87553		0.95133	

Vasquez noted, as shown in Exhibit 18, that although the two equity classes had much greater variances and covariance than the two bond classes, the correlation between the two equity classes was lower than the correlation between the two bond classes. She also noted that although long-term bonds were more volatile (higher variance) than intermediate-term bonds, long- and intermediate-term bond returns still had a high correlation.

6 BAYES' FORMULA

m calculate and interpret an updated probability using Bayes' formula

A topic that is often useful in solving investment problems is Bayes' formula: what probability theory has to say about learning from experience.

6.1 Bayes' Formula

When we make decisions involving investments, we often start with viewpoints based on our experience and knowledge. These viewpoints may be changed or confirmed by new knowledge and observations. **Bayes' formula** is a rational method for adjusting our viewpoints as we confront new information. Bayes' formula and related concepts have been applied in many business and investment decision-making contexts.

Bayes' formula makes use of Equation 6, the total probability rule. To review, that rule expressed the probability of an event as a weighted average of the probabilities of the event, given a set of scenarios. Bayes' formula works in reverse; more precisely, it reverses the "given that" information. Bayes' formula uses the occurrence of the event to infer the probability of the scenario generating it. For that reason, Bayes' formula is sometimes called an inverse probability. In many applications, including those illustrating its use in this section, an individual is updating his/her beliefs concerning the causes that may have produced a new observation.

- **Bayes' Formula.** Given a set of prior probabilities for an event of interest, if you receive new information, the rule for updating your probability of the event is

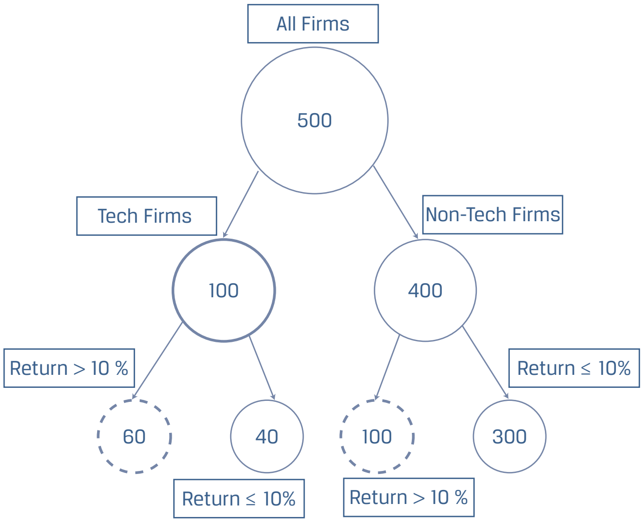
  $$\text{Updated probability of event given the new information} = \frac{\text{Probability of the new information given event}}{\text{Unconditional probability of the new information}} \times \text{Prior probability of event}$$

  In probability notation, this formula can be written concisely as

  $$P(\text{Event} \mid \text{Information}) = \frac{P(\text{Information} \mid \text{Event})}{P(\text{Information})} P(\text{Event}) \tag{20}$$

Consider the following example using frequencies—which may be more straightforward initially than probabilities—for illustrating and understanding Bayes' formula. Assume a hypothetical large-cap stock index has 500 member firms, of which 100 are technology firms, and 60 of these had returns of > 10%, and 40 had returns of ≤ 10%. Of the 400 non-technology firms in the index, 100 had returns of > 10%, and 300 had returns of ≤ 10%. The tree map in Exhibit 19 is useful for visualizing this example, which is summarized in the table in Exhibit 20.

Exhibit 19 Tree Map for Visualizing Bayes' Formula Using Frequencies



P (*Tech* | *R* > 10%) = 60/(60+100)

Exhibit 20 Summary of Returns for Tech and Non-Tech Firms in Hypothetical Large-Cap Equity Index

	Type of Firm in Stock Index		
Rate of Return (R)	**Non-Tech**	**Tech**	**Total**
R > 10%	100	60	**160**
R ≤ 10%	300	40	**340**
Total	**400**	**100**	**500**

What is the probability a firm is a tech firm given that it has a return of > 10% or *P*(*tech* | *R > 10%)?* Looking at the frequencies in the tree map and in the table, we can see many empirical probabilities, such as the following:

- *P(tech)* = 100 / 500 = 0.20,
- *P*(*non-tech*) = 400 / 500 = 0.80,
- *P(R > 10%* | *tech)* = 60 / 100 = 0.60,
- *P*(*R > 10%* | *non-tech*) = 100 / 400 = 0.25,
- *P(R > 10%)* = 160 / 500 = 0.32, and, finally,
- *P*(*tech* | *R > 10%*) = 60/ 160 = 0.375. This probability is the answer to our initial question.

Without looking at frequencies, let us use Bayes' formula to find the probability that a firm has a return of > 10% and then the probability that a firm with a return of > 10% is a tech firm, *P*(*tech* | *R > 10%*). First,

$$P(R > 10\%) = P(R > 10\% \mid tech) \times P(tech) + P(R > 10\% \mid non\text{-}tech) \times P(non\text{-}tech)$$

$$= 0.60 \times 0.20 + 0.25 \times 0.80 = 0.32.$$

Now we can implement the Bayes' formula answer to our question:

$$P(tech \mid R > 10\%) = \frac{P(R > 10\% \mid tech) \times P(tech)}{P(R > 10\%)} = \frac{0.60 \times 0.20}{0.32} = 0.375$$

The probability that a firm with a return of > 10% is a tech firm is 0.375, which is impressive because the probability that a firm is a tech firm (from the whole sample) is only 0.20. In sum, it can be readily seen from the tree map and the underlying frequency data (Exhibits 19 and 20, respectively) or from the probabilities in Bayes' formula that there are 160 firms with R > 10%, and 60 of them are tech firms, so $P(tech \mid R > 10\%) = 60/160 = .375$.

Users of Bayesian statistics do not consider probabilities (or likelihoods) to be known with certainty but that these should be subject to modification whenever new information becomes available. Our beliefs or probabilities are continually updated as new information arrives over time.

To further illustrate Bayes' formula, we work through an investment example that can be adapted to any actual problem. Suppose you are an investor in the stock of DriveMed, Inc. Positive earnings surprises relative to consensus EPS estimates often result in positive stock returns, and negative surprises often have the opposite effect. DriveMed is preparing to release last quarter's EPS result, and you are interested in which of these three events happened: *last quarter's EPS exceeded the consensus EPS estimate, last quarter's EPS exactly met the consensus EPS estimate,* or *last quarter's EPS fell short of the consensus EPS estimate.* This list of the alternatives is mutually exclusive and exhaustive.

On the basis of your own research, you write down the following **prior probabilities** (or priors, for short) concerning these three events:

- $P(EPS\ exceeded\ consensus) = 0.45$
- $P(EPS\ met\ consensus) = 0.30$
- $P(EPS\ fell\ short\ of\ consensus) = 0.25$

These probabilities are "prior" in the sense that they reflect only what you know now, before the arrival of any new information.

The next day, DriveMed announces that it is expanding factory capacity in Singapore and Ireland to meet increased sales demand. You assess this new information. The decision to expand capacity relates not only to current demand but probably also to the prior quarter's sales demand. You know that sales demand is positively related to EPS. So now it appears more likely that last quarter's EPS will exceed the consensus.

The question you have is, "In light of the new information, what is the updated probability that the prior quarter's EPS exceeded the consensus estimate?"

Bayes' formula provides a rational method for accomplishing this updating. We can abbreviate the new information as *DriveMed expands.* The first step in applying Bayes' formula is to calculate the probability of the new information (here: *DriveMed expands*), given a list of events or scenarios that may have generated it. The list of events should cover all possibilities, as it does here. Formulating these conditional probabilities is the key step in the updating process. Suppose your view, based on research of DriveMed and its industry, is

$$P(DriveMed\ expands \mid EPS\ exceeded\ consensus) = 0.75$$

$$P(DriveMed\ expands \mid EPS\ met\ consensus) = 0.20$$

$$P(DriveMed\ expands \mid EPS\ fell\ short\ of\ consensus) = 0.05$$

Conditional probabilities of an observation (here: *DriveMed expands*) are sometimes referred to as **likelihoods**. Again, likelihoods are required for updating the probability.

Next, you combine these conditional probabilities or likelihoods with your prior probabilities to get the unconditional probability for DriveMed expanding, $P(DriveMed\ expands)$, as follows:

$$
\begin{aligned}
&P(DriveMed\ expands)\\
&= P(DriveMed\ expands \mid EPS\ exceeded\ consensus)\\
&\quad \times P(EPS\ exceeded\ consensus)\\
&+ P(DriveMed\ expands \mid EPS\ met\ consensus)\\
&\quad \times P(EPS\ met\ consensus)\\
&+ P(DriveMed\ expands \mid EPS\ fell\ short\ of\ consensus)\\
&\quad \times P(EPS\ fell\ short\ of\ consensus)\\
&= 0.75(0.45) + 0.20(0.30) + 0.05(0.25) = 0.41, \text{ or } 41\%
\end{aligned}
$$

This is Equation 6, the total probability rule, in action. Now you can answer your question by applying Bayes' formula:

$$
\begin{aligned}
&P(EPS\ exceeded\ consensus \mid DriveMed\ expands)\\
&= \frac{P(DriveMed\ expands \mid EPS\ exceeded\ consensus)}{P(DriveMed\ expands)} P(EPS\ exceeded\ consensus)\\
&= (0.75/0.41)(0.45) = 1.829268(0.45) = 0.823171
\end{aligned}
$$

Prior to DriveMed's announcement, you thought the probability that DriveMed would beat consensus expectations was 45%. On the basis of your interpretation of the announcement, you update that probability to 82.3%. This updated probability is called your **posterior probability** because it reflects or comes after the new information.

The Bayes' calculation takes the prior probability, which was 45%, and multiplies it by a ratio—the first term on the right-hand side of the equal sign. The denominator of the ratio is the probability that DriveMed expands, as you view it without considering (conditioning on) anything else. Therefore, this probability is unconditional. The numerator is the probability that DriveMed expands, if last quarter's EPS actually exceeded the consensus estimate. This last probability is larger than unconditional probability in the denominator, so the ratio (1.83 roughly) is greater than 1. As a result, your updated or posterior probability is larger than your prior probability. Thus, the ratio reflects the impact of the new information on your prior beliefs.

EXAMPLE 15

Inferring Whether DriveMed's EPS Met Consensus EPS

You are still an investor in DriveMed stock. To review the givens, your prior probabilities are $P(EPS\ exceeded\ consensus) = 0.45$, $P(EPS\ met\ consensus) = 0.30$, and $P(EPS\ fell\ short\ of\ consensus) = 0.25$. You also have the following conditional probabilities:

$$P(DriveMed\ expands \mid EPS\ exceeded\ consensus) = 0.75$$

$$P(DriveMed\ expands \mid EPS\ met\ consensus) = 0.20$$

$$P(DriveMed\ expands \mid EPS\ fell\ short\ of\ consensus) = 0.05$$

Recall that you updated your probability that last quarter's EPS exceeded the consensus estimate from 45% to 82.3% after DriveMed announced it would expand. Now you want to update your other priors.

1 Update your prior probability that DriveMed's EPS met consensus.

2 Update your prior probability that DriveMed's EPS fell short of consensus.

3 Show that the three updated probabilities sum to 1. (Carry each probability to four decimal places.)

4 Suppose, because of lack of prior beliefs about whether DriveMed would meet consensus, you updated on the basis of prior probabilities that all three possibilities were equally likely: $P(EPS\ exceeded\ consensus) = P(EPS\ met\ consensus) = P(EPS\ fell\ short\ of\ consensus) = 1/3$.

What is your estimate of the probability $P(EPS\ exceeded\ consensus \mid DriveMed\ expands)$?

Solution to 1:

The probability is $P(EPS\ met\ consensus \mid DriveMed\ expands) =$

$$\frac{P(DriveMed\ expands \mid EPS\ met\ consensus)}{P(DriveMed\ expands)}P(EPS\ met\ consensus)$$

The probability $P(DriveMed\ expands)$ is found by taking each of the three conditional probabilities in the statement of the problem, such as $P(DriveMed\ expands \mid EPS\ exceeded\ consensus)$; multiplying each one by the prior probability of the conditioning event, such as $P(EPS\ exceeded\ consensus)$; then adding the three products. The calculation is unchanged from the problem in the text above: $P(DriveMed\ expands) = 0.75(0.45) + 0.20(0.30) + 0.05(0.25) = 0.41$, or 41%. The other probabilities needed, $P(DriveMed\ expands \mid EPS\ met\ consensus) = 0.20$ and $P(EPS\ met\ consensus) = 0.30$, are givens. So

$$P(EPS\ met\ consensus \mid DriveMed\ expands)$$

$$= [P(DriveMed\ expands \mid EPS\ met\ consensus)/P(DriveMed\ expands)]P(EPS\ met\ consensus)$$

$$= (0.20/0.41)(0.30) = 0.487805(0.30) = 0.146341$$

After taking account of the announcement on expansion, your updated probability that last quarter's EPS for DriveMed just met consensus is 14.6% compared with your prior probability of 30%.

Solution to 2:

$P(DriveMed\ expands)$ was already calculated as 41%. Recall that $P(DriveMed\ expands \mid EPS\ fell\ short\ of\ consensus) = 0.05$ and $P(EPS\ fell\ short\ of\ consensus) = 0.25$ are givens.

$$P(EPS\ fell\ short\ of\ consensus \mid DriveMed\ expands)$$

$$= \left[P(DriveMed\ expands \mid EPS\ fell\ short\ of\ consensus)\ /\ P(DriveMed\ expands)\right]P(EPS\ fell\ short\ of\ consensus)$$

$$= (0.05\ /\ 0.41)(0.25) = 0.121951(0.25) = 0.030488$$

As a result of the announcement, you have revised your probability that DriveMed's EPS fell short of consensus from 25% (your prior probability) to 3%.

Solution to 3:

The sum of the three updated probabilities is

$$P(EPS\ exceeded\ consensus \mid DriveMed\ expands) + P(EPS\ met\ consensus \mid DriveMed\ expands) + P(EPS\ fell\ short\ of\ consensus \mid DriveMed\ expands)$$

$$= 0.8232 + 0.1463 + 0.0305 = 1.0000$$

The three events (*EPS exceeded consensus*, *EPS met consensus*, *EPS fell short of consensus*) are mutually exclusive and exhaustive: One of these events or statements must be true, so the conditional probabilities must sum to 1. Whether we are talking about conditional or unconditional probabilities, whenever we have a complete set of distinct possible events or outcomes, the probabilities must sum to 1. This calculation serves to check your work.

Solution to 4:

Using the probabilities given in the question,

$$\begin{aligned} &P(DriveMed\ expands) \\ &= P(DriveMed\ expands \mid EPS\ exceeded\ consensus) \\ &\quad P(EPS\ exceeded\ consensus) + P(DriveMed\ expands \mid \\ &\quad EPS\ met\ consensus)P(EPS\ met\ consensus) + P(DriveMed\ expands \mid \\ &\quad EPS\ fell\ short\ of\ consensus)P(EPS\ fell\ short\ of\ consensus) \\ &= 0.75(1/3) + 0.20(1/3) + 0.05(1/3) = 1/3 \end{aligned}$$

Not surprisingly, the probability of DriveMed expanding is 1/3 because the decision maker has no prior beliefs or views regarding how well EPS performed relative to the consensus estimate.

Now we can use Bayes' formula to find $P(EPS\ exceeded\ consensus \mid DriveMed\ expands) = [P(DriveMed\ expands \mid EPS\ exceeded\ consensus)/P(DriveMed\ expands)]\ P(EPS\ exceeded\ consensus) = [(0.75/(1/3)](1/3) = 0.75$ or 75%. This probability is identical to your estimate of $P(DriveMed\ expands \mid EPS\ exceeded\ consensus)$.

When the prior probabilities are equal, the probability of information given an event equals the probability of the event given the information. When a decision maker has equal prior probabilities (called **diffuse priors**), the probability of an event is determined by the information.

Example 16 shows how Bayes' formula is used in credit granting where the probability of payment given credit information is higher than the probability of payment without the information.

EXAMPLE 16

Bayes' Formula and the Probability of Payment

Jake Bronson is predicting the probability that consumer finance applicants granted credit will repay in a timely manner (i.e., their accounts will not become "past due"). Using Bayes' formula, he has structured the problem as

$$P(\text{Event} \mid \text{Information}) = \frac{P(\text{Information} \mid \text{Event})}{P(\text{Information})} P(\text{Event})$$

where the event (A) is "timely repayment" and the information (B) is having a "good credit report."

Bronson estimates that the unconditional probability of receiving timely payment, $P(A)$, is 0.90 and that the unconditional probability of having a good credit report, $P(B)$, is 0.80. The probability of having a good credit report given that borrowers paid on time, $P(B \mid A)$, is 0.85.

What is the probability that applicants with good credit reports will repay in a timely manner?

A 0.720

B 0.944

C 0.956

Solution:

The correct answer is C. The probability of timely repayment given a good credit report, $P(A \mid B)$, is

$$P(A \mid B) = \frac{P(B \mid A)}{P(B)}P(A) = \frac{0.85}{0.80} \times 0.90 = 0.956$$

7 PRINCIPLES OF COUNTING

- **identify the most appropriate method to solve a particular counting problem and analyze counting problems using factorial, combination, and permutation concepts**

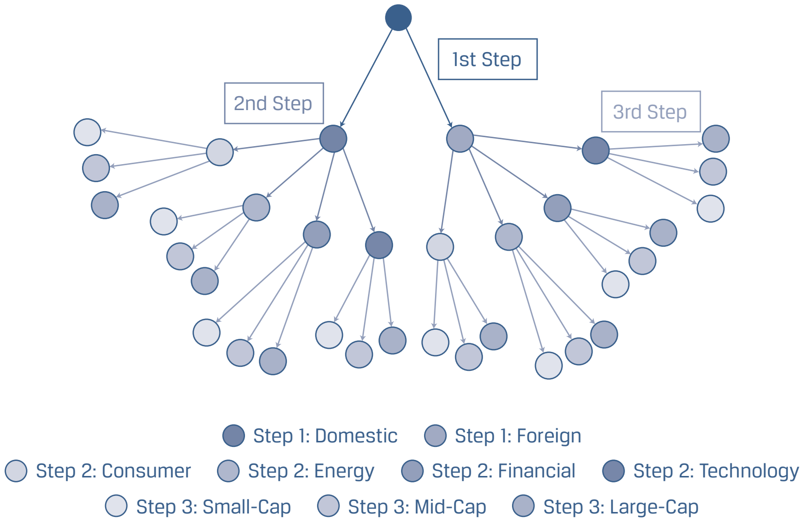
The first step in addressing a question often involves determining the different logical possibilities. We may also want to know the number of ways that each of these possibilities can happen. In the back of our mind is often a question about probability. How likely is it that I will observe this particular possibility? Records of success and failure are an example. For instance, the counting methods presented in this section have been used to evaluate a market timer's record. We can also use the methods in this section to calculate what we earlier called a priori probabilities. When we can assume that the possible outcomes of a random variable are equally likely, the probability of an event equals the number of possible outcomes favorable for the event divided by the total number of outcomes.

In counting, enumeration (counting the outcomes one by one) is of course the most basic resource. What we discuss in this section are shortcuts and principles. Without these shortcuts and principles, counting the total number of outcomes can be very difficult and prone to error. The first and basic principle of counting is the multiplication rule.

- **Multiplication Rule for Counting**. If one task can be done in n_1 ways, and a second task, given the first, can be done in n_2 ways, and a third task, given the first two tasks, can be done in n_3 ways, and so on for k tasks, then the number of ways the k tasks can be done is $(n_1)(n_2)(n_3) \ldots (n_k)$.

Exhibit 21 illustrates the multiplication rule where, for example, we have three steps in an investment decision process. In the first step, stocks are classified two ways, as domestic or foreign (represented by dark- and light-shaded circles, respectively). In the second step, stocks are assigned to one of four industries in our investment universe: consumer, energy, financial, or technology (represented by four circles with progressively darker shades, respectively). In the third step, stocks are classified three ways by size: small-cap, mid-cap, and large-cap (represented by light-, medium-, and dark-shaded circles, respectively). Because the first step can be done in two ways, the second in four ways, and the third in three ways, using the multiplication rule, we can carry out the three steps in (2)(4)(3) = 24 different ways.

Exhibit 21 **Investment Decision Process Using Multiplication Rule: $n_1 = 2$, $n_2 = 4$, $n_3 = 3$**



Another illustration is the assignment of members of a group to an equal number of positions. For example, suppose you want to assign three security analysts to cover three different industries. In how many ways can the assignments be made? The first analyst can be assigned in three different ways. Then two industries remain. The second analyst can be assigned in two different ways. Then one industry remains. The third and last analyst can be assigned in only one way. The total number of different assignments equals (3)(2)(1) = 6. The compact notation for the multiplication we have just performed is 3! (read: 3 factorial). If we had n analysts, the number of ways we could assign them to n tasks would be

$$n! = n(n - 1)(n - 2)(n - 3)\ldots 1$$

or ***n* factorial**. (By convention, 0! = 1.) To review, in this application, we repeatedly carry out an operation (here, job assignment) until we use up all members of a group (here, three analysts). With n members in the group, the multiplication formula reduces to n factorial.

The next type of counting problem can be called labeling problems.[1] We want to give each object in a group a label, to place it in a category. The following example illustrates this type of problem.

A mutual fund guide ranked 18 bond mutual funds by total returns for the last year. The guide also assigned each fund one of five risk labels: *high risk* (four funds), *above-average risk* (four funds), *average risk* (three funds), *below-average risk* (four funds), and *low risk* (three funds); as 4 + 4 + 3 + 4 + 3 = 18, all the funds are accounted for. How many different ways can we take 18 mutual funds and label 4 of them *high risk*, 4 *above-average risk*, 3 *average risk*, 4 *below-average risk*, and 3 *low risk*, so that each fund is labeled?

The answer is close to 13 billion. We can label any of 18 funds *high risk* (the first slot), then any of 17 remaining funds, then any of 16 remaining funds, then any of 15 remaining funds (now we have 4 funds in the *high risk* group); then we can label any of 14 remaining funds *above-average risk*, then any of 13 remaining funds, and so forth. There are 18! possible sequences. However, order of assignment within a category does not matter. For example, whether a fund occupies the first or third slot of the four funds labeled *high risk*, the fund has the same label (*high risk*). Thus, there are 4! ways to assign a given group of four funds to the four *high risk* slots. Making the same argument for the other categories, in total there are (4!)(4!)(3!)(4!)(3!) equivalent sequences. To eliminate such redundancies from the 18! total, we divide 18! by (4!)(4!)(3!)(4!)(3!). We have 18!/[(4!)(4!)(3!)(4!)(3!)] = 18!/[(24)(24)(6)(24)(6)] = 12,864,852,000. This procedure generalizes as follows.

---

[1] This discussion follows Kemeny, Schleifer, Snell, and Thompson (1972) in terminology and approach.

- **Multinomial Formula (General Formula for Labeling Problems)**. The number of ways that n objects can be labeled with k different labels, with n_1 of the first type, n_2 of the second type, and so on, with $n_1 + n_2 + \ldots + n_k = n$, is given by

$$\frac{n!}{n_1!n_2!\ldots n_k!} \tag{21}$$

The multinomial formula with two different labels ($k = 2$) is especially important. This special case is called the combination formula. A **combination** is a listing in which the order of the listed items does not matter. We state the combination formula in a traditional way, but no new concepts are involved. Using the notation in the formula below, the number of objects with the first label is $r = n_1$ and the number with the second label is $n - r = n_2$ (there are just two categories, so $n_1 + n_2 = n$). Here is the formula:

- **Combination Formula (Binomial Formula)**. The number of ways that we can choose r objects from a total of n objects, when the order in which the r objects are listed does not matter, is

$$_nC_r = \binom{n}{r} = \frac{n!}{(n-r)!r!} \tag{22}$$

Here $_nC_r$ and $\binom{n}{r}$ are shorthand notations for $n!/(n - r)!r!$ (read: n choose r, or n combination r).

If we label the r objects as *belongs to the group* and the remaining objects as *does not belong to the group*, whatever the group of interest, the combination formula tells us how many ways we can select a group of size r. We can illustrate this formula with the binomial option pricing model. (The binomial pricing model is covered later in the CFA curriculum. The only intuition we are concerned with here is that a number of different pricing paths can end up with the same final stock price.) This model describes the movement of the underlying asset as a series of moves, price up (U) or price down (D). For example, two sequences of five moves containing three up moves, such as UUUDD and UDUUD, result in the same final stock price. At least for an option with a payoff dependent on final stock price, the number but not the order of up moves in a sequence matters. How many sequences of five moves *belong to the group with three up moves?* The answer is 10, calculated using the combination formula ("5 choose 3"):

$$_5C_3 = 5!/[(5 - 3)!3!]$$
$$= [(5)(4)(3)(2)(1)]/[(2)(1)(3)(2)(1)] = 120/12 = 10 \text{ ways}$$

A useful fact can be illustrated as follows: $_5C_3 = 5!/(2!3!)$ equals $_5C_2 = 5!/(3!2!)$, as 3 + 2 = 5; $_5C_4 = 5!/(1!4!)$ equals $_5C_1 = 5!/(4!1!)$, as 4 + 1 = 5. This symmetrical relationship can save work when we need to calculate many possible combinations.

Suppose jurors want to select three companies out of a group of five to receive the first-, second-, and third-place awards for the best annual report. In how many ways can the jurors make the three awards? Order does matter if we want to distinguish among the three awards (the rank within the group of three); clearly the question makes order important. On the other hand, if the question were "In how many ways can the jurors choose three winners, without regard to place of finish?" we would use the combination formula.

To address the first question above, we need to count ordered listings such as *first place*, *New Company*; *second place*, *Fir Company*; *third place*, *Well Company*. An ordered listing is known as a **permutation**, and the formula that counts the number of permutations is known as the permutation formula. A more formal definition states that a permutation is an ordered subset of n distinct objects.

- **Permutation Formula**. The number of ways that we can choose r objects from a total of n objects, when the order in which the r objects are listed does matter, is

$$_{n}P_{r} = \frac{n!}{(n-r)!} \tag{23}$$

So the jurors have $_5P_3 = 5!/(5-3)! = [(5)(4)(3)(2)(1)]/[(2)(1)] = 120/2 = 60$ ways in which they can make their awards. To see why this formula works, note that [(5)(4)(3)(2)(1)]/[(2)(1)] reduces to (5)(4)(3), after cancellation of terms. This calculation counts the number of ways to fill three slots choosing from a group of five companies, according to the multiplication rule of counting. This number is naturally larger than it would be if order did not matter (compare 60 to the value of 10 for "5 choose 3" that we calculated above). For example, *first place*, *Well Company*; *second place*, *Fir Company*; *third place*, *New Company* contains the same three companies as *first place*, *New Company*; *second place*, *Fir Company*; *third place*, *Well Company*. If we were concerned only with award winners (without regard to place of finish), the two listings would count as one combination. But when we are concerned with the order of finish, the listings count as two permutations.

EXAMPLE 17

Permutations and Combinations for Two Out of Four Outcomes

There are four balls numbered 1, 2, 3, and 4 in a basket. You are running a contest in which two of the four balls are selected at random from the basket. To win, a player must have correctly chosen the numbers of the two randomly selected balls. Suppose the winning numbers are numbers 1 and 3. If the player must choose the balls in the same order in which they are drawn, she wins if she chose 1 first and 3 second. On the other hand, if order is not important, the player wins if the balls drawn are 1 and then 3 or if the balls drawn are 3 and then 1. The number of possible outcomes for permutations and combinations of choosing 2 out of 4 items is illustrated in Exhibit 22. If order is not important, for choosing 2 out of 4 items, the winner wins twice as often.

Exhibit 22 Permutations and Combinations for Choosing 2 out of 4 Items

Permutations: Order matters	Combinations: Order does not matter
List of all possible outcomes: (1 2) (2 1) (3 1) (4 1) (1 3) (2 3) (3 2) (4 2) (1 4) (2 4) (3 4) (4 3)	List of all possible outcomes: (1 2) (2 3) (3 4) (1 3) (2 4) (1 4)
Number of permutations: $_nP_r = \frac{n!}{(n-r)!}$ $_4P_2 = \frac{4!}{(4-2)!} = \frac{4 \times 3 \times 2 \times 1}{2 \times 1} = 12$	Number of combinations: $_nC_r = \frac{n!}{(n-r)!r!}$ $_4C_2 = \frac{4!}{(4-2)!2!} = \frac{4 \times 3 \times 2 \times 1}{2 \times 1 \times 2 \times 1} = 6$

If order is important, the number of permutations (possible outcomes) is much larger than the number of combinations when order is not important.

EXAMPLE 18

Reorganizing the Analyst Team Assignments

Gehr-Flint Investors classifies the stocks in its investment universe into 11 industries and is assigning each research analyst one or two industries. Five of the industries have been assigned, and you are asked to cover two industries from the remaining six.

How many possible pairs of industries remain?

A 12

B 15

C 36

Solution:

B is correct. The number of combinations of selecting two industries out of six is equal to

$$_nC_r = \begin{bmatrix} n \\ r \end{bmatrix} = \frac{n!}{(n-r)!r!} = \frac{6!}{4!2!} = 15$$

The number of possible combinations for picking two industries out of six is 15.

EXAMPLE 19

Australian Powerball Lottery

To win the Australian Powerball jackpot, you must match the numbers of seven balls pulled from a basket (the balls are numbered 1 through 35) plus the number of the Powerball (numbered 1 through 20). The order in which the seven balls are drawn is not important. The number of combinations of matching 7 out of 35 balls is

$$_nC_r = \begin{bmatrix} n \\ r \end{bmatrix} = \frac{n!}{(n-r)!r!} = \frac{35!}{28!7!} = 6{,}724{,}520$$

The number of combinations for picking the Powerball, 1 out of 20, is

$$_nC_r = \begin{bmatrix} n \\ r \end{bmatrix} = \frac{n!}{(n-r)!r!} = \frac{20!}{19!1!} = 20$$

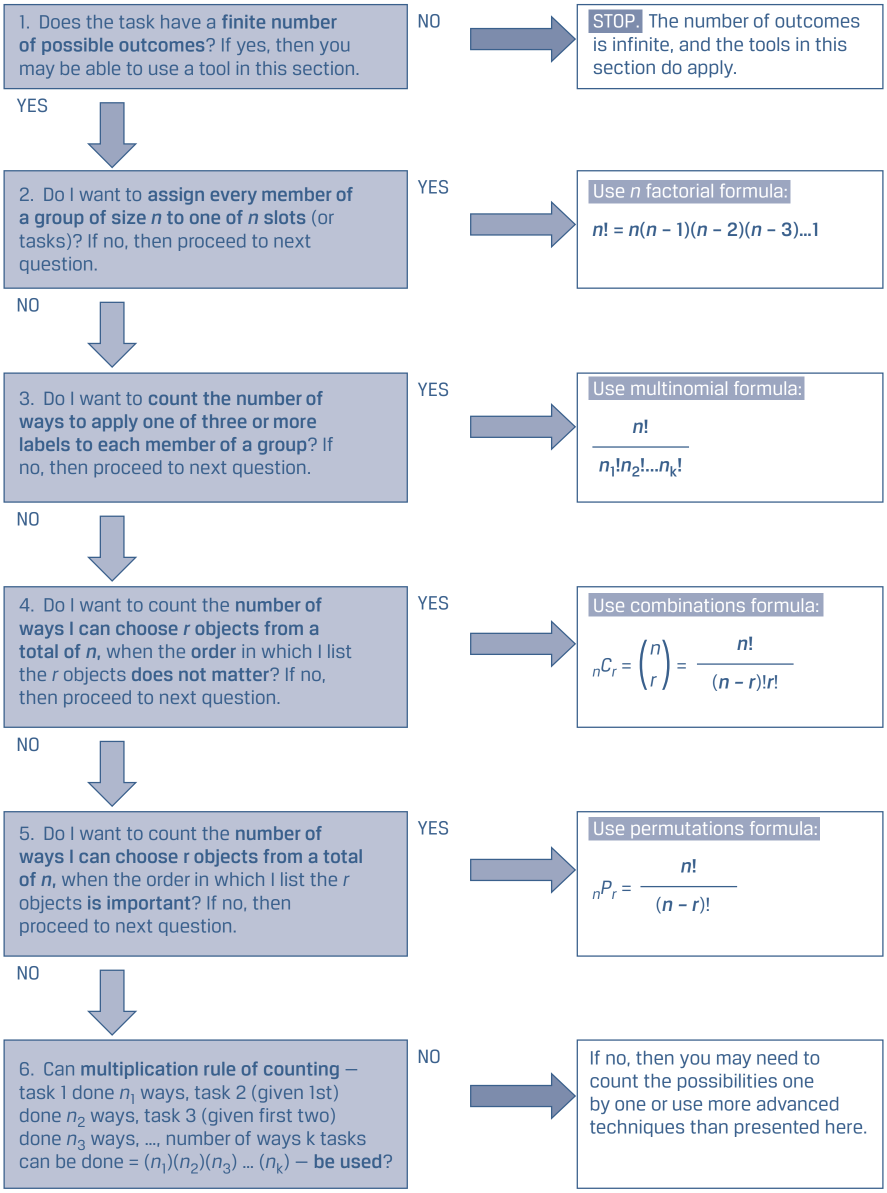
The number of ways to pick the seven balls plus the Powerball is

$$_{35}C_7 \times {}_{20}C_1 = 6{,}724{,}520 \times 20 = 134{,}490{,}400$$

Your probability of winning the Australian Powerball with one ticket is 1 in 134,490,400.

Exhibit 23 is a flow chart that may help you apply the counting methods we have presented in this section.

Exhibit 23 Summary of Counting Methods



1. Does the task have a **finite number of possible outcomes**? If yes, then you may be able to use a tool in this section.

NO → STOP. The number of outcomes is infinite, and the tools in this section do apply.

YES ↓

2. Do I want to **assign every member of a group of size *n* to one of *n* slots** (or tasks)? If no, then proceed to next question.

YES → Use *n* factorial formula: $n! = n(n-1)(n-2)(n-3)\ldots1$

NO ↓

3. Do I want to **count the number of ways to apply one of three or more labels to each member of a group**? If no, then proceed to next question.

YES → Use multinomial formula: $\dfrac{n!}{n_1!n_2!\ldots n_k!}$

NO ↓

4. Do I want to count the **number of ways I can choose *r* objects from a total of *n***, when the **order** in which I list the *r* objects **does not matter**? If no, then proceed to next question.

YES → Use combinations formula: ${}_nC_r = \binom{n}{r} = \dfrac{n!}{(n-r)!r!}$

NO ↓

5. Do I want to count the **number of ways I can choose r objects from a total of *n*,** when the order in which I list the *r* objects **is important**? If no, then proceed to next question.

YES → Use permutations formula: ${}_nP_r = \dfrac{n!}{(n-r)!}$

NO ↓

6. Can **multiplication rule of counting** — task 1 done n_1 ways, task 2 (given 1st) done n_2 ways, task 3 (given first two) done n_3 ways, ..., number of ways k tasks can be done = $(n_1)(n_2)(n_3)\ldots(n_k)$ — **be used**?

NO → If no, then you may need to count the possibilities one by one or use more advanced techniques than presented here.

SUMMARY

In this reading, we have discussed the essential concepts and tools of probability. We have applied probability, expected value, and variance to a range of investment problems.

- A random variable is a quantity whose outcome is uncertain.
- Probability is a number between 0 and 1 that describes the chance that a stated event will occur.
- An event is a specified set of outcomes of a random variable.

- Mutually exclusive events can occur only one at a time. Exhaustive events cover or contain all possible outcomes.
- The two defining properties of a probability are, first, that $0 \le P(E) \le 1$ (where $P(E)$ denotes the probability of an event E) and, second, that the sum of the probabilities of any set of mutually exclusive and exhaustive events equals 1.
- A probability estimated from data as a relative frequency of occurrence is an empirical probability. A probability drawing on personal or subjective judgment is a subjective probability. A probability obtained based on logical analysis is an a priori probability.
- A probability of an event E, $P(E)$, can be stated as odds for $E = P(E)/[1 - P(E)]$ or odds against $E = [1 - P(E)]/P(E)$.
- Probabilities that are inconsistent create profit opportunities, according to the Dutch Book Theorem.
- A probability of an event *not* conditioned on another event is an unconditional probability. The unconditional probability of an event A is denoted $P(A)$. Unconditional probabilities are also called marginal probabilities.
- A probability of an event given (conditioned on) another event is a conditional probability. The probability of an event A given an event B is denoted $P(A \mid B)$, and $P(A \mid B) = P(AB)/P(B)$, $P(B) \neq 0$.
- The probability of both A and B occurring is the joint probability of A and B, denoted $P(AB)$.
- The multiplication rule for probabilities is $P(AB) = P(A \mid B)P(B)$.
- The probability that A or B occurs, or both occur, is denoted by $P(A \text{ or } B)$.
- The addition rule for probabilities is $P(A \text{ or } B) = P(A) + P(B) - P(AB)$.
- When events are independent, the occurrence of one event does not affect the probability of occurrence of the other event. Otherwise, the events are dependent.
- The multiplication rule for independent events states that if A and B are independent events, $P(AB) = P(A)P(B)$. The rule generalizes in similar fashion to more than two events.
- According to the total probability rule, if $S_1, S_2, \ldots, S_n$ are mutually exclusive and exhaustive scenarios or events, then $P(A) = P(A \mid S_1)P(S_1) + P(A \mid S_2)P(S_2) + \ldots + P(A \mid S_n)P(S_n)$.
- The expected value of a random variable is a probability-weighted average of the possible outcomes of the random variable. For a random variable X, the expected value of X is denoted $E(X)$.
- The total probability rule for expected value states that $E(X) = E(X \mid S_1)P(S_1) + E(X \mid S_2)P(S_2) + \ldots + E(X \mid S_n)P(S_n)$, where $S_1, S_2, \ldots, S_n$ are mutually exclusive and exhaustive scenarios or events.
- The variance of a random variable is the expected value (the probability-weighted average) of squared deviations from the random variable's expected value $E(X)$: $\sigma^2(X) = E\{[X - E(X)]^2\}$, where $\sigma^2(X)$ stands for the variance of X.
- Variance is a measure of dispersion about the mean. Increasing variance indicates increasing dispersion. Variance is measured in squared units of the original variable.
- Standard deviation is the positive square root of variance. Standard deviation measures dispersion (as does variance), but it is measured in the same units as the variable.
- Covariance is a measure of the co-movement between random variables.

- The covariance between two random variables R_i and R_j in a forward-looking sense is the expected value of the cross-product of the deviations of the two random variables from their respective means: $\text{Cov}(R_i,R_j) = E\{[R_i - E(R_i)][R_j - E(R_j)]\}$. The covariance of a random variable with itself is its own variance.
- The historical or sample covariance between two random variables R_i and R_j based on a sample of past data of size n is the average value of the product of the deviations of observations on two random variables from their sample means:

$$\text{Cov}\left(R_i,R_j\right) = \sum_{n=1}^{n}\left(R_{i,t} - \bar{R}_i\right)\left(R_{j,t} - \bar{R}_j\right)\Big/(n-1)$$

- Correlation is a number between −1 and +1 that measures the co-movement (linear association) between two random variables: $\rho(R_i,R_j) = \text{Cov}(R_i,R_j)/[\sigma(R_i)\,\sigma(R_j)]$.
- If two variables have a very strong (inverse) linear relation, then the absolute value of their correlation will be close to 1 (-1). If two variables have a weak linear relation, then the absolute value of their correlation will be close to 0.
- If the correlation coefficient is positive, the two variables are positively related; if the correlation coefficient is negative, the two variables are inversely related.
- To calculate the variance of return on a portfolio of n assets, the inputs needed are the n expected returns on the individual assets, n variances of return on the individual assets, and $n(n - 1)/2$ distinct covariances.
- Portfolio variance of return is $\sigma^2\left(R_p\right) = \sum_{i=1}^{n}\sum_{j=1}^{n} w_i w_j \text{Cov}\left(R_i,R_j\right)$.
- The calculation of covariance in a forward-looking sense requires the specification of a joint probability function, which gives the probability of joint occurrences of values of the two random variables.
- When two random variables are independent, the joint probability function is the product of the individual probability functions of the random variables.
- Bayes' formula is a method for updating probabilities based on new information.
- Bayes' formula is expressed as follows: Updated probability of event given the new information = [(Probability of the new information given event)/(Unconditional probability of the new information)] × Prior probability of event.
- The multiplication rule of counting says, for example, that if the first step in a process can be done in 10 ways, the second step, given the first, can be done in 5 ways, and the third step, given the first two, can be done in 7 ways, then the steps can be carried out in (10)(5)(7) = 350 ways.
- The number of ways to assign every member of a group of size n to n slots is $n! = n\,(n-1)\,(n-2)(n-3)\ldots 1$. (By convention, $0! = 1$.)
- The number of ways that n objects can be labeled with k different labels, with n_1 of the first type, n_2 of the second type, and so on, with $n_1 + n_2 + \ldots + n_k = n$, is given by $n!/(n_1!n_2!\ldots n_k!)$. This expression is the multinomial formula.
- A special case of the multinomial formula is the combination formula. The number of ways to choose r objects from a total of n objects, when the order in which the r objects are listed does not matter, is

$${}_nC_r = \binom{n}{r} = \frac{n!}{(n-r)!r!}$$

- The number of ways to choose r objects from a total of n objects, when the order in which the r objects are listed does matter, is

  $${}_nP_r = \frac{n!}{(n-r)!}$$

  This expression is the permutation formula.

PRACTICE PROBLEMS

1. Suppose that 5% of the stocks meeting your stock-selection criteria are in the telecommunications (telecom) industry. Also, dividend-paying telecom stocks are 1% of the total number of stocks meeting your selection criteria. What is the probability that a stock is dividend paying, given that it is a telecom stock that has met your stock selection criteria?

2. You are using the following three criteria to screen potential acquisition targets from a list of 500 companies:

Criterion	Fraction of the 500 Companies Meeting the Criterion
Product lines compatible	0.20
Company will increase combined sales growth rate	0.45
Balance sheet impact manageable	0.78

If the criteria are independent, how many companies will pass the screen?

3. Florence Hixon is screening a set of 100 stocks based on two criteria (Criterion 1 and Criterion 2). She set the passing level such that 50% of the stocks passed each screen. For these stocks, the values for Criterion 1 and Criterion 2 are not independent but are positively related. How many stocks should pass Hixon's two screens?

   A Less than 25

   B 25

   C More than 25

4. You apply both valuation criteria and financial strength criteria in choosing stocks. The probability that a randomly selected stock (from your investment universe) meets your valuation criteria is 0.25. Given that a stock meets your valuation criteria, the probability that the stock meets your financial strength criteria is 0.40. What is the probability that a stock meets both your valuation and financial strength criteria?

5. Suppose the prospects for recovering principal for a defaulted bond issue depend on which of two economic scenarios prevails. Scenario 1 has probability 0.75 and will result in recovery of $0.90 per $1 principal value with probability 0.45, or in recovery of $0.80 per $1 principal value with probability 0.55. Scenario 2 has probability 0.25 and will result in recovery of $0.50 per $1 principal value with probability 0.85, or in recovery of $0.40 per $1 principal value with probability 0.15.

   A Compute the probability of each of the four possible recovery amounts: $0.90, $0.80, $0.50, and $0.40.

   B Compute the expected recovery, given the first scenario.

   C Compute the expected recovery, given the second scenario.

   D Compute the expected recovery.

   E Graph the information in a probability tree diagram.

6. You have developed a set of criteria for evaluating distressed credits. Companies that do not receive a passing score are classed as likely to go bankrupt within 12 months. You gathered the following information when validating the criteria:

© 2021 CFA Institute. All rights reserved.

- Forty percent of the companies to which the test is administered will go bankrupt within 12 months: *P*(*non-survivor*) = 0.40.
- Fifty-five percent of the companies to which the test is administered pass it: *P*(*pass test*) = 0.55.
- The probability that a company will pass the test given that it will subsequently survive 12 months, is 0.85: *P*(*pass test* | *survivor*) = 0.85.

A What is P(*pass test* | *non-survivor*)?

B Using Bayes' formula, calculate the probability that a company is a survivor, given that it passes the test; that is, calculate *P*(*survivor* | *pass test*).

C What is the probability that a company is a *non-survivor*, given that it fails the test?

D Is the test effective?

7 In probability theory, exhaustive events are *best* described as the set of events that:

A have a probability of zero.

B are mutually exclusive.

C include all potential outcomes.

8 Which probability estimate *most likely* varies greatly between people?

A An *a priori* probability

B An empirical probability

C A subjective probability

9 If the probability that Zolaf Company sales exceed last year's sales is 0.167, the odds for exceeding sales are *closest* to:

A 1 to 5.

B 1 to 6.

C 5 to 1.

10 After six months, the growth portfolio that Rayan Khan manages has outperformed its benchmark. Khan states that his odds of beating the benchmark for the year are 3 to 1. If these odds are correct, what is the probability that Khan's portfolio will beat the benchmark for the year?

A 0.33

B 0.67

C 0.75

11 The probability of an event given that another event has occurred is a:

A joint probability.

B marginal probability.

C conditional probability.

12 After estimating the probability that an investment manager will exceed his benchmark return in each of the next two quarters, an analyst wants to forecast the probability that the investment manager will exceed his benchmark return over the two-quarter period in total. Assuming that each quarter's performance is independent of the other, which probability rule should the analyst select?

A Addition rule

B Multiplication rule

C Total probability rule

13 Which of the following is a property of two dependent events?

A The two events must occur simultaneously.

B The probability of one event influences the probability of the other event.

C The probability of the two events occurring is the product of each event's probability.

14 Which of the following *best* describes how an analyst would estimate the expected value of a firm under the scenarios of bankruptcy and survivorship? The analyst would use:

A the addition rule.

B conditional expected values.

C the total probability rule for expected value.

15 An analyst developed two scenarios with respect to the recovery of $100,000 principal from defaulted loans:

Scenario	Probability of Scenario (%)	Amount Recovered ($)	Probability of Amount (%)
1	40	50,000	60
		30,000	40
2	60	80,000	90
		60,000	10

The amount of the expected recovery is *closest* to:

A $36,400.

B $55,000.

C $63,600.

16 US and Spanish bonds have return standard deviations of 0.64 and 0.56, respectively. If the correlation between the two bonds is 0.24, the covariance of returns is *closest* to:

A 0.086.

B 0.335.

C 0.390.

17 The covariance of returns is positive when the returns on two assets tend to:

A have the same expected values.

B be above their expected value at different times.

C be on the same side of their expected value at the same time.

18 Which of the following correlation coefficients indicates the weakest linear relationship between two variables?

A –0.67

B –0.24

C 0.33

19 An analyst develops the following covariance matrix of returns:

	Hedge Fund	Market Index
Hedge fund	256	110
Market index	110	81

The correlation of returns between the hedge fund and the market index is *closest* to:

A 0.005.

B 0.073.

C 0.764.

20 All else being equal, as the correlation between two assets approaches +1.0, the diversification benefits:

A decrease.

B stay the same.

C increase.

21 Given a portfolio of five stocks, how many unique covariance terms, excluding variances, are required to calculate the portfolio return variance?

A 10

B 20

C 25

22 The probability distribution for a company's sales is:

Probability	Sales ($ millions)
0.05	70
0.70	40
0.25	25

The standard deviation of sales is *closest* to:

A $9.81 million.

B $12.20 million.

C $32.40 million.

23 Which of the following statements is *most* accurate? If the covariance of returns between two assets is 0.0023, then:

A the assets' risk is near zero.

B the asset returns are unrelated.

C the asset returns have a positive relationship.

24 An analyst produces the following joint probability function for a foreign index (FI) and a domestic index (DI).

	R_{DI} = 30%	R_{DI} = 25%	R_{DI} = 15%
R_{FI} = 25%	0.25		
R_{FI} = 15%		0.50	
R_{FI} = 10%			0.25

The covariance of returns on the foreign index and the returns on the domestic index is *closest* to:

A 26.39.

B 26.56.

C 28.12.

25 A two-stock portfolio includes stocks with the following characteristics:

	Stock 1	Stock 2
Expected return	7%	10%
Standard deviation	12%	25%
Portfolio weights	0.30	0.70
Correlation	0.20	

What is the standard deviation of portfolio returns?

A 14.91%

B 18.56%

C 21.10%

26 Lena Hunziger has designed the three-asset portfolio summarized below:

	Asset 1	Asset 2	Asset 3
Expected return	5%	6%	7%
Portfolio weight	**0.20**	0.30	0.50
Variance-Covariance Matrix			
	Asset 1	**Asset 2**	**Asset 3**
Asset 1	196	105	140
Asset 2	105	225	150
Asset 3	140	150	400

Hunziger estimated the portfolio return to be 6.3%. What is the portfolio standard deviation?

A 13.07%

B 13.88%

C 14.62%

27 An analyst estimates that 20% of high-risk bonds will fail (go bankrupt). If she applies a bankruptcy prediction model, she finds that 70% of the bonds will receive a "good" rating, implying that they are less likely to fail. Of the bonds that failed, only 50% had a "good" rating. Use Bayes' formula to predict the probability of failure given a "good" rating. (Hint, let $P(A)$ be the probability of failure, $P(B)$ be the probability of a "good" rating, $P(B \mid A)$ be the likelihood of a "good" rating given failure, and $P(A \mid B)$ be the likelihood of failure given a "good" rating.)

A 5.7%

B 14.3%

C 28.6%

28 In a typical year, 5% of all CEOs are fired for "performance" reasons. Assume that CEO performance is judged according to stock performance and that 50% of stocks have above-average returns or "good" performance. Empirically, 30% of all CEOs who were fired had "good" performance. Using Bayes' formula, what is the probability that a CEO will be fired given "good" performance? (Hint, let $P(A)$ be the probability of a CEO being fired, $P(B)$ be the probability of a "good" performance rating, $P(B \mid A)$ be the likelihood of a "good" performance rating given that the CEO was fired, and $P(A \mid B)$ be the likelihood of the CEO being fired given a "good" performance rating.)

A 1.5%

B 2.5%

C 3.0%

29 A manager will select 20 bonds out of his universe of 100 bonds to construct a portfolio. Which formula provides the number of possible portfolios?

A Permutation formula

B Multinomial formula

C Combination formula

30 A firm will select two of four vice presidents to be added to the investment committee. How many different groups of two are possible?

A 6

B 12

C 24

31 From an approved list of 25 funds, a portfolio manager wants to rank 4 mutual funds from most recommended to least recommended. Which formula is *most* appropriate to calculate the number of possible ways the funds could be ranked?

A Permutation formula

B Multinomial formula

C Combination formula

32 Himari Fukumoto has joined a new firm and is selecting mutual funds in the firm's pension plan. If 10 mutual funds are available, and she plans to select four, how many different sets of mutual funds can she choose?

A 210

B 720

C 5,040

Items 33, 34, and 35 are based on the following setup:

Gerd Sturm wants to sponsor a contest with a $1 million prize. The winner must pick the stocks that will be the top five performers next year among the 30 stocks in a well-known large-cap stock index. He asks you to estimate the chances that contestants can win the contest.

33 What are the chances of winning if the contestants must pick the five stocks in the correct order of their total return? If choosing five stocks randomly, a contestant's chance of winning is one out of:

A 142,506.

B 17,100,720.

C 24,300,000.

34 What are the chances of winning if the contestants must pick the top five stocks without regard to order? If choosing five stocks randomly, a contestant's chance of winning is one out of:

A 142,506.

B 17,100,720.

C 24,300,000.

35 Sturm asks, "Can we trust these probabilities of winning?"

SOLUTIONS

1 Use this equation to find this conditional probability: P(*stock is dividend paying* | *telecom stock that meets criteria*) = P(*stock is dividend paying and telecom stock that meets criteria*)/P(*telecom stock that meets criteria*) = 0.01/0.05 = 0.20.

2 According to the multiplication rule for independent events, the probability of a company meeting all three criteria is the product of the three probabilities. Labeling the event that a company passes the first, second, and third criteria, A, B, and C, respectively, $P(ABC) = P(A)P(B)P(C) = (0.20)(0.45)(0.78) = 0.0702$. As a consequence, (0.0702)(500) = 35.10, so 35 companies pass the screen.

3 C is correct. Let event A be a stock passing the first screen (Criterion 1) and event B be a stock passing the second screen (Criterion 2). The probability of passing each screen is $P(A) = 0.50$ and $P(B) = 0.50$. If the two criteria are independent, the joint probability of passing both screens is $P(AB) = P(A)P(B) = 0.50 \times 0.50 = 0.25$, so 25 out of 100 stocks would pass both screens. However, the two criteria are positively related, and $P(AB) \neq 0.25$. Using the multiplication rule for probabilities, the joint probability of A and B is $P(AB) = P(A \mid B)P(B)$. If the two criteria are not independent, and if $P(B) = 0.50$, then the contingent probability of $P(A \mid B)$ is greater than 0.50. So the joint probability of $P(AB) = P(A \mid B)P(B)$ is greater than 0.25. More than 25 stocks should pass the two screens.

4 Use the equation for the multiplication rule for probabilities $P(AB) = P(A \mid B)P(B)$, defining A as the event that *a stock meets the financial strength criteria* and defining B as the event that *a stock meets the valuation criteria*. Then $P(AB) = P(A \mid B)P(B) = 0.40 \times 0.25 = 0.10$. The probability that a stock meets both the financial and valuation criteria is 0.10.

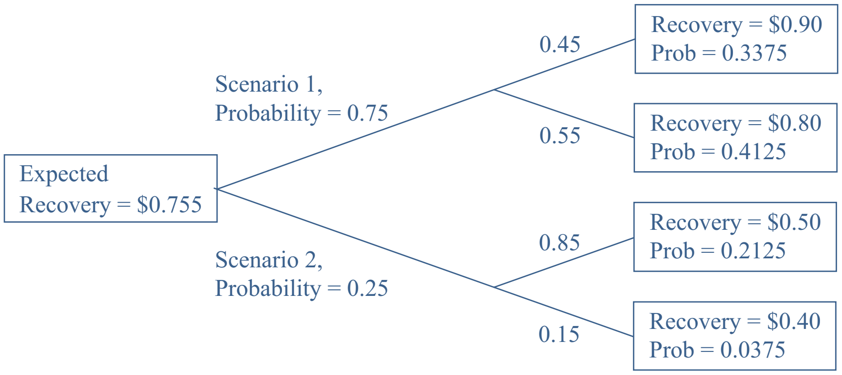
5 **A** *Outcomes associated with Scenario 1:* With a 0.45 probability of a \$0.90 recovery per \$1 principal value, given Scenario 1, and with the probability of Scenario 1 equal to 0.75, the probability of recovering \$0.90 is 0.45 (0.75) = 0.3375. By a similar calculation, the probability of recovering \$0.80 is 0.55(0.75) = 0.4125.

Outcomes associated with Scenario 2: With a 0.85 probability of a \$0.50 recovery per \$1 principal value, given Scenario 2, and with the probability of Scenario 2 equal to 0.25, the probability of recovering \$0.50 is 0.85(0.25) = 0.2125. By a similar calculation, the probability of recovering \$0.40 is 0.15(0.25) = 0.0375.

B $E(\textit{recovery} \mid \textit{Scenario 1}) = 0.45(\$0.90) + 0.55(\$0.80) = \$0.845$

C $E(\textit{recovery} \mid \textit{Scenario 2}) = 0.85(\$0.50) + 0.15(\$0.40) = \$0.485$

D $E(\textit{recovery}) = 0.75(\$0.845) + 0.25(\$0.485) = \$0.755$



6 **A** We can set up the equation using the total probability rule:

$$\begin{aligned} P(\mathit{pass\ test}) &= P(\mathit{pass\ test} \mid \mathit{survivor})P(\mathit{survivor}) \\ &\quad + P(\mathit{pass\ test} \mid \mathit{non\text{-}survivor})P(\mathit{non\text{-}survivor}) \end{aligned}$$

We know that $P(\mathit{survivor}) = 1 - P(\mathit{non\text{-}survivor}) = 1 - 0.40 = 0.60$. Therefore, $P(\mathit{pass\ test}) = 0.55 = 0.85(0.60) + P(\mathit{pass\ test} \mid \mathit{non\text{-}survivor})(0.40)$.

Thus, $P(\mathit{pass\ test} \mid \mathit{non\text{-}survivor}) = [0.55 - 0.85(0.60)]/0.40 = 0.10$.

B

$$\begin{aligned} P(\mathit{survivor} \mid \mathit{pass\ test}) &= \left[P(\mathit{pass\ test} \mid \mathit{survivor})/P(\mathit{pass\ test})\right]P(\mathit{survivor}) \\ &= (0.85/0.55)0.60 = 0.927273 \end{aligned}$$

The information that a company passes the test causes you to update your probability that it is a survivor from 0.60 to approximately 0.927.

C According to Bayes' formula, $P(\mathit{non\text{-}survivor} \mid \mathit{fail\ test}) = [P(\mathit{fail\ test} \mid \mathit{non\text{-}survivor})/ P(\mathit{fail\ test})]P(\mathit{non\text{-}survivor}) = [P(\mathit{fail\ test} \mid \mathit{non\text{-}survivor})/0.45]0.40$.

We can set up the following equation to obtain $P(\mathit{fail\ test} \mid \mathit{non\text{-}survivor})$:

$$\begin{aligned} P(\mathit{fail\ test}) &= P(\mathit{fail\ test} \mid \mathit{non\text{-}survivor})P(\mathit{non\text{-}survivor}) \\ &\quad + P(\mathit{fail\ test} \mid \mathit{survivor})P(\mathit{survivor}) \\ 0.45 &= P(\mathit{fail\ test} \mid \mathit{non\text{-}survivor})0.40 + 0.15(0.60) \end{aligned}$$

where $P(\mathit{fail\ test} \mid \mathit{survivor}) = 1 - P(\mathit{pass\ test} \mid \mathit{survivor}) = 1 - 0.85 = 0.15$. So $P(\mathit{fail\ test} \mid \mathit{non\text{-}survivor}) = [0.45 - 0.15(0.60)]/0.40 = 0.90$.

Using this result with the formula above, we find $P(\mathit{non\text{-}survivor} \mid \mathit{fail\ test}) = [0.90/0.45]0.40 = 0.80$. Seeing that a company fails the test causes us to update the probability that it is a non-survivor from 0.40 to 0.80.

D A company passing the test greatly increases our confidence that it is a survivor. A company failing the test doubles the probability that it is a non-survivor. Therefore, the test appears to be useful.

7 C is correct. The term "exhaustive" means that the events cover all possible outcomes.

8 C is correct. A subjective probability draws on personal or subjective judgment that may be without reference to any particular data.

9 A is correct. Given odds for E of a to b, the implied probability of $E = a/(a + b)$. Stated in terms of odds a to b with $a = 1$, $b = 5$, the probability of $E = 1/(1 + 5) = 1/6 = 0.167$. This result confirms that a probability of 0.167 for beating sales is odds of 1 to 5.

10 C is correct. The odds for beating the benchmark = $P(\mathit{beating\ benchmark}) / [1 - P(\mathit{beating\ benchmark})]$. Let $P(A) = P(\mathit{beating\ benchmark})$. Odds for beating the benchmark = $P(A) / [1 - P(A)]$.

$$3 = P(A) / [1 - P(A)]$$

Solving for $P(A)$, the probability of beating the benchmark is 0.75.

11 C is correct. A conditional probability is the probability of an event given that another event has occurred.

12 B is correct. Because the events are independent, the multiplication rule is most appropriate for forecasting their joint probability. The multiplication rule for independent events states that the joint probability of both A and B occurring is $P(AB) = P(A)P(B)$.

13 B is correct. The probability of the occurrence of one is related to the occurrence of the other. If we are trying to forecast one event, information about a dependent event may be useful.

14 C is correct. The total probability rule for expected value is used to estimate an expected value based on mutually exclusive and exhaustive scenarios.

15 C is correct. If Scenario 1 occurs, the expected recovery is 60% ($50,000) + 40% ($30,000) = $42,000, and if Scenario 2 occurs, the expected recovery is 90% ($80,000) + 10%($60,000) = $78,000. Weighting by the probability of each scenario, the expected recovery is 40%($42,000) + 60%($78,000) = $63,600. Alternatively, first calculating the probability of each amount occurring, the expected recovery is (40%)(60%)($50,000) + (40%)(40%)($30,000) + (60%)(90%)($80,000) + (60%)(10%)($60,000) = $63,600.

16 A is correct. The covariance is the product of the standard deviations and correlation using the formula Cov(US bond returns, Spanish bond returns) = σ(US bonds) × σ (Spanish bonds) × ρ(US bond returns, Spanish bond returns) = 0.64 × 0.56 × 0.24 = 0.086.

17 C is correct. The covariance of returns is positive when the returns on both assets tend to be on the same side (above or below) their expected values at the same time, indicating an average positive relationship between returns.

18 B is correct. Correlations near +1 exhibit strong positive linearity, whereas correlations near −1 exhibit strong negative linearity. A correlation of 0 indicates an absence of any linear relationship between the variables. The closer the correlation is to 0, the weaker the linear relationship.

19 C is correct. The correlation between two random variables R_i and R_j is defined as $\rho(R_i,R_j) = \text{Cov}(R_i,R_j)/[\sigma(R_i)\sigma(R_j)]$. Using the subscript i to represent hedge funds and the subscript j to represent the market index, the standard deviations are $\sigma(R_i) = 256^{1/2} = 16$ and $\sigma(R_j) = 81^{1/2} = 9$. Thus, $\rho(R_i,R_j) = \text{Cov}(R_i,R_j)/[\sigma(R_i)\sigma(R_j)] = 110/(16 \times 9) = 0.764$.

20 A is correct. As the correlation between two assets approaches +1, diversification benefits decrease. In other words, an increasingly positive correlation indicates an increasingly strong positive linear relationship and fewer diversification benefits.

21 A is correct. A covariance matrix for five stocks has 5 × 5 = 25 entries. Subtracting the 5 diagonal variance terms results in 20 off-diagonal entries. Because a covariance matrix is symmetrical, only 10 entries are unique (20/2 = 10).

22 A is correct. The analyst must first calculate expected sales as 0.05 × $70 + 0.70 × $40 + 0.25 × $25 = $3.50 million + $28.00 million + $6.25 million = $37.75 million.

After calculating expected sales, we can calculate the variance of sales:

$$\sigma^2 \text{ (Sales)} = P(\$70)[\$70 - E(\text{Sales})]^2 + P(\$40)[\$40 - E(\text{Sales})]^2 + P(\$25)[\$25 - E(\text{Sales})]^2$$

$$= 0.05(\$70 - 37.75)^2 + 0.70(\$40 - 37.75)^2 + 0.25(\$25 - 37.75)^2$$

$$= \$52.00 \text{ million} + \$3.54 \text{ million} + \$40.64 \text{ million} = \$96.18 \text{ million.}$$

The standard deviation of sales is thus $\sigma = (\$96.18)^{1/2} = \$9.81$ million.

23 C is correct. The covariance of returns is positive when the returns on both assets tend to be on the same side (above or below) their expected values at the same time.

24 B is correct. The covariance is 26.56, calculated as follows. First, expected returns are

$$E(R_{FI}) = (0.25 \times 25) + (0.50 \times 15) + (0.25 \times 10)$$

$$= 6.25 + 7.50 + 2.50 = 16.25 \text{ and}$$

$$E(R_{DI}) = (0.25 \times 30) + (0.50 \times 25) + (0.25 \times 15)$$

$$= 7.50 + 12.50 + 3.75 = 23.75.$$

Covariance is

$$\mathrm{Cov}(R_{FI},R_{DI}) = \sum_i \sum_j P\left(R_{FI,i}, R_{DI,j}\right)\left(R_{FI,i} - ER_{FI}\right)\left(R_{DI,j} - ER_{DI}\right)$$

$$= 0.25[(25 - 16.25)(30 - 23.75)] + 0.50[(15 - 16.25)(25 - 23.75)] + 0.25[(10 - 16.25)(15 - 23.75)]$$

$$= 13.67 + (-0.78) + 13.67 = 26.56.$$

25 B is correct. The covariance between the returns for the two stocks is $\mathrm{Cov}(R_1,R_2) = \rho(R_1,R_2)\,\sigma(R_1)\,\sigma(R_2) = 0.20\,(12)\,(25) = 60$. The portfolio variance is

$$\sigma^2(R_p) = w_1^2\sigma^2(R_1) + w_2^2\sigma^2(R_2) + 2w_1w_2\mathrm{Cov}(R_1,R_2)$$

$$= (0.30)^2(12)^2 + (0.70)^2(25)^2 + 2(0.30)(0.70)(60)$$

$$= 12.96 + 306.25 + 25.2 = 344.41$$

The portfolio standard deviation is

$$\sigma^2(R_p) = 344.41^{1/2} = 18.56\%$$

26 C is correct. For a three-asset portfolio, the portfolio variance is

$$\sigma^2(R_p) = w_1^2\sigma^2(R_1) + w_2^2\sigma^2(R_2) + w_3^2\sigma^2(R_3) + 2w_1w_2\mathrm{Cov}(R_1,R_2) + 2w_1w_3\mathrm{Cov}(R_1,R_3) + 2w_2w_3\mathrm{Cov}(R_2,R_3)$$

$$= (0.20)^2(196) + (0.30)^2(225) + (0.50)^2(400) + 2(0.20)(0.30)(105) + (2)(0.20)(0.50)(140) + (2)(0.30)(0.50)(150)$$

$$= 7.84 + 20.25 + 100 + 12.6 + 28 + 45 = 213.69$$

The portfolio standard deviation is

$$\sigma^2(R_p) = 213.69^{1/2} = 14.62\%$$

27 B is correct. With Bayes' formula, the probability of failure given a "good" rating is

$$P(A \mid B) = \frac{P(B \mid A)}{P(B)}P(A)$$

where

$P(A) = 0.20$ = probability of failure
$P(B) = 0.70$ = probability of a "good" rating
$P(B \mid A) = 0.50$ = probability of a "good" rating given failure

With these estimates, the probability of failure given a "good" rating is

$$P(A \mid B) = \frac{P(B \mid A)}{P(B)}P(A) = \frac{0.50}{0.70} \times 0.20 = 0.143$$

If the analyst uses the bankruptcy prediction model as a guide, the probability of failure declines from 20% to 14.3%.

28 C is correct. With Bayes' formula, the probability of the CEO being fired given a "good" rating is

$$P(A \mid B) = \frac{P(B \mid A)}{P(B)}P(A)$$

where

$P(A)$ = 0.05 = probability of the CEO being fired
$P(B)$ = 0.50 = probability of a "good" rating
$P(B \mid A)$ = 0.30 = probability of a "good" rating given that the CEO is fired

With these estimates, the probability of the CEO being fired given a "good" rating is

$$P(A \mid B) = \frac{P(B \mid A)}{P(B)}P(A) = \frac{0.30}{0.50} \times 0.05 = 0.03$$

Although 5% of all CEOs are fired, the probability of being fired given a "good" performance rating is 3%.

29 C is correct. The combination formula provides the number of ways that *r* objects can be chosen from a total of *n* objects, when the order in which the *r* objects are listed does not matter. The order of the bonds within the portfolio does not matter.

30 A is correct. The answer is found using the combination formula

$$_{n}C_{r} = \binom{n}{r} = \frac{n!}{(n-r)!r!}$$

Here, $n = 4$ and $r = 2$, so the answer is $4!/[(4-2)!2!] = 24/[(2) \times (2)] = 6$. This result can be verified by assuming there are four vice presidents, VP1–VP4. The six possible additions to the investment committee are VP1 and VP2, VP1 and VP3, VP1 and VP4, VP2 and VP3, VP2 and VP4, and VP3 and VP4.

31 A is correct. The permutation formula is used to choose *r* objects from a total of *n* objects when order matters. Because the portfolio manager is trying to rank the four funds from most recommended to least recommended, the order of the funds matters; therefore, the permutation formula is most appropriate.

32 A is correct. The number of combinations is the number of ways to pick four mutual funds out of 10 without regard to order, which is

$$_{n}C_{r} = \frac{n!}{(n-r)!r!}$$

$$_{10}C_{4} = \frac{10!}{(10-4)!4!} = \frac{10 \times 9 \times 8 \times 7}{4 \times 3 \times 2 \times 1} = 210$$

33 B is correct. The number of permutations is the number of ways to pick five stocks out of 30 in the correct order.

$$_{n}P_{r} = \frac{n!}{(n-r)!r!}$$

$$_{30}P_{5} = \frac{30!}{(30-5)!} = \frac{30!}{25!} = 30 \times 29 \times 28 \times 27 \times 26 = 17{,}100{,}720$$

The contestant's chance of winning is one out of 17,100,720.

34 A is correct. The number of combinations is the number of ways to pick five stocks out of 30 without regard to order.

$$_nC_r = \frac{n!}{(n-r)!r!}$$

$$_{30}C_5 = \frac{30!}{(30-5)!5!} = \frac{30 \times 29 \times 28 \times 27 \times 26}{5 \times 4 \times 3 \times 2 \times 1} = 142{,}506$$

The contestant's chance of winning is one out of 142,506.

35 This contest does not resemble a usual lottery. Each of the 30 stocks does not have an equal chance of having the highest returns. Furthermore, contestants may have some favored investments, and the 30 stocks will not be chosen with the same frequencies. To guard against more than one person selecting the winners correctly, Sturm may wish to stipulate that if there is more than one winner, the winners will share the $1 million prize.

QUANTITATIVE METHODS
STUDY SESSION
2

Quantitative Methods (2)

This study session introduces the common probability distributions used to describe the behavior of random variables, such as asset prices and returns. How to estimate measures of a population (mean, standard deviation) based on a population sample is shown. The study session provides a framework for hypothesis testing, used for validating dataset hypotheses, along with techniques to test a hypothesis. Finally, simple linear regression is presented as a method for understanding the relationship between two variables as a way of making predictions.

Richard A. DeFusco, PhD, CFA, is at the University of Nebraska–Lincoln (USA). Dennis W. McLeavey, DBA, CFA, is at the University of Rhode Island (USA). Jerald E. Pinto, PhD, CFA. David E. Runkle, PhD, CFA, is at Jacobs Levy Equity Management (USA).

CFA Institute would like to thank Adam Kobor, PhD, CFA, at New York University Investment Office (USA), for this major revision of "Common Probability Distributions," including new visuals, graphics, Microsoft Excel functions, code snippets, and related text content throughout the reading.

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** define a probability distribution and compare and contrast discrete and continuous random variables and their probability functions;
☐	**b.** calculate and interpret probabilities for a random variable given its cumulative distribution function;
☐	**c.** describe the properties of a discrete uniform random variable, and calculate and interpret probabilities given the discrete uniform distribution function;
☐	**d.** describe the properties of the continuous uniform distribution, and calculate and interpret probabilities given a continuous uniform distribution;
☐	**e.** describe the properties of a Bernoulli random variable and a binomial random variable, and calculate and interpret probabilities given the binomial distribution function;
☐	**f.** explain the key properties of the normal distribution;
☐	**g.** contrast a multivariate distribution and a univariate distribution, and explain the role of correlation in the multivariate normal distribution;
☐	**h.** calculate the probability that a normally distributed random variable lies inside a given interval;
☐	**i.** explain how to standardize a random variable;
☐	**j.** calculate and interpret probabilities using the standard normal distribution;

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**k.** define shortfall risk, calculate the safety-first ratio, and identify an optimal portfolio using Roy's safety-first criterion;
☐	**l.** explain the relationship between normal and lognormal distributions and why the lognormal distribution is used to model asset prices;
☐	**m.** calculate and interpret a continuously compounded rate of return, given a specific holding period return;
☐	**n.** describe the properties of the Student's *t*-distribution, and calculate and interpret its degrees of freedom;
☐	**o.** describe the properties of the chi-square distribution and the *F*-distribution, and calculate and interpret their degrees of freedom;
☐	**p.** describe Monte Carlo simulation.

1

INTRODUCTION AND DISCRETE RANDOM VARIABLES

a define a probability distribution and compare and contrast discrete and continuous random variables and their probability functions

Probabilities play a critical role in investment decisions. Although we cannot predict the future, informed investment decisions are based on some kind of probabilistic thinking. An analyst may put probability estimates behind the success of her high-conviction or low-conviction stock recommendations. Risk managers would typically think in probabilistic terms: What is the probability of not achieving the target return, or what kind of losses are we facing with high likelihood over the relevant time horizon? Probability distributions also underpin validating trade signal–generating models: For example, does earnings revision play a significant role in forecasting stock returns?

In nearly all investment decisions, we work with random variables. The return on a stock and its earnings per share are familiar examples of random variables. To make probability statements about a random variable, we need to understand its probability distribution. A **probability distribution** specifies the probabilities associated with the possible outcomes of a random variable.

In this reading, we present important facts about seven probability distributions and their investment uses. These seven distributions—the uniform, binomial, normal, lognormal, Student's *t*-, chi-square, and *F*-distributions—are used extensively in investment analysis. Normal and binomial distributions are used in such basic valuation models as the Black–Scholes–Merton option pricing model, the binomial option pricing model, and the capital asset pricing model. Student's *t*-, chi-square, and *F*-distributions are applied in validating statistical significance and in hypothesis testing. With the working knowledge of probability distributions provided in this reading, you will be better prepared to study and use other quantitative methods, such as regression analysis, time-series analysis, and hypothesis testing. After discussing probability distributions, we end with an introduction to Monte Carlo simulation, a computer-based tool for obtaining information on complex investment problems.

We start by defining basic concepts and terms, then illustrate the operation of these concepts through the simplest distribution, the uniform distribution, and then address probability distributions that have more applications in investment work but also greater complexity.

1.1 Discrete Random Variables

b calculate and interpret probabilities for a random variable given its cumulative distribution function

A **random variable** is a quantity whose future outcomes are uncertain. The two basic types of random variables are discrete random variables and continuous random variables. A **discrete random variable** can take on at most a countable (possibly infinite) number of possible values. For example, a discrete random variable X can take on a limited number of outcomes $x_1, x_2, \ldots, x_n$ (n possible outcomes), or a discrete random variable Y can take on an unlimited number of outcomes $y_1, y_2, \ldots$ (without end). The number of "yes" votes at a corporate board meeting, for example, is a discrete variable that is countable and finite (from 0 to the voting number of board members). The number of trades at a stock exchange is also countable but is infinite, since there is no limit to the number of trades by the market participants. Note that X refers to the random variable, and x refers to an outcome of X. We subscript outcomes, as in x_1 and x_2, when we need to distinguish among different outcomes in a list of outcomes of a random variable. Since we can count all the possible outcomes of X and Y (even if we go on forever in the case of Y), both X and Y satisfy the definition of a discrete random variable.

In contrast, we cannot count the outcomes of a **continuous random variable**. We cannot describe the possible outcomes of a continuous random variable Z with a list $z_1, z_2, \ldots$, because the outcome $(z_1 + z_2)/2$, not in the list, would always be possible. The volume of water in a glass is an example of a continuous random variable since we cannot "count" water on a discrete scale but can only measure its volume. In finance, unless a variable exhibits truly discrete behavior—for example, a positive or negative earnings surprise or the number of central bank board members voting for a rate hike—it is practical to work with a continuous distribution in many cases. The rate of return on an investment is an example of such a continuous random variable.

In working with a random variable, we need to understand its possible outcomes. For example, a majority of the stocks traded on the New Zealand Stock Exchange are quoted in increments of NZ$0.01. Quoted stock price is thus a discrete random variable with possible values NZ$0, NZ$0.01, NZ$0.02, . . ., but we can also model stock price as a continuous random variable (as a lognormal random variable, to look ahead). In many applications, we have a choice between using a discrete or a continuous distribution. We are usually guided by which distribution is most efficient for the task we face. This opportunity for choice is not surprising, because many discrete distributions can be approximated with a continuous distribution, and vice versa. In most practical cases, a probability distribution is only a mathematical idealization, or approximate model, of the relative frequencies of a random variable's possible outcomes.

Every random variable is associated with a probability distribution that describes the variable completely. We can view a probability distribution in two ways. The basic view is the **probability function**, which specifies the probability that the random variable takes on a specific value: $P(X = x)$ is the probability that a random variable X takes on the value x. For a discrete random variable, the shorthand notation for the probability function (sometimes referred to as the "probability mass function") is $p(x) = P(X = x)$. For continuous random variables, the probability function is denoted $f(x)$ and called the **probability density function** (pdf), or just the density.

A probability function has two key properties (which we state, without loss of generality, using the notation for a discrete random variable):

- $0 \le p(x) \le 1$, because probability is a number between 0 and 1.
- The sum of the probabilities $p(x)$ over all values of X equals 1. If we add up the probabilities of all the distinct possible outcomes of a random variable, that sum must equal 1.
- calculate and interpret probabilities for a random variable given its cumulative distribution function

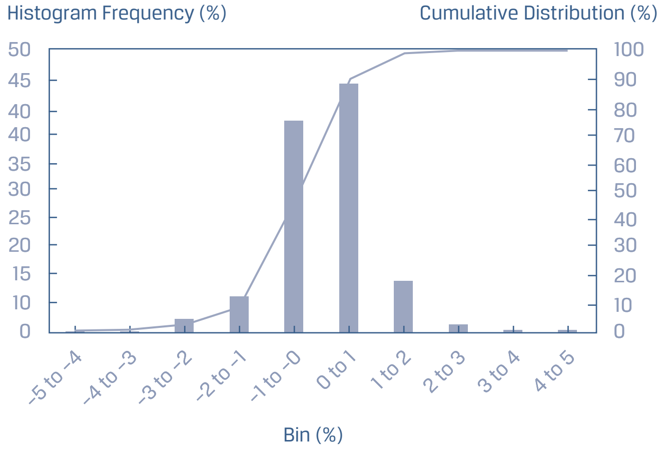
We are often interested in finding the probability of a range of outcomes rather than a specific outcome. In these cases, we take the second view of a probability distribution, the cumulative distribution function (cdf). The **cumulative distribution function**, or distribution function for short, gives the probability that a random variable X is less than or equal to a particular value x, $P(X \le x)$. For both discrete and continuous random variables, the shorthand notation is $F(x) = P(X \le x)$. How does the cumulative distribution function relate to the probability function? The word "cumulative" tells the story. To find $F(x)$, we sum up, or accumulate, values of the probability function for all outcomes less than or equal to x. The function of the cdf is parallel to that of cumulative relative frequency.

We illustrate the concepts of probability density functions and cumulative distribution functions with an empirical example using daily returns (i.e., percentage changes) of the fictitious Euro-Asia-Africa (EAA) Equity Index. This dataset spans five years and consists of 1,258 observations, with a minimum value of −4.1%, a maximum value of 5.0%, a range of 9.1%, and a mean daily return of 0.04%.

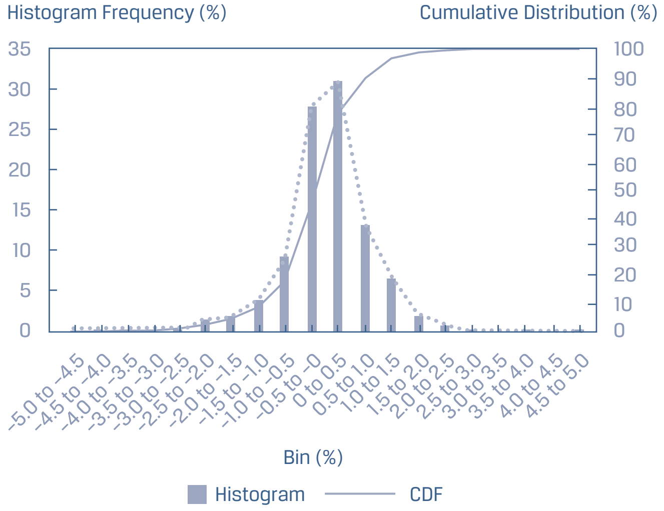
Exhibit 1 depicts the histograms, representing pdfs, and empirical cdfs (i.e., accumulated values of the bars in the histograms) based on daily returns of the EAA Equity Index. Panels A and B represent the same dataset; the only difference is the histogram bins used in Panel A are wider than those used in Panel B, so naturally Panel B has more bins. Note that in Panel A, we divided the range of observed daily returns (−5% to 5%) into 10 bins, so we chose the bin width to be 1.0%. In Panel B, we wanted a more granular histogram with a narrower range, so we divided the range into 20 bins, resulting in a bin width of 0.5%. Panel A gives a sense of the observed range of daily index returns, whereas Panel B is much more granular, so it more closely resembles continuous pdf and cdf graphs.

Exhibit 1 PDFs and CDFs of Daily Returns for EAA Equity Index

A. Wide Bin Widths



B. Narrow Bin Widths



EXAMPLE 1

Using PDFs and CDFs of Discrete and Continuous Random Variables to Calculate Probabilities

A. Discrete Random Variables: Rolling a Die

The example of rolling a six-sided die is an easy and intuitive way to illustrate a discrete random variable's pdf and cdf.

1 What is the probability that you would roll the number 3?

2 What is the probability that you would roll a number less than or equal to 3?

B. Continuous Random Variables: EAA Index Return

We use the EAA Index to illustrate the pdf and cdf for a continuously distributed random variable. Since daily returns can take on *any* numbers within a reasonable range rather than having discrete outcomes, we represent the pdf in the context of bins (as shown in the following table).

Bin	PDF	Bin	PDF
−5% to −4%	0.1%	0% to 1%	44.1%
−4% to −3%	0.6%	1% to 2%	8.8%
−3% to −2%	1.8%	2% to 3%	1.0%
−2% to −1%	6.1%	3% to 4%	0.1%
−1% to 0%	37.4%	4% to 5%	0.1%

In our sample, we did not find any daily returns below −5%, and we found only 0.1% of the total observations between −5% and −4%. In the next bin, −4% to −3%, we found 0.6% of the total observations, and so on.

3 If this empirical pdf is a guide for the future, what is the probability that we will see a daily return less than −2%?

Solution to 1:

Assuming the die is fair, rolling any number from 1 to 6 has a probability of 1/6 each, so the chance of rolling the number 3 would also equal 1/6. This outcome represents the pdf of this game; the pdf at number 3 takes a value of 1/6. In fact, it takes a value of 1/6 at every number from 1 to 6.

Solution to 2:

Answering this question involves the cdf of the die game. Three possible events would satisfy our criterion—namely, rolling 1, 2, or 3. The probability of rolling any of these numbers would be 1/6, so by accumulating them from 1 to 3, we get a probability of 3/6, or ½. The cdf of rolling a die takes a value of 1/6 at number 1, 3/6 (or 50%) at number 3, and 6/6 (or 100%) at number 6.

Solution to 3:

We must calculate the cdf up to −2%. The answer is the sum of the pdfs of the first three bins (see the shaded rectangle in the table provided); 0.1% + 0.6% + 1.8% = 2.5%. So, the probability that we will see a daily return less than −2% is 2.5%.

Next, we illustrate these concepts with examples and show how we use discrete and continuous distributions. We start with the simplest distribution, the discrete uniform distribution.

2 DISCRETE AND CONTINUOUS UNIFORM DISTRIBUTION

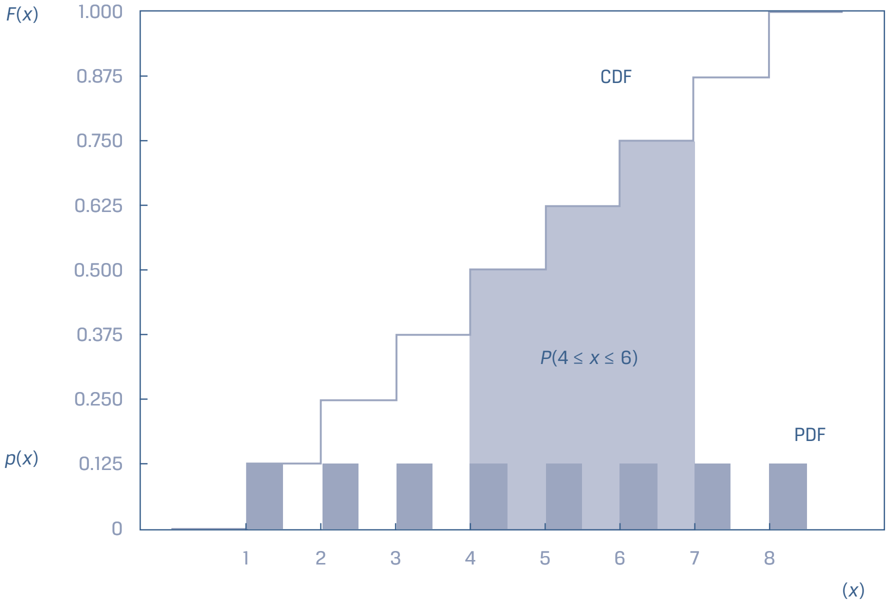
c describe the properties of a discrete uniform random variable, and calculate and interpret probabilities given the discrete uniform distribution function

The simplest of all probability distributions is the discrete uniform distribution. Suppose that the possible outcomes are the integers (whole numbers) 1–8, inclusive, and the probability that the random variable takes on any of these possible values is the same for all outcomes (that is, it is uniform). With eight outcomes, $p(x) = 1/8$, or 0.125, for all values of X ($X = 1, 2, 3, 4, 5, 6, 7, 8$); this statement is a complete description of this discrete uniform random variable. The distribution has a finite number of specified outcomes, and each outcome is equally likely. Exhibit 2 summarizes the two views of this random variable, the probability function and the cumulative distribution function, with Panel A in tabular form and Panel B in graphical form.

Exhibit 2 PDF and DCF for Discrete Uniform Random Variable

A. Probability Function and Cumulative Distribution Function for a Discrete Uniform Random Variable

$X = x$	Probability Function $p(x) = P(X = x)$	Cumulative Distribution Function $F(x) = P(X \le x)$
1	0.125	0.125
2	0.125	0.250
3	0.125	0.375
4	0.125	0.500
5	0.125	0.625
6	0.125	0.750
7	0.125	0.875
8	0.125	1.000



B. Graph of PDF and CDF for Discrete Uniform Random Variable

We can use the table in Panel A to find three probabilities: $P(X \le 7)$, $P(4 \le X \le 6)$, and $P(4 < X \le 6)$. The following examples illustrate how to use the cdf to find the probability that a random variable will fall in any interval (for any random variable, not only the uniform one). The results can also be gleaned visually from the graph in Panel B.

- The probability that X is less than or equal to 7, $P(X \le 7)$, is the next-to-last entry in the third column: 0.875, or 87.5%.
- To find $P(4 \le X \le 6)$, we need to find the sum of three probabilities: $p(4)$, $p(5)$, and $p(6)$. We can find this sum in two ways. We can add $p(4)$, $p(5)$, and $p(6)$ from the second column. Or we can calculate the probability as the difference between two values of the cumulative distribution function:

  $$F(6) = P(X \le 6) = p(6) + p(5) + p(4) + p(3) + p(2) + p(1),$$

  and

  $$F(3) = P(X \le 3) = p(3) + p(2) + p(1),$$

  so

  $$P(4 \le X \le 6) = F(6) - F(3) = p(6) + p(5) + p(4) = 3/8.$$

  So, we calculate the second probability as $F(6) - F(3) = 3/8$. This can be seen as the shaded area under the step function cdf graph in Panel B.
- The third probability, $P(4 < X \le 6)$, the probability that X is less than or equal to 6 but greater than 4, is $p(5) + p(6)$. We compute it as follows, using the cdf:

  $$P(4 < X \le 6) = P(X \le 6) - P(X \le 4) = F(6) - F(4) = p(6) + p(5) = 2/8.$$

  So we calculate the third probability as $F(6) - F(4) = 2/8$.

Suppose we want to check that the discrete uniform probability function satisfies the general properties of a probability function given earlier. The first property is $0 \le p(x) \le 1$. We see that $p(x) = 1/8$ for all x in the first column of in Panel A. [Note that $p(x)$ equals 0 for numbers x that are not in that column, such as −14 or 12.215.] The first property is satisfied. The second property is that the probabilities sum to 1. The entries in the second column of Panel A do sum to 1.

The cdf has two other characteristic properties:

- The cdf lies between 0 and 1 for any x: $0 \le F(x) \le 1$.
- As x increases, the cdf either increases or remains constant.

Check these statements by looking at the third column in the table in Panel A and at the graph in Panel B.

We now have some experience working with probability functions and cdfs for discrete random variables. Later, we will discuss Monte Carlo simulation, a methodology driven by random numbers. As we will see, the uniform distribution has an important technical use: It is the basis for generating random numbers, which, in turn, produce random observations for all other probability distributions.

2.1 Continuous Uniform Distribution

d describe the properties of the continuous uniform distribution, and calculate and interpret probabilities given a continuous uniform distribution

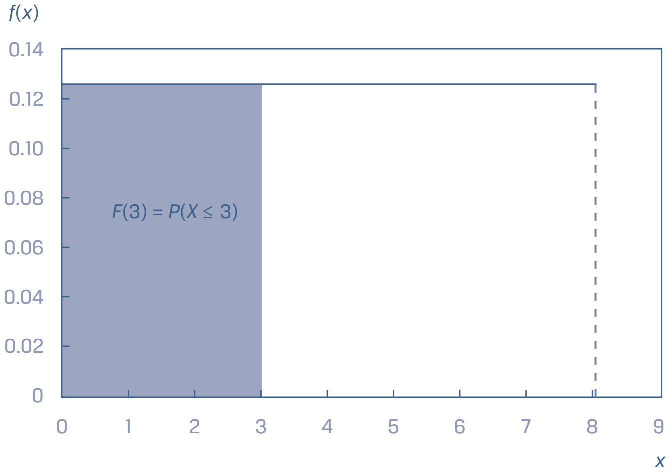
The continuous uniform distribution is the simplest continuous probability distribution. The uniform distribution has two main uses. As the basis of techniques for generating random numbers, the uniform distribution plays a role in Monte Carlo simulation. As the probability distribution that describes equally likely outcomes, the uniform distribution is an appropriate probability model to represent a particular kind of uncertainty in beliefs in which all outcomes appear equally likely.

The pdf for a uniform random variable is

$$f(x) = \begin{cases} \dfrac{1}{b-a} & \text{for } a \le x \le b \\ 0 & \text{otherwise} \end{cases}$$

For example, with $a = 0$ and $b = 8$, $f(x) = 1/8$, or 0.125. We graph this density in Exhibit 3.

Exhibit 3 Probability Density Function for a Continuous Uniform Distribution



The graph of the density function plots as a horizontal line with a value of 0.125.

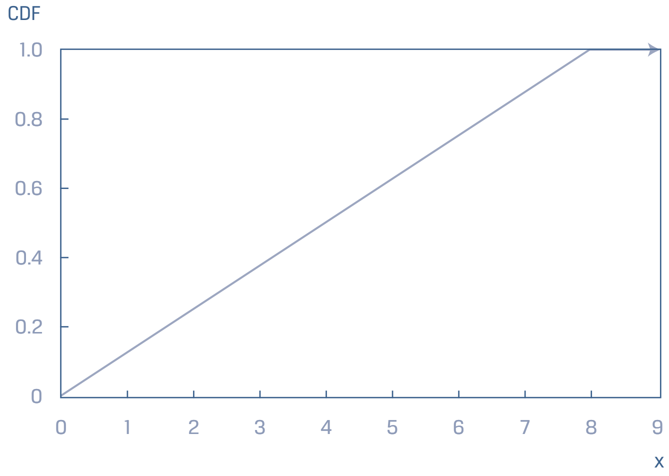
What is the probability that a uniform random variable with limits $a = 0$ and $b = 8$ is less than or equal to 3, or $F(3) = P(X \le 3)$? When we were working with the discrete uniform random variable with possible outcomes 1, 2, . . ., 8, we summed individual probabilities: $p(1) + p(2) + p(3) = 0.375$. In contrast, the probability that a continuous uniform random variable or any continuous random variable assumes any given fixed value is 0. To illustrate this point, consider the narrow interval 2.510–2.511. Because that interval holds an infinity of possible values, the sum of the probabilities of values in that interval alone would be infinite if each individual value in it had a positive probability. To find the probability $F(3)$, we find the area under the curve graphing the pdf, between 0 and 3 on the x-axis (shaded area in Exhibit 3). In calculus, this operation is called integrating the probability function $f(x)$ from 0 to 3. This area under the curve is a rectangle with base $3 - 0 = 3$ and height 1/8. The area of this rectangle equals base times height: $3(1/8) = 3/8$, or 0.375. So $F(3) = 3/8$, or 0.375.

The interval from 0 to 3 is three-eighths of the total length between the limits of 0 and 8, and $F(3)$ is three-eighths of the total probability of 1. The middle line of the expression for the cdf captures this relationship:

$$F(x) = \begin{cases} 0 \text{ for } x < a \\ \dfrac{x-a}{b-a} \text{ for } a \le x \le b. \\ 1 \text{ for } x < b \end{cases}$$

For our problem, $F(x) = 0$ for $x \le 0$, $F(x) = x/8$ for $0 < x < 8$, and $F(x) = 1$ for $x \ge 8$. Exhibit 4 shows a graph of this cdf.

Exhibit 4 Continuous Uniform Cumulative Distribution



The mathematical operation that corresponds to finding the area under the curve of a pdf $f(x)$ from a to b is the definite integral of $f(x)$ from a to b:

$$P(a \le X \le b) = \int_a^b f(x)dx, \tag{1}$$

where $\int dx$ is the symbol for summing $\int$ over small changes dx and the limits of integration (a and b) can be any real numbers or $-\infty$ and $+\infty$. All probabilities of continuous random variables can be computed using Equation 1. For the uniform distribution example considered previously, $F(7)$ is Equation 1 with lower limit $a = 0$ and upper limit $b = 7$. The integral corresponding to the cdf of a uniform distribution reduces to the three-line expression given previously. To evaluate Equation 1 for nearly all other continuous distributions, including the normal and lognormal, we rely on spreadsheet functions, computer programs, or tables of values to calculate probabilities. Those tools use various numerical methods to evaluate the integral in Equation 1.

Recall that the probability of a continuous random variable equaling any fixed point is 0. This fact has an important consequence for working with the cumulative distribution function of a continuous random variable: For any continuous random variable X, $P(a \le X \le b) = P(a < X \le b) = P(a \le X < b) = P(a < X < b)$, because the probabilities at the endpoints a and b are 0. For discrete random variables, these relations of equality are not true, because for them probability accumulates at points.

EXAMPLE 2

Probability That a Lending Facility Covenant Is Breached

You are evaluating the bonds of a below-investment-grade borrower at a low point in its business cycle. You have many factors to consider, including the terms of the company's bank lending facilities. The contract creating a bank lending facility such as an unsecured line of credit typically has clauses known as covenants. These covenants place restrictions on what the borrower can do. The company will be in breach of a covenant in the lending facility if the interest coverage ratio, EBITDA/interest, calculated on EBITDA over the four trailing quarters, falls below 2.0. EBITDA is earnings before interest, taxes, depreciation, and amortization. Compliance with the covenants will be checked at the end of the current quarter. If the covenant is breached, the bank can demand immediate repayment of all borrowings on the facility. That action would probably trigger a liquidity crisis for the company. With a high degree of confidence, you forecast interest charges of $25 million. Your estimate of EBITDA runs from $40 million on the low end to $60 million on the high end.

Address two questions (treating projected interest charges as a constant):

1. If the outcomes for EBITDA are equally likely, what is the probability that EBITDA/interest will fall below 2.0, breaching the covenant?
2. Estimate the mean and standard deviation of EBITDA/interest. For a continuous uniform random variable, the mean is given by $\mu = (a + b)/2$ and the variance is given by $\sigma^2 = (b - a)^2/12$.

Solution to 1:

EBITDA/interest is a continuous uniform random variable because all outcomes are equally likely. The ratio can take on values between 1.6 = ($40 million)/($25 million) on the low end and 2.4 = ($60 million/$25 million) on the high end. The range of possible values is 2.4 − 1.6 = 0.8. The fraction of possible values falling below 2.0, the level that triggers default, is the distance between 2.0 and 1.6, or 0.40; the value 0.40 is one-half the total length of 0.8, or 0.4/0.8 = 0.50. So, the probability that the covenant will be breached is 50%.

Solution to 2:

In Solution 1, we found that the lower limit of EBITDA/interest is 1.6. This lower limit is a. We found that the upper limit is 2.4. This upper limit is b. Using the formula given previously,

$$\mu = (a + b)/2 = (1.6 + 2.4)/2 = 2.0.$$

The variance of the interest coverage ratio is

$$\sigma^2 = (b - a)^2/12 = (2.4 - 1.6)^2/12 = 0.053333.$$

The standard deviation is the positive square root of the variance, $0.230940 = (0.053333)^{1/2}$. However, the standard deviation is not particularly useful as a risk measure for a uniform distribution. The probability that lies within various standard deviation bands around the mean is sensitive to different specifications of the upper and lower. Here, a one standard deviation interval around the mean of 2.0 runs from 1.769 to 2.231 and captures 0.462/0.80 = 0.5775, or 57.8%, of the probability. A two standard deviation interval runs from 1.538 to 2.462, which extends past both the lower and upper limits of the random variable.

3 BINOMIAL DISTRIBUTION

e describe the properties of a Bernoulli random variable and a binomial random variable, and calculate and interpret probabilities given the binomial distribution function

In many investment contexts, we view a result as either a success or a failure or as binary (twofold) in some other way. When we make probability statements about a record of successes and failures or about anything with binary outcomes, we often use the binomial distribution. What is a good model for how a stock price moves over time? Different models are appropriate for different uses. Cox, Ross, and Rubinstein (1979) developed an option pricing model based on binary moves—price up or price down—for the asset underlying the option. Their binomial option pricing model was the first of a class of related option pricing models that have played an important role in the development of the derivatives industry. That fact alone would be sufficient reason for studying the binomial distribution, but the binomial distribution has uses in decision making as well.

The building block of the binomial distribution is the **Bernoulli random variable**, named after the Swiss probabilist Jakob Bernoulli (1654–1704). Suppose we have a trial (an event that may repeat) that produces one of two outcomes. Such a trial is a **Bernoulli trial**. If we let Y equal 1 when the outcome is success and Y equal 0 when the outcome is failure, then the probability function of the Bernoulli random variable Y is

$$p(1) = P(Y = 1) = p$$

and

$$p(0) = P(Y = 0) = 1 - p,$$

where p is the probability that the trial is a success.

In n Bernoulli trials, we can have 0 to n successes. If the outcome of an individual trial is random, the total number of successes in n trials is also random. A **binomial random variable** X is defined as the number of successes in n Bernoulli trials. A binomial random variable is the sum of Bernoulli random variables Y_i, where $i = 1, 2, \ldots, n$:

$$X = Y_1 + Y_2 + \ldots + Y_n,$$

where Y_i is the outcome on the ith trial (1 if a success, 0 if a failure). We know that a Bernoulli random variable is defined by the parameter p. The number of trials, n, is the second parameter of a binomial random variable. The binomial distribution makes these assumptions:

- The probability, p, of success is constant for all trials.
- The trials are independent.

The second assumption has great simplifying force. If individual trials were correlated, calculating the probability of a given number of successes in n trials would be much more complicated.

Under these two assumptions, a binomial random variable is completely described by two parameters, n and p. We write

$$X \sim B(n, p),$$

which we read as "X has a binomial distribution with parameters n and p." You can see that a Bernoulli random variable is a binomial random variable with $n = 1$: $Y \sim B(1, p)$.

Now we can find the general expression for the probability that a binomial random variable shows x successes in n trials (also known as the probability mass function). We can think in terms of a model of stock price dynamics that can be generalized to allow any possible stock price movements if the periods are made extremely small.

Each period is a Bernoulli trial: With probability p, the stock price moves up; with probability $1 - p$, the price moves down. A success is an up move, and x is the number of up moves or successes in n periods (trials). With each period's moves independent and p constant, the number of up moves in n periods is a binomial random variable. We now develop an expression for $P(X = x)$, the probability function for a binomial random variable.

Any sequence of n periods that shows exactly x up moves must show $n - x$ down moves. We have many different ways to order the up moves and down moves to get a total of x up moves, but given independent trials, any sequence with x up moves must occur with probability $p^x(1 - p)^{n-x}$. Now we need to multiply this probability by the number of different ways we can get a sequence with x up moves. Using a basic result in counting, there are

$$\frac{n!}{(n-x)!x!}$$

different sequences in n trials that result in x up moves (or successes) and $n - x$ down moves (or failures). Recall that for positive integers n, n factorial ($n!$) is defined as $n(n - 1)(n - 2) \ldots 1$ (and $0! = 1$ by convention). For example, $5! = (5)(4)(3)(2)(1) = 120$. The combination formula $n!/[(n - x)!x!]$ is denoted by

$$\binom{n}{x}$$

(read "n combination x" or "n choose x"). For example, over three periods, exactly three different sequences have two up moves: *uud*, *udu*, and *duu*. We confirm this by

$$\binom{3}{2} = \frac{3!}{(3-2)!2!} = \frac{(3)(2)(1)}{(1)(2)(1)} = 3.$$

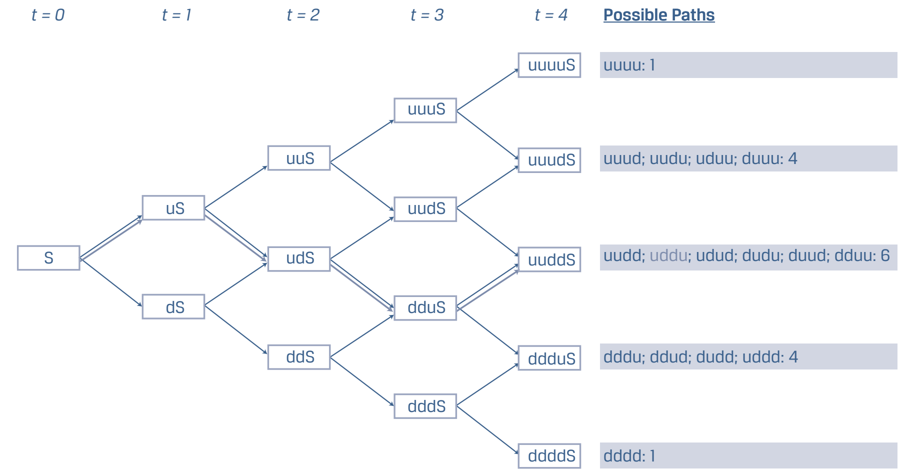
If, hypothetically, each sequence with two up moves had a probability of 0.15, then the total probability of two up moves in three periods would be 3 × 0.15 = 0.45. This example should persuade you that for X distributed $B(n, p)$, the probability of x successes in n trials is given by

$$p(x) = P(X = x) = \binom{n}{x} p^x (1-p)^{n-x} = \frac{n!}{(n-x)!x!} p^x (1-p)^{n-x}. \tag{2}$$

Some distributions are always symmetric, such as the normal, and others are always asymmetric or skewed, such as the lognormal. The binomial distribution is symmetric when the probability of success on a trial is 0.50, but it is asymmetric or skewed otherwise.

We illustrate Equation 2 (the probability function) and the cdf through the symmetrical case by modeling the behavior of stock price movements on four consecutive trading days in a binomial tree framework. Each day is an independent trial. The stock moves up with constant probability p (the **up transition probability**); if it moves up, u is 1 plus the rate of return for an up move. The stock moves down with constant probability $1 - p$ (the **down transition probability**); if it moves down, d is 1 plus the rate of return for a down move. The **binomial tree** is shown in Exhibit 5, where we now associate each of the $n = 4$ stock price moves with time indexed by t; the shape of the graph suggests why it is a called a binomial tree. Each boxed value from which successive moves or outcomes branch out in the tree is called a **node**. The initial node, at $t = 0$, shows the beginning stock price, S. Each subsequent node represents a potential value for the stock price at the specified future time.

Exhibit 5 A Binomial Model of Stock Price Movement



We see from the tree that the stock price at $t = 4$ has five possible values: *uuuuS*, *uuudS*, *uuddS*, *ddduS*, and *ddddS*. The probability that the stock price equals *any* one of these five values is given by the binomial distribution. For example, four sequences of moves result in a final stock price of *uuudS*: These are *uuud*, *uudu*, *uduu*, and *duuu*. These sequences have three up moves out of four moves in total; the combination formula confirms that the number of ways to get three up moves (successes) in four periods (trials) is $4!/(4 - 3)!3! = 4$. Next, note that each of these sequences—*uuud*, *uudu*, *uduu*, and *duuu*—has probability $p^3(1 - p)^1$, which equals 0.0625 ($= 0.50^3 \times 0.50^1$). So, $P(S_4 = uuudS) = 4[p^3(1 - p)]$, or 0.25, where S_4 indicates the stock's price after four moves. This is shown numerically in Panel A of Exhibit 6, in the line indicating three up moves in x, as well as graphically in Panel B, as the height of the bar above $x = 3$. Note that in Exhibit 6, columns 5 and 6 in Panel A show the pdf and cdf, respectively, for this binomial distribution, and in Panel B, the pdf and cdf are represented by the bars and the line graph, respectively.

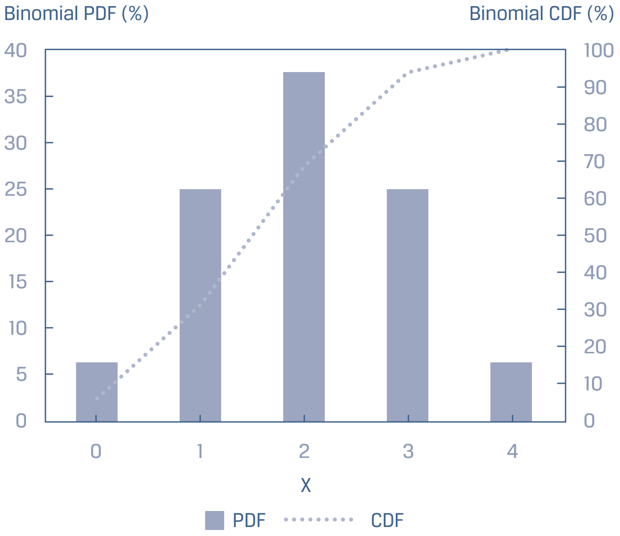
Exhibit 6 (Continued)

B. Graphs of Binomial PDF and CDF



To be clear, the binomial random variable in this application is the number of up moves. Final stock price distribution is a function of the initial stock price, the *number* of up moves, and the *size* of the up moves and down moves. We cannot say that stock price itself is a binomial random variable; rather, it is a function of a binomial random variable, as well as of u and d, and initial price, S. This richness is actually one key to why this way of modeling stock price is useful: It allows us to choose values of these parameters to approximate various distributions for stock price (using a large number of time periods). One distribution that can be approximated is the lognormal, an important continuous distribution model for stock price that we will discuss later. The flexibility extends further. In the binomial tree shown in Exhibit 5, the transition probabilities are the same at each node: p for an up move and $1 - p$ for a down move. That standard formula describes a process in which stock return volatility is constant over time. Derivatives experts, however, sometimes model changing volatility over time using a binomial tree in which the probabilities for up and down moves differ at different nodes.

EXAMPLE 3

A Trading Desk Evaluates Block Brokers

Blocks are orders to sell or buy that are too large for the liquidity ordinarily available in dealer networks or stock exchanges. Your firm has known interests in certain kinds of stock. Block brokers call your trading desk when they want to sell blocks of stocks that they think your firm may be interested in buying. You know that these transactions have definite risks. For example, if the broker's client (the seller) has unfavorable information on the stock or if the total amount he or she is selling through all channels is not truthfully communicated, you may see an immediate loss on the trade. Your firm regularly audits the performance of block brokers by calculating the post-trade, market-risk-adjusted returns on stocks purchased from block brokers. On that basis, you classify each trade as unprofitable or profitable. You have summarized the performance of the brokers in a spreadsheet, excerpted in the following table for November of last year. The broker names are coded BB001 and BB002.

Block Trading Gains and Losses

	Profitable Trades	Losing Trades
BB001	3	9
BB002	5	3

You now want to evaluate the performance of the block brokers, and you begin with two questions:

1. If you are paying a fair price on average in your trades with a broker, what should be the probability of a profitable trade?
2. Did each broker meet or miss that expectation on probability?

You also realize that the brokers' performance has to be evaluated in light of the sample sizes, and for that you need to use the binomial probability function (Equation 2).

3. Under the assumption that the prices of trades were fair,
   - **A** calculate the probability of three or fewer profitable trades with broker BB001.
   - **B** calculate the probability of five or more profitable trades with broker BB002.

Solution to 1:

If the price you trade at is fair, then 50% of the trades you do with a broker should be profitable.

Solution to 2:

Your firm has logged 3 + 9 = 12 trades with block broker BB001. Since 3 of the 12 trades were profitable, the portion of profitable trades was 3/12, or 25%. With broker BB002, the portion of profitable trades was 5/8, or 62.5%. The rate of profitable trades with broker BB001 of 25% clearly missed your performance expectation of 50%. Broker BB002, at 62.5% profitable trades, exceeded your expectation.

Solution to 3:

A For broker BB001, the number of trades (the trials) was $n = 12$, and 3 were profitable. You are asked to calculate the probability of three or fewer profitable trades, $F(3) = p(3) + p(2) + p(1) + p(0)$.

Suppose the underlying probability of a profitable trade with BB001 is $p = 0.50$. With $n = 12$ and $p = 0.50$, according to Equation 2 the probability of three profitable trades is

$$p(3) = \binom{n}{x} p^x (1-p)^{n-x} = \binom{12}{3}\left(0.50^3\right)\left(0.50^9\right)$$

$$= \frac{12!}{(12-3)!3!}0.50^{12} = 220(0.000244) = 0.053711.$$

The probability of exactly 3 profitable trades out of 12 is 5.4% if broker BB001 were giving you fair prices. Now you need to calculate the other probabilities:

$$p(2) = [12!/(12-2)!2!](0.50^2)(0.50^{10}) = 66(0.000244) = 0.016113.$$

$p(1) = [12!/(12 - 1)!1!](0.50^1)(0.50^{11}) = 12(0.000244) = 0.00293.$

$p(0) = [12!/(12 - 0)!0!](0.50^0)(0.50^{12}) = 1(0.000244) = 0.000244.$

Adding all the probabilities, $F(3) = 0.053711 + 0.016113 + 0.00293 + 0.000244 = 0.072998$, or 7.3%. The probability of making 3 or fewer profitable trades out of 12 would be 7.3% if your trading desk were getting fair prices from broker BB001.

B For broker BB002, you are assessing the probability that the underlying probability of a profitable trade with this broker was 50%, despite the good results. The question was framed as the probability of making five or more profitable trades if the underlying probability is 50%: $1 - F(4) = p(5) + p(6) + p(7) + p(8)$. You could calculate $F(4)$ and subtract it from 1, but you can also calculate $p(5) + p(6) + p(7) + p(8)$ directly.

You begin by calculating the probability that exactly five out of eight trades would be profitable if BB002 were giving you fair prices:

$$p(5) = \binom{8}{5}\left(0.50^5\right)\left(0.50^3\right)$$

$$= 56(0.003906) = 0.21875.$$

The probability is about 21.9%. The other probabilities are as follows:

$p(6) = 28(0.003906) = 0.109375.$

$p(7) = 8(0.003906) = 0.03125.$

$p(8) = 1(0.003906) = 0.003906.$

So, $p(5) + p(6) + p(7) + p(8) = 0.21875 + 0.109375 + 0.03125 + 0.003906 = 0.363281$, or 36.3%. A 36.3% probability is substantial; the underlying probability of executing a fair trade with BB002 might well have been 0.50 despite your success with BB002 in November of last year. If one of the trades with BB002 had been reclassified from profitable to unprofitable, exactly half the trades would have been profitable. In summary, your trading desk is getting at least fair prices from BB002; you will probably want to accumulate additional evidence before concluding that you are trading at better-than-fair prices.

The magnitude of the profits and losses in these trades is another important consideration. If all profitable trades had small profits but all unprofitable trades had large losses, for example, you might lose money on your trades even if the majority of them were profitable.

Two descriptors of a distribution that are often used in investments are the mean and the variance (or the standard deviation, the positive square root of variance). Exhibit 7 gives the expressions for the mean and variance of binomial random variables.

Exhibit 7 Mean and Variance of Binomial Random Variables

	Mean	Variance
Bernoulli, $B(1, p)$	P	$p(1 - p)$
Binomial, $B(n, p)$	Np	$np(1 - p)$

Because a single Bernoulli random variable, $Y \sim B(1, p)$, takes on the value 1 with probability p and the value 0 with probability $1 - p$, its mean or weighted-average outcome is p. Its variance is $p(1 - p)$. A general binomial random variable, $B(n, p)$, is the sum of n Bernoulli random variables, and so the mean of a $B(n, p)$ random variable is np. Given that a $B(1, p)$ variable has variance $p(1 - p)$, the variance of a $B(n, p)$ random variable is n times that value, or $np(1 - p)$, assuming that all the trials (Bernoulli random variables) are independent. We can illustrate the calculation for two binomial random variables with differing probabilities as follows:

Random Variable	Mean	Variance
$B(n = 5, p = 0.50)$	$2.50 = 5(0.50)$	$1.25 = 5(0.50)(0.50)$
$B(n = 5, p = 0.10)$	$0.50 = 5(0.10)$	$0.45 = 5(0.10)(0.90)$

For a $B(n = 5, p = 0.50)$ random variable, the expected number of successes is 2.5, with a standard deviation of $1.118 = (1.25)^{1/2}$; for a $B(n = 5, p = 0.10)$ random variable, the expected number of successes is 0.50, with a standard deviation of $0.67 = (0.45)^{1/2}$.

EXAMPLE 4

The Expected Number of Defaults in a Bond Portfolio

Suppose as a bond analyst you are asked to estimate the number of bond issues expected to default over the next year in an unmanaged high-yield bond portfolio with 25 US issues from distinct issuers. The credit ratings of the bonds in the portfolio are tightly clustered around Moody's B2/Standard & Poor's B, meaning that the bonds are speculative with respect to the capacity to pay interest and repay principal. The estimated annual default rate for B2/B rated bonds is 10.7%.

1. Over the next year, what is the expected number of defaults in the portfolio, assuming a binomial model for defaults?
2. Estimate the standard deviation of the number of defaults over the coming year.
3. Critique the use of the binomial probability model in this context.

Solution to 1:

For each bond, we can define a Bernoulli random variable equal to 1 if the bond defaults during the year and zero otherwise. With 25 bonds, the expected number of defaults over the year is $np = 25(0.107) = 2.675$, or approximately 3.

Solution to 2:

The variance is $np(1 - p) = 25(0.107)(0.893) = 2.388775$. The standard deviation is $(2.388775)^{1/2} = 1.55$. Thus, a two standard deviation confidence interval (± 3.10) about the expected number of defaults (≈ 3), for example, would run from approximately 0 to approximately 6.

Solution to 3:

An assumption of the binomial model is that the trials are independent. In this context, a trial relates to whether an individual bond issue will default over the next year. Because the issuing companies probably share exposure to common economic factors, the trials may not be independent. Nevertheless, for a quick estimate of the expected number of defaults, the binomial model may be adequate.

NORMAL DISTRIBUTION

4

f explain the key properties of the normal distribution

g contrast a multivariate distribution and a univariate distribution, and explain the role of correlation in the multivariate normal distribution

In this section, we focus on the two most important continuous distributions in investment work, the normal and lognormal.

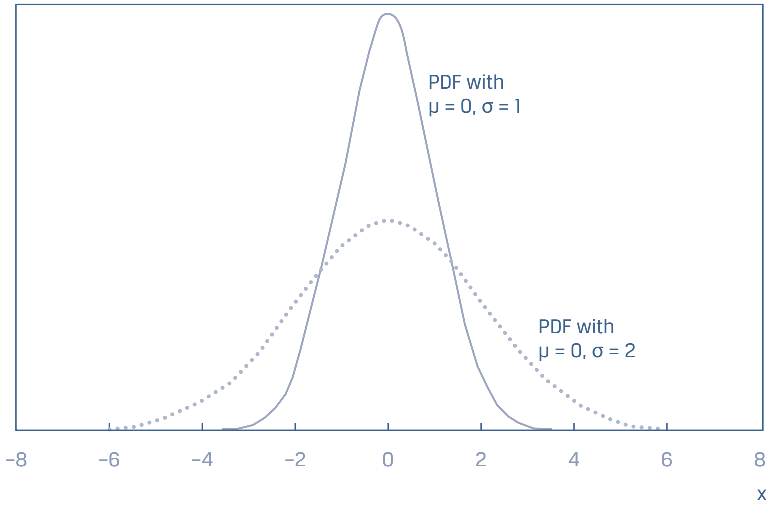
4.1 The Normal Distribution

The normal distribution may be the most extensively used probability distribution in quantitative work. It plays key roles in modern portfolio theory and in several risk management technologies. Because it has so many uses, the normal distribution must be thoroughly understood by investment professionals.

The role of the normal distribution in statistical inference and regression analysis is vastly extended by a crucial result known as the central limit theorem. The central limit theorem states that the sum (and mean) of a large number of independent random variables (with finite variance) is approximately normally distributed.

The French mathematician Abraham de Moivre (1667–1754) introduced the normal distribution in 1733 in developing a version of the central limit theorem. As Exhibit 8 shows, the normal distribution is symmetrical and bell-shaped. The range of possible outcomes of the normal distribution is the entire real line: all real numbers lying between $-\infty$ and $+\infty$. The tails of the bell curve extend without limit to the left and to the right.

Exhibit 8 PDFs of Two Different Normal Distributions



The defining characteristics of a normal distribution are as follows:

- The normal distribution is completely described by two parameters—its mean, μ, and variance, σ^2. We indicate this as $X \sim N(\mu, \sigma^2)$ (read "X follows a normal distribution with mean μ and variance σ^2"). We can also define a normal distribution in terms of the mean and the standard deviation, σ (this is often convenient because σ is measured in the same units as X and μ). As a consequence, we can answer any probability question about a normal random variable if we know its mean and variance (or standard deviation).
- The normal distribution has a skewness of 0 (it is symmetric). The normal distribution has a kurtosis of 3; its excess kurtosis (kurtosis − 3.0) equals 0. As a consequence of symmetry, the mean, the median, and the mode are all equal for a normal random variable.
- A linear combination of two or more normal random variables is also normally distributed.
- contrast a multivariate distribution and a univariate distribution, and explain the role of correlation in the multivariate normal distribution

The foregoing bullet points and descriptions concern a single variable or univariate normal distribution: the distribution of one normal random variable. A **univariate distribution** describes a single random variable. A **multivariate distribution** specifies the probabilities for a group of related random variables. You will encounter the **multivariate normal distribution** in investment work and readings and should know the following about it.

When we have a group of assets, we can model the distribution of returns on each asset individually or on the assets as a group. "As a group" implies that we take account of all the statistical interrelationships among the return series. One model that has often been used for security returns is the multivariate normal distribution. A multivariate normal distribution for the returns on n stocks is completely defined by three lists of parameters:

- the list of the mean returns on the individual securities (n means in total);
- the list of the securities' variances of return (n variances in total); and
- the list of all the distinct pairwise return correlations: $n(n - 1)/2$ distinct correlations in total.

The need to specify correlations is a distinguishing feature of the multivariate normal distribution in contrast to the univariate normal distribution.

The statement "assume returns are normally distributed" is sometimes used to mean a joint normal distribution. For a portfolio of 30 securities, for example, portfolio return is a weighted average of the returns on the 30 securities. A weighted average is a linear combination. Thus, portfolio return is normally distributed if the individual security returns are (joint) normally distributed. To review, in order to specify the normal distribution for portfolio return, we need the means, the variances, and the distinct pairwise correlations of the component securities.

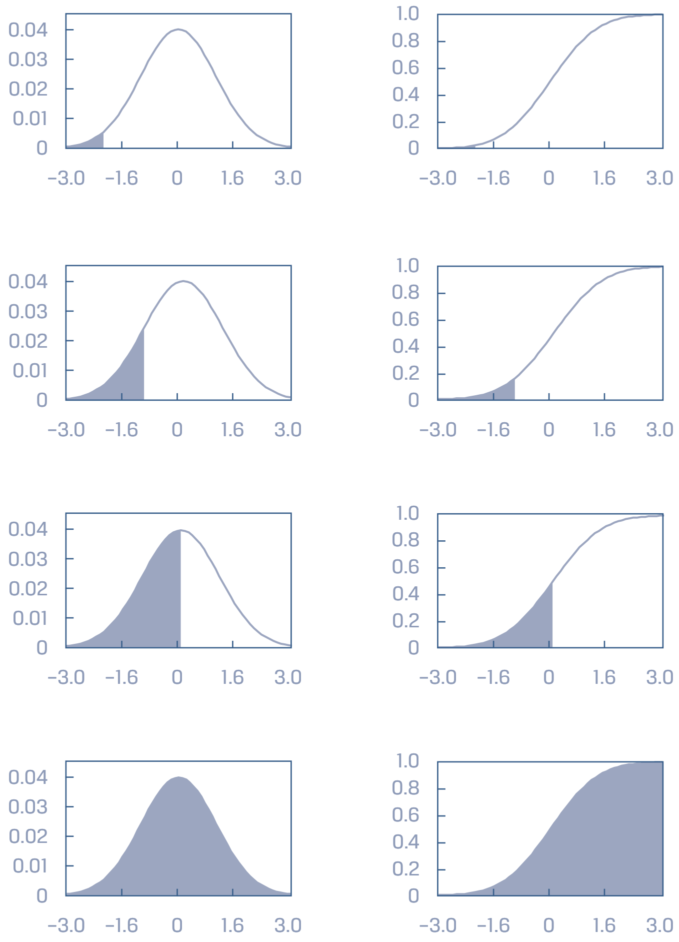
With these concepts in mind, we can return to the normal distribution for one random variable. The curves graphed in Exhibit 8 are the normal density function:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}}\exp\left(\frac{-(x-\mu)^2}{2\sigma^2}\right) \text{ for } -\infty < x < +\infty. \tag{3}$$

The two densities graphed in Exhibit 8 correspond to a mean of $\mu = 0$ and standard deviations of $\sigma = 1$ and $\sigma = 2$. The normal density with $\mu = 0$ and $\sigma = 1$ is called the **standard normal distribution** (or **unit normal distribution**). Plotting two normal distributions with the same mean and different standard deviations helps us appreciate why standard deviation is a good measure of dispersion for the normal distribution: Observations are much more concentrated around the mean for the normal distribution with $\sigma = 1$ than for the normal distribution with $\sigma = 2$.

Exhibit 9 illustrates the relationship between the pdf (density function) and cdf (distribution function) of the standard normal distribution (mean = 0, standard deviation = 1). Most of the time, we associate a normal distribution with the "bell curve," which, in fact, is the probability density function of the normal distribution, depicted in Panel A. The cumulative distribution function, depicted in Panel B, in fact plots the size of the shaded areas of the pdfs. Let's take a look at the third row: In Panel A, we have shaded the bell curve up to $x = 0$, the mean of the standard normal distribution. This shaded area corresponds to 50% in the cdf graph, as seen in Panel B, meaning that 50% of the observations of a normally distributed random variable would be equal or less than the mean.

Exhibit 9 Density and Distribution Functions of the Standard Normal Distribution



A. PDFs

B. CDFs

Although not literally accurate, the normal distribution can be considered an approximate model for asset returns. Nearly all the probability of a normal random variable is contained within three standard deviations of the mean. For realistic values of mean return and return standard deviation for many assets, the normal probability of outcomes below −100% is very small.

Whether the approximation is useful in a given application is an empirical question. For example, Fama (1976) and Campbell, Lo, and MacKinlay (1997) showed that the normal distribution is a closer fit for quarterly and yearly holding period returns on a diversified equity portfolio than it is for daily or weekly returns. A persistent departure from normality in most equity return series is kurtosis greater than 3, the fat-tails problem. So when we approximate equity return distributions with the normal distribution, we should be aware that the normal distribution tends to underestimate the probability of extreme returns.

Fat tails can be modeled, among other things, by a mixture of normal random variables or by a Student’s *t*-distribution (which we shall cover shortly). In addition, since option returns are skewed, we should be cautious in using the symmetrical normal distribution to model the returns on portfolios containing significant positions in options.

The normal distribution is also less suitable as a model for asset prices than as a model for returns. An asset price can drop only to 0, at which point the asset becomes worthless. As a result, practitioners generally do not use the normal distribution to model the distribution of asset prices but work with the lognormal distribution, which we will discuss later.

4.2 Probabilities Using the Normal Distribution

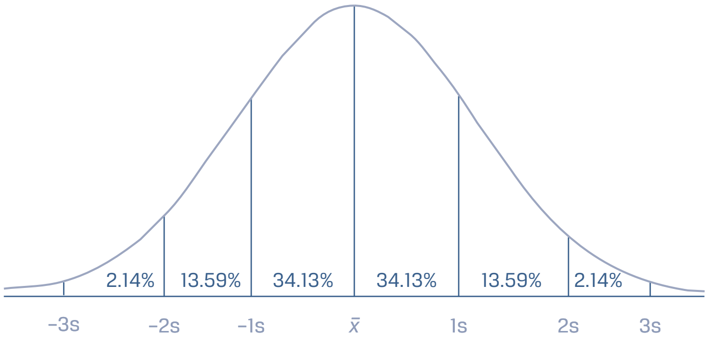
h calculate the probability that a normally distributed random variable lies inside a given interval

Having established that the normal distribution is the appropriate model for a variable of interest, we can use it to make the following probability statements:

- Approximately 50% of all observations fall in the interval $\mu \pm (2/3)\sigma$.
- Approximately 68% of all observations fall in the interval $\mu \pm \sigma$.
- Approximately 95% of all observations fall in the interval $\mu \pm 2\sigma$.
- Approximately 99% of all observations fall in the interval $\mu \pm 3\sigma$.

One, two, and three standard deviation intervals are illustrated in Exhibit 10. The intervals indicated are easy to remember but are only approximate for the stated probabilities. More precise intervals are $\mu \pm 1.96\sigma$ for 95% of the observations and $\mu \pm 2.58\sigma$ for 99% of the observations.

Exhibit 10 Units of Standard Deviation



In general, we do not observe the mean or the standard deviation of the distribution of the whole population, so we need to estimate them from an observable sample. We estimate the population mean, μ, using the sample mean, $\overline{X}$ (sometimes denoted as $\hat{\mu}$), and estimate the population standard deviation, σ, using the sample standard deviation, *s* (sometimes denoted as $\hat{\sigma}$).

EXAMPLE 5

Calculating Probabilities from the Normal Distribution

The chief investment officer of Fund XYZ would like to present some investment return scenarios to the Investment Committee, so she asks your assistance with some indicative numbers. Assuming daily asset returns are normally distributed, she would like to know the following:

1. What is the probability that returns would be less than or equal to 1 standard deviation below the mean?
2. What is the probability that returns would be between +1 and −1 standard deviation around the mean?
3. What is the probability that returns would be less than or equal to −2 standard deviations below the mean?
4. How far (in terms of standard deviation) must returns fall below the mean for the probability to equal 95%?

Note on Answering Questions 1–4:

Normal distribution–related functions are part of spreadsheets, R, Python, and all statistical packages. Here, we use Microsoft Excel functions to answer these questions. When we speak in terms of "number of standard deviations above or below the mean," we are referring to the standard normal distribution (i.e., mean of 0 and standard deviation of 1), so it is best to use Excel's "=NORM.S.DIST(Z, 0 or 1)" function. "Z" represents the distance in number of standard deviations away from the mean, and the second parameter of the function is either 0 (Excel returns pdf value) or 1 (Excel returns cdf value).

Solution to 1:

To answer Question 1, we need the normal cdf value (so, set the second parameter equal to 1) that is associated with a Z value of −1 (i.e., one standard deviation below the mean). Thus, "=NORM.S.DIST(-1,1)" returns 0.1587, or 15.9%.

Solution to 2:

Here, we need to calculate the area under the normal pdf within the range of the mean ±1 standard deviation. The area under the pdf is the cdf, so we must calculate the difference between the cdf one standard deviation above the mean and the cdf one standard deviation below the mean. Note that "=NORM.S.DIST(1,1)" returns 0.8413, or 84.1%, which means that 84.1% of all observations of a normally distributed random variable would fall below the mean plus one standard deviation. We already calculated 15.9% for the probability that observations for such a variable would fall less than one standard deviation below the mean in the Solution to 1, so the answer here is 84.1% − 15.9% = 68.3%.

Solution to 3:

Similar to Solution 1, use the Excel function "=NORM.S.DIST(-2,1)"—which returns a probability of 0.0228, or 2.3%.

Solution to 4:

This question is a typical way of phrasing "value at risk." In statistical terms, we want to know the lowest return value below which only 5% of the observations would fall. Thus, we need to find the Z value for which the normal cdf would be 5% probability. To do this, we use the inverse of the cdf function—that is,

"=NORM.S.INV(0.05)"—which results in −1.6449, or −1.64. In other words, only 5% of the observations should fall below the mean minus 1.64 standard deviations, or equivalently, 95% of the observations should exceed this threshold.

There are as many different normal distributions as there are choices for mean (μ) and variance (σ^2). We can answer all the previous questions in terms of any normal distribution. Spreadsheets, for example, have functions for the normal cdf for any specification of mean and variance. For the sake of efficiency, however, we would like to refer all probability statements to a single normal distribution. The standard normal distribution (the normal distribution with $\mu = 0$ and $\sigma = 1$) fills that role.

4.3 Standardizing a Random Variable

i. explain how to standardize a random variable

There are two steps in **standardizing** a normal random variable *X*: Subtract the mean of *X* from *X* and then divide that result by the standard deviation of *X* (this is also known as computing the *Z*-score). If we have a list of observations on a normal random variable, *X*, we subtract the mean from each observation to get a list of deviations from the mean and then divide each deviation by the standard deviation. The result is the standard normal random variable, *Z* (*Z* is the conventional symbol for a standard normal random variable). If we have $X \sim N(\mu, \sigma^2)$ (read "*X* follows the normal distribution with parameters μ and σ^2"), we standardize it using the formula

$$Z = (X - \mu)/\sigma. \tag{4}$$

Suppose we have a normal random variable, *X*, with $\mu = 5$ and $\sigma = 1.5$. We standardize *X* with $Z = (X - 5)/1.5$. For example, a value $X = 9.5$ corresponds to a standardized value of 3, calculated as $Z = (9.5 - 5)/1.5 = 3$. The probability that we will observe a value as small as or smaller than 9.5 for $X \sim N(5, 1.5)$ is exactly the same as the probability that we will observe a value as small as or smaller than 3 for $Z \sim N(0, 1)$.

4.4 Probabilities Using the Standard Normal Distribution

j calculate and interpret probabilities using the standard normal distribution

We can answer all probability questions about *X* using standardized values. We generally do not know the population mean and standard deviation, so we often use the sample mean $\overline{X}$ for μ and the sample standard deviation *s* for σ. Standard normal probabilities are computed with spreadsheets, statistical and econometric software, and programming languages. Tables of the cumulative distribution function for the standard normal random variable are also readily available.

To find the probability that a standard normal variable is less than or equal to 0.24, for example, calculate NORM.S.DIST(0.24,1)=0.5948; thus, $P(Z \leq 0.24) = 0.5948$, or 59.48%. If we want to find the probability of observing a value 1.65 standard deviations below the mean, calculate NORM.S.DIST(-1.65,1)=0.04947, or roughly 5%.

The following are some of the most frequently referenced values when using the normal distribution, and for these values, =NORM.S.INV(Probability) is a convenient Excel function:

- The 90th percentile point is 1.282, or NORM.S.INV(0.90)=1.28155. Thus, only 10% of values remain in the right tail beyond the mean plus 1.28 standard deviations;

- The 95th percentile point is 1.65, or NORM.S.INV(0.95)=1.64485, which means that $P(Z \leq 1.65) = N(1.65) = 0.95$, or 95%, and 5% of values remain in the right tail. The 5th percentile point, in contrast, is NORM.S.INV(0.05)=-1.64485—that is, the same number as for 95%, but with a negative sign.
- Note the difference between the use of a percentile point when dealing with one tail rather than two tails. We used 1.65 because we are concerned with the 5% of values that lie only on one side, the right tail. If we want to cut off both the left and right 5% tails, then 90% of values would stay within the mean ±1.65 standard deviations range.
- The 99th percentile point is 2.327: $P(Z \leq 2.327) = N(2.327) = 0.99$, or 99%, and 1% of values remain in the right tail.

EXAMPLE 6

Probabilities for a Common Stock Portfolio

Assume the portfolio mean return is 12% and the standard deviation of return estimate is 22% per year. Note also that if X is portfolio return, the standardized portfolio return is $Z = (X - \bar{X})/s = (X - 12\%)/22\%$. We use this expression throughout the solutions.
You want to calculate the following probabilities, assuming that a normal distribution describes returns.

1. What is the probability that portfolio return will exceed 20%?
2. What is the probability that portfolio return will be between 12% and 20%? In other words, what is $P(12\% \leq \text{portfolio return} \leq 20\%)$?
3. You can buy a one-year T-bill that yields 5.5%. This yield is effectively a one-year risk-free interest rate. What is the probability that your portfolio's return will be equal to or less than the risk-free rate?

Solution to 1:

For $X = 20\%$, $Z = (20\% - 12\%)/22\% = 0.363636$. You want to find $P(Z > 0.363636)$. First, note that $P(Z > x) = P(Z \geq x)$ because the normal distribution is a continuous distribution. Also, recall that $P(Z \geq x) = 1.0 - P(Z \leq x)$ or $1 - N(x)$. Next, NORM.S.DIST(0.363636,1)=0.64194, so, $1 - 0.6419 = 0.3581$. Therefore, the probability that portfolio return will exceed 20% is about 36% if your normality assumption is accurate.

Solution to 2:

$P(12\% \leq \text{Portfolio return} \leq 20\%) = N(Z \text{ corresponding to } 20\%) - N(Z \text{ corresponding to } 12\%)$. For the first term, $Z = (20\% - 12\%)/22\% = 0.363636$, and $N(0.363636) = 0.6419$ (as in Solution 1). To get the second term immediately, note that 12% is the mean, and for the normal distribution, 50% of the probability lies on either side of the mean. Therefore, $N(Z$ corresponding to 12%) must equal 50%. So $P(12\% \leq \text{Portfolio return} \leq 20\%) = 0.6419 - 0.50 = 0.1419$, or approximately 14%.

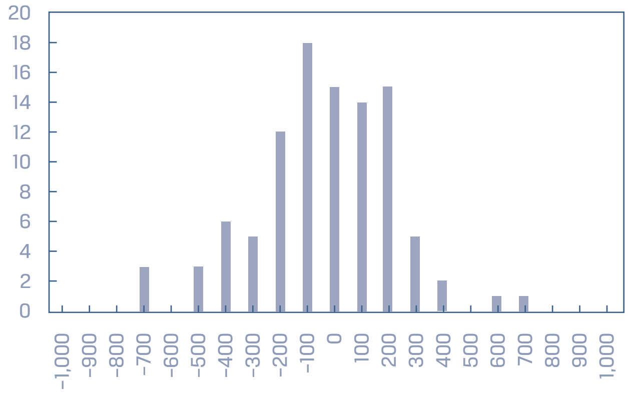
Solution to 3:

If X is portfolio return, then we want to find $P(\text{Portfolio return} \leq 5.5\%)$. For $X = 5.5\%$, $Z = (5.5\% - 12\%)/22\% = -0.2955$. Using NORM.S.DIST(-0.2955,1)=0.3838, we see an approximately 38% chance the portfolio's return will be equal to or less than the risk-free rate.

Next, we will briefly discuss and illustrate the concept of the **central limit theorem**, according to which the sum (as well as the mean) of a set of independent, identically distributed random variables with finite variances is normally distributed, whatever distribution the random variables follow.

To illustrate this concept, consider a sample of 30 observations of a random variable that can take a value of just −100, 0, or 100, with equal probability. Clearly, this sample is drawn from a simple discrete uniform distribution, where the possible values of −100, 0, and 100 each have 1/3 probability. We randomly pick 10 elements of this sample and calculate the sum of these elements, and then we repeat this process a total of 100 times. The histogram in Exhibit 11 shows the distribution of these sums: The underlying distribution is a very simple discrete uniform distribution, but the sums converge toward a normal distribution.

Exhibit 11 Central Limit Theorem: Sums of Elements from Discrete Uniform Distribution Converge to Normal Distribution



APPLICATIONS OF THE NORMAL DISTRIBUTION

5

k define shortfall risk, calculate the safety-first ratio, and identify an optimal portfolio using Roy's safety-first criterion

Modern portfolio theory (MPT) makes wide use of the idea that the value of investment opportunities can be meaningfully measured in terms of mean return and variance of return. In economic theory, **mean–variance analysis** holds exactly when investors are risk averse; when they choose investments so as to maximize expected utility, or satisfaction; and when either (1) returns are normally distributed or (2) investors have quadratic utility functions, a concept used in economics for a mathematical representation of attitudes toward risk and return. Mean–variance analysis, however, can still be useful—that is, it can hold approximately—when either Assumption 1 or 2 is violated. Because practitioners prefer to work with observables, such as returns, the proposition that returns are at least approximately normally distributed has played a key role in much of MPT.

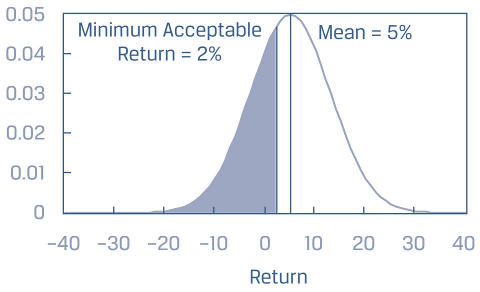
To illustrate this concept, assume an investor is saving for retirement, and although her goal is to earn the highest real return possible, she believes that the portfolio should at least achieve real capital preservation over the long term. Assuming a long-term expected inflation rate of 2%, the minimum acceptable return would be 2%.

Exhibit 12 compares three investment alternatives in terms of their expected returns and standard deviation of returns. The probability of falling below 2% is calculated on basis of the assumption of normally distributed returns. In the table, we see that Portfolio II, which combines the highest expected return and the lowest volatility, has the lowest probability of earning less than 2% (or equivalently, the highest probability of earning at least 2%). This can also be seen in Panel B, where Portfolio II has the smallest shaded area to the left of 2% (the probability of earning less than the minimum acceptable return).

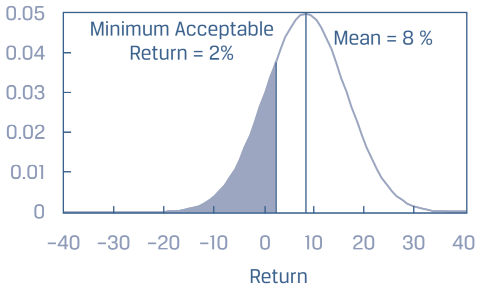
Exhibit 12 Probability of Earning a Minimum Acceptable Return

Portfolio	I	II	II
Expected return	5%	8%	5%
Standard deviation of return	8%	8%	12%
Probability of earning < 2% [$P(x < 2)$]	37.7%	24.6%	41.7%
Probability of earning ≥ 2% [$P(x \geq 2)$]	62.3%	75.4%	58.3%

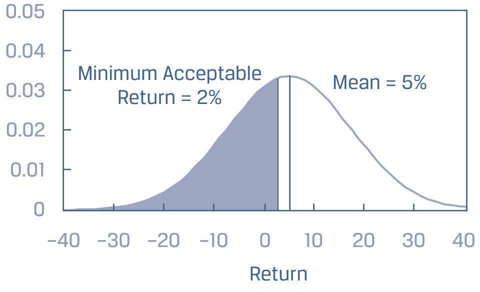
A. Portfolio I



B. Portfolio II



C. Portfolio III



Mean–variance analysis generally considers risk symmetrically in the sense that standard deviation captures variability both above and below the mean. An alternative approach evaluates only downside risk. We discuss one such approach, safety-first rules, because they provide an excellent illustration of the application of normal distribution theory to practical investment problems. **Safety-first rules** focus on **shortfall risk**, the risk that portfolio value (or portfolio return) will fall below some minimum acceptable level over some time horizon. The risk that the assets in a defined benefit plan will fall below plan liabilities is an example of a shortfall risk.

Suppose an investor views any return below a level of R_L as unacceptable. Roy's safety-first criterion (Roy 1952) states that the optimal portfolio minimizes the probability that portfolio return, R_P, will fall below the threshold level, R_L. In symbols, the investor's objective is to choose a portfolio that minimizes $P(R_P < R_L)$. When portfolio returns are normally distributed, we can calculate $P(R_P < R_L)$ using the number of standard deviations that R_L lies below the expected portfolio return, $E(R_P)$. The portfolio for which $E(R_P) - R_L$ is largest relative to standard deviation minimizes $P(R_P < R_L)$. Therefore, if returns are normally distributed, the safety-first optimal portfolio *maximizes* the safety-first ratio (SFRatio):

$$\text{SFRatio} = [E(R_P) - R_L]/\sigma_P \,. \tag{5}$$

The quantity $E(R_P) - R_L$ is the distance from the mean return to the shortfall level. Dividing this distance by σ_P gives the distance in units of standard deviation. There are two steps in choosing among portfolios using Roy's criterion (assuming normality):

1. Calculate each portfolio's SFRatio.
2. Choose the portfolio with the highest SFRatio.

For a portfolio with a given safety-first ratio, the probability that its return will be less than R_L is $N(-\text{SFRatio})$, and the safety-first optimal portfolio has the lowest such probability. For example, suppose an investor's threshold return, R_L, is 2%. He is presented with two portfolios. Portfolio 1 has an expected return of 12%, with a standard deviation of 15%. Portfolio 2 has an expected return of 14%, with a standard deviation of 16%. The SFRatios, using Equation 5, are 0.667 = (12 – 2)/15 and 0.75 = (14 – 2)/16 for Portfolios 1 and 2, respectively. For the superior Portfolio 2, the probability that portfolio return will be less than 2% is $N(-0.75) = 1 - N(0.75) = 1 - 0.7734 = 0.227$, or about 23%, assuming that portfolio returns are normally distributed.

You may have noticed the similarity of the SFRatio to the Sharpe ratio. If we substitute the risk-free rate, R_F, for the critical level R_L, the SFRatio becomes the Sharpe ratio. The safety-first approach provides a new perspective on the Sharpe ratio: When we evaluate portfolios using the Sharpe ratio, the portfolio with the highest Sharpe ratio is the one that minimizes the probability that portfolio return will be less than the risk-free rate (given a normality assumption).

EXAMPLE 7

The Safety-First Optimal Portfolio for a Client

You are researching asset allocations for a client in Canada with a C$800,000 portfolio. Although her investment objective is long-term growth, at the end of a year she may want to liquidate C$30,000 of the portfolio to fund educational expenses. If that need arises, she would like to be able to take out the C$30,000 without invading the initial capital of C$800,000. The table below shows three alternative allocations.

Mean and Standard Deviation for Three Allocations (in Percent)

Allocation	A	B	C
Expected annual return	25	11	14
Standard deviation of return	27	8	20

Address these questions (assume normality for Questions 2 and 3):

1 Given the client's desire not to invade the C$800,000 principal, what is the shortfall level, R_L? Use this shortfall level to answer Question 2.

2 According to the safety-first criterion, which of the three allocations is the best?

3 What is the probability that the return on the safety-first optimal portfolio will be less than the shortfall level?

Solution to 1:

Because C$30,000/C$800,000 is 3.75%, for any return less than 3.75% the client will need to invade principal if she takes out C$30,000. So, $R_L = 3.75\%$.

Solution to 2:

To decide which of the three allocations is safety-first optimal, select the alternative with the highest ratio $[E(R_P) - R_L]/\sigma_P$:

Allocation A: $0.787037 = (25 - 3.75)/27$.

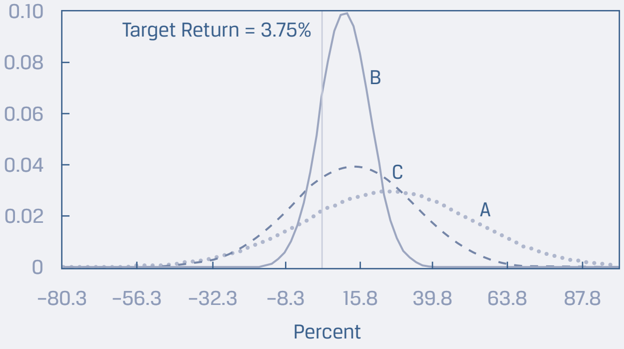
Allocation B: $0.90625 = (11 - 3.75)/8$.

Allocation C: $0.5125 = (14 - 3.75)/20$.

Allocation B, with the largest ratio (0.90625), is the best alternative according to the safety-first criterion.

Solution to 3:

To answer this question, note that $P(R_B < 3.75) = N(-0.90625)$. We can round 0.90625 to 0.91 for use with tables of the standard normal cdf. First, we calculate $N(-0.91) = 1 - N(0.91) = 1 - 0.8186 = 0.1814$, or about 18.1%. Using a spreadsheet function for the standard normal cdf on −0.90625 without rounding, we get 0.182402, or about 18.2%. The safety-first optimal portfolio has a roughly 18% chance of not meeting a 3.75% return threshold. This can be seen in the following graphic, where Allocation B has the smallest area under the distribution curve to the left of 3.75%.



Several points are worth noting. First, if the inputs were slightly different, we could get a different ranking. For example, if the mean return on B were 10% rather than 11%, Allocation A would be superior to B. Second, if meeting the 3.75% return threshold were a necessity rather than a wish, C$830,000 in one year could be modeled as a liability. Fixed-income strategies, such as cash flow matching, could be used to offset or immunize the C$830,000 quasi-liability.

In many investment contexts besides Roy's safety-first criterion, we use the normal distribution to estimate a probability. Another arena in which the normal distribution plays an important role is financial risk management. Financial institutions, such as investment banks, security dealers, and commercial banks, have formal systems to measure and control financial risk at various levels, from trading positions to the overall risk for the firm. Two mainstays in managing financial risk are value at risk (VaR) and stress testing/scenario analysis. **Stress testing** and **scenario analysis** refer to a set of techniques for estimating losses in extremely unfavorable combinations of events or scenarios. **Value at risk** (VaR) is a money measure of the minimum value of losses expected over a specified time period (for example, a day, a quarter, or a year) at a given level of probability (often 0.05 or 0.01). Suppose we specify a one-day time horizon and a level of probability of 0.05, which would be called a 95% one-day VaR. If this VaR equaled €5 million for a portfolio, there would be a 0.05 probability that the portfolio would lose €5 million or more in a single day (assuming our assumptions were correct). One of the basic approaches to estimating VaR, the variance–covariance or analytical method, assumes that returns follow a normal distribution.

LOGNORMAL DISTRIBUTION AND CONTINUOUS COMPOUNDING

6

6.1 The Lognormal Distribution

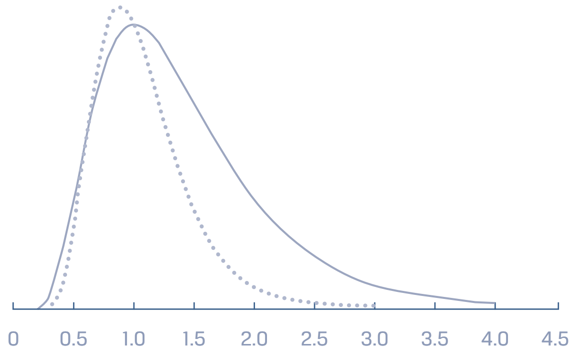
l. explain the relationship between normal and lognormal distributions and why the lognormal distribution is used to model asset prices

Closely related to the normal distribution, the lognormal distribution is widely used for modeling the probability distribution of share and other asset prices. For example, the lognormal distribution appears in the Black–Scholes–Merton option pricing model. The Black–Scholes–Merton model assumes that the price of the asset underlying the option is lognormally distributed.

A random variable Y follows a lognormal distribution if its natural logarithm, ln Y, is normally distributed. The reverse is also true: If the natural logarithm of random variable Y, ln Y, is normally distributed, then Y follows a lognormal distribution. If you think of the term lognormal as "the log is normal," you will have no trouble remembering this relationship.

The two most noteworthy observations about the lognormal distribution are that it is bounded below by 0 and it is skewed to the right (it has a long right tail). Note these two properties in the graphs of the pdfs of two lognormal distributions in Exhibit 13. Asset prices are bounded from below by 0. In practice, the lognormal distribution has been found to be a usefully accurate description of the distribution of prices for many financial assets. However, the normal distribution is often a good approximation for returns. For this reason, both distributions are very important for finance professionals.

Exhibit 13 Two Lognormal Distributions

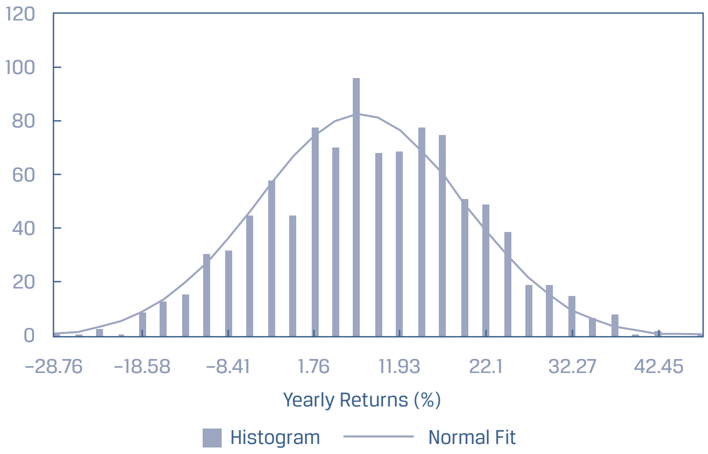


Like the normal distribution, the lognormal distribution is completely described by two parameters. Unlike the other distributions we have considered, a lognormal distribution is defined in terms of the parameters of a *different* distribution. The two parameters of a lognormal distribution are the mean and standard deviation (or variance) of its associated normal distribution: the mean and variance of ln Y, given that Y is lognormal. Remember, we must keep track of two sets of means and standard deviations (or variances): the mean and standard deviation (or variance) of the associated normal distribution (these are the parameters) and the mean and standard deviation (or variance) of the lognormal variable itself.

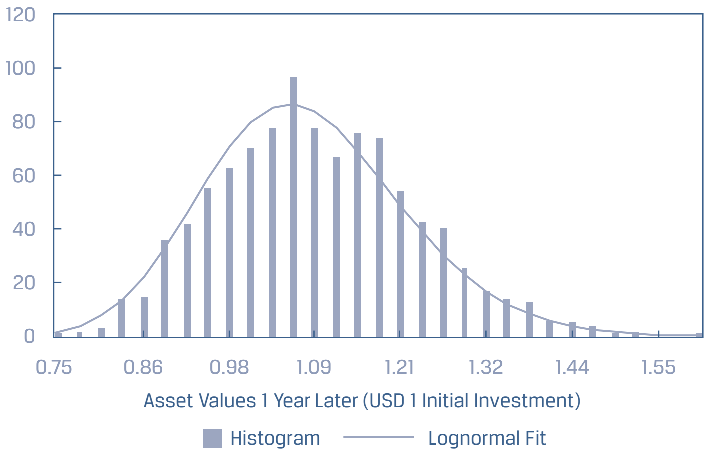
To illustrate this relationship, we simulated 1,000 scenarios of yearly asset returns, assuming that returns are normally distributed with 7% mean and 12% standard deviation. For each scenario i, we converted the simulated continuously compounded returns (r_i) to future asset prices with the formula Price(1 year later)$_i$ = \$1 x exp(r_i), where exp is the exponential function and assuming that the asset's price is \$1 today. In Exhibit 14, Panel A shows the distribution of the simulated returns together with the fitted normal pdf, whereas Panel B shows the distribution of the corresponding future asset prices together with the fitted lognormal pdf. Again, note that the lognormal distribution of future asset prices is bounded below by 0 and has a long right tail.

Exhibit 14 **Simulated Returns (Normal PDF) and Asset Prices (Lognormal PDF)**

A. Normal PDF



B. Lognormal PDF



The expressions for the mean and variance of the lognormal variable itself are challenging. Suppose a normal random variable X has expected value μ and variance σ^2. Define $Y = \exp(X)$. Remember that the operation indicated by $\exp(X)$ or e^X (where $e \approx 2.7183$) is the opposite operation from taking logs. Because $\ln Y = \ln[\exp(X)] = X$ is normal (we assume X is normal), Y is lognormal. What is the expected value of $Y = \exp(X)$? A guess might be that the expected value of Y is $\exp(\mu)$. The expected value is actually $\exp(\mu + 0.50\sigma^2)$, which is larger than $\exp(\mu)$ by a factor of $\exp(0.50\,\sigma^2) > 1$. To get some insight into this concept, think of what happens if we increase σ^2. The distribution spreads out; it can spread upward, but it cannot spread downward past 0. As a result, the center of its distribution is pushed to the right: The distribution's mean increases.

The expressions for the mean and variance of a lognormal variable are summarized below, where μ and σ^2 are the mean and variance of the associated normal distribution (refer to these expressions as needed, rather than memorizing them):

- Mean (μ_L) of a lognormal random variable = $\exp(\mu + 0.50\sigma^2)$.
- Variance ($\sigma_L{}^2$) of a lognormal random variable = $\exp(2\mu + \sigma^2) \times [\exp(\sigma^2) - 1]$.

6.2 Continuously Compounded Rates of Return

m calculate and interpret a continuously compounded rate of return, given a specific holding period return

We now explore the relationship between the distribution of stock return and stock price. In this section, we show that if a stock's continuously compounded return is normally distributed, then future stock price is necessarily lognormally distributed. Furthermore, we show that stock price may be well described by the lognormal distribution even when continuously compounded returns do not follow a normal distribution. These results provide the theoretical foundation for using the lognormal distribution to model asset prices.

To outline the presentation that follows, we first show that the stock price at some future time T, S_T, equals the current stock price, S_0, multiplied by e raised to power $r_{0,T}$, the continuously compounded return from 0 to T; this relationship is expressed as $S_T = S_0\exp(r_{0,T})$. We then show that we can write $r_{0,T}$ as the sum of shorter-term continuously compounded returns and that if these shorter-period returns are normally distributed, then $r_{0,T}$ is normally distributed (given certain assumptions) or approximately normally distributed (not making those assumptions). As S_T is proportional to the log of a normal random variable, S_T is lognormal.

To supply a framework for our discussion, suppose we have a series of equally spaced observations on stock price: S_0, S_1, S_2, . . ., S_T. Current stock price, S_0, is a known quantity and thus is nonrandom. The future prices (such as S_1), however, are random variables. The **price relative**, S_1/S_0, is an ending price, S_1, over a beginning price, S_0; it is equal to 1 plus the holding period return on the stock from $t = 0$ to $t = 1$:

$$S_1/S_0 = 1 + R_{0,1}.$$

For example, if S_0 = \$30 and S_1 = \$34.50, then S_1/S_0 = \$34.50/\$30 = 1.15. Therefore, $R_{0,1} = 0.15$, or 15%. In general, price relatives have the form

$$S_{t+1}/S_t = 1 + R_{t,t+1},$$

where $R_{t,t+1}$ is the rate of return from t to $t + 1$.

An important concept is the continuously compounded return associated with a holding period return, such as $R_{0,1}$. The **continuously compounded return** associated with a holding period return is the natural logarithm of 1 plus that holding period return, or equivalently, the natural logarithm of the ending price over the beginning price (the price relative). Note that here we are using lowercase r to refer specifically to continuously compounded returns. For example, if we observe a one-week holding period return of 0.04, the equivalent continuously compounded return, called the one-week continuously compounded return, is ln(1.04) = 0.039221; €1.00 invested for one week at 0.039221 continuously compounded gives €1.04, equivalent to a 4% one-week holding period return. The continuously compounded return from t to $t + 1$ is

$$r_{t,t+1} = \ln(S_{t+1}/S_t) = \ln(1 + R_{t,t+1}). \tag{6}$$

For our example, $r_{0,1} = \ln(S_1/S_0) = \ln(1 + R_{0,1}) = \ln(\$34.50/\$30) = \ln(1.15) = 0.139762$. Thus, 13.98% is the continuously compounded return from $t = 0$ to $t = 1$. The continuously compounded return is smaller than the associated holding period return. If our investment horizon extends from $t = 0$ to $t = T$, then the continuously compounded return to T is

$$r_{0,T} = \ln(S_T/S_0).$$

Applying the function exp to both sides of the equation, we have $\exp(r_{0,T}) = \exp[\ln(S_T/S_0)] = S_T/S_0$, so

$$S_T = S_0\exp(r_{0,T}).$$

We can also express S_T/S_0 as the product of price relatives:

$$S_T/S_0 = (S_T/S_{T-1})(S_{T-1}/S_{T-2}) \ldots (S_1/S_0).$$

Taking logs of both sides of this equation, we find that the continuously compounded return to time T is the sum of the one-period continuously compounded returns:

$$r_{0,T} = r_{T-1,T} + r_{T-2,T-1} + \ldots + r_{0,1}. \tag{7}$$

Using holding period returns to find the ending value of a \$1 investment involves the multiplication of quantities (1 + holding period return). Using continuously compounded returns involves addition (as shown in Equation 7).

A key assumption in many investment applications is that returns are **independently and identically distributed** (i.i.d.). Independence captures the proposition that investors cannot predict future returns using past returns. Identical distribution captures the assumption of stationarity, a property implying that the mean and variance of return do not change from period to period.

Assume that the one-period continuously compounded returns (such as $r_{0,1}$) are i.i.d. random variables with mean μ and variance σ^2 (but making no normality or other distributional assumption). Then,

$$E(r_{0,T}) = E(r_{T-1,T}) + E(r_{T-2,T-1}) + \ldots + E(r_{0,1}) = \mu T \tag{8}$$

(we add up μ for a total of T times), and

$$\sigma^2(r_{0,T}) = \sigma^2 T \tag{9}$$

(as a consequence of the independence assumption). The variance of the T holding period continuously compounded return is T multiplied by the variance of the one-period continuously compounded return; also, $\sigma(r_{0,T}) = \sigma\sqrt{T}$. If the one-period continuously compounded returns on the right-hand side of Equation 7 are normally distributed, then the T holding period continuously compounded return, $r_{0,T}$, is also normally distributed with mean μT and variance $\sigma^2 T$. This relationship is so because a linear combination of normal random variables is also normal. But even if the one-period continuously compounded returns are not normal, their sum, $r_{0,T}$, is approximately normal according to the central limit theorem. Now compare $S_T = S_0\exp(r_{0,T})$ to $Y = \exp(X)$, where X is normal and Y is lognormal (as we discussed previously). Clearly, we can model future stock price S_T as a lognormal random variable because $r_{0,T}$ should be at least approximately normal. This assumption of normally distributed returns is the basis in theory for the lognormal distribution as a model for the distribution of prices of shares and other assets.

Continuously compounded returns play a role in many asset pricing models, as well as in risk management. **Volatility** measures the standard deviation of the continuously compounded returns on the underlying asset; by convention, it is stated as an annualized measure. In practice, we very often estimate volatility using a historical series of continuously compounded daily returns. We gather a set of daily holding period returns and then use Equation 6 to convert them into continuously compounded daily returns. We then compute the standard deviation of the continuously compounded daily returns and annualize that number using Equation 9.

To compute the standard deviation of a set (or sample) of *n* returns, we sum the squared deviation of each return from the mean return and then divide that sum by $n - 1$. The result is the sample variance. Taking the square root of the sample variance gives the sample standard deviation. Annualizing is typically done on the basis of 250 days in a year, the approximate number of days markets are open for trading. Thus if daily volatility were 0.01, we would state volatility (on an annual basis) as $0.01\sqrt{250} = 0.1581$. Example 8 illustrates the estimation of volatility for the shares of Astra International.

EXAMPLE 8

Volatility of Share Price

Suppose you are researching Astra International (Indonesia Stock Exchange: ASII) and are interested in Astra's price action in a week in which international economic news had significantly affected the Indonesian stock market. You decide to use volatility as a measure of the variability of Astra shares during that week. The following shows closing prices during that week.

Astra International Daily Closing Prices

Day	Closing Price (IDR)
Monday	6,950
Tuesday	7,000
Wednesday	6,850
Thursday	6,600
Friday	6,350

Use the data provided to do the following:

1. Estimate the volatility of Astra shares. (Annualize volatility on the basis of 250 days in a year.)
2. Identify the probability distribution for Astra share prices if continuously compounded daily returns follow the normal distribution.

Solution to 1:

First, use Equation 6 to calculate the continuously compounded daily returns; then, find their standard deviation in the usual way. In calculating sample variance, to get sample standard deviation, the divisor is sample size minus 1.

$\ln(7{,}000/6{,}950) = 0.007168.$

$\ln(6{,}850/7{,}000) = -0.021661.$

$\ln(6{,}600/6{,}850) = -0.037179.$

$\ln(6{,}350/6{,}600) = -0.038615.$

Sum = −0.090287.

Mean = −0.022572.

Variance = 0.000452.

Standard deviation = 0.021261.

The standard deviation of continuously compounded daily returns is 0.021261. Equation 9 states that $\hat{\sigma}\left(r_{0,T}\right) = \hat{\sigma}\sqrt{T}$. In this example, $\hat{\sigma}$ is the sample standard deviation of one-period continuously compounded returns. Thus, $\hat{\sigma}$ refers to 0.021261. We want to annualize, so the horizon T corresponds to one year. Because $\hat{\sigma}$ is in days, we set T equal to the number of trading days in a year (250).

We find that annualized volatility for Astra stock that week was 33.6%, calculated as $0.021261\sqrt{250} = 0.336165$.

Note that the sample mean, −0.022572, is a possible estimate of the mean, μ, of the continuously compounded one-period or daily returns. The sample mean can be translated into an estimate of the expected continuously compounded annual return using Equation 8: $\hat{\mu}T = -0.022572(250)$ (using 250 to be consistent with the calculation of volatility). But four observations are far too few to estimate expected returns. The variability in the daily returns overwhelms any information about expected return in a series this short.

Solution to 2:

Astra share prices should follow the lognormal distribution if the continuously compounded daily returns on Astra shares follow the normal distribution.

We have shown that the distribution of stock price is lognormal, given certain assumptions. What are the mean and variance of S_T if S_T follows the lognormal distribution? Earlier we gave bullet-point expressions for the mean and variance of a lognormal random variable. In the bullet-point expressions, the $\hat{\mu}$ and $\hat{\sigma}^2$ would refer, in the context of this discussion, to the mean and variance of the T horizon (not the one-period) continuously compounded returns (assumed to follow a normal distribution), compatible with the horizon of S_T. Related to the use of mean and variance (or standard deviation), previously we used those quantities to construct intervals in which we expect to find a certain percentage of the observations of a normally distributed random variable. Those intervals were symmetric about the mean. Can we state similar symmetric intervals for a lognormal random variable? Unfortunately, we cannot; because the lognormal distribution is not symmetric, such intervals are more complicated than for the normal distribution, and we will not discuss this specialist topic here.

STUDENT'S *T*-, CHI-SQUARE, AND *F*-DISTRIBUTIONS

7

7.1 Student's *t*-Distribution

- describe the properties of the Student's *t*-distribution, and calculate and interpret its degrees of freedom

To complete the review of probability distributions commonly used in finance, we discuss Student's *t*-, chi-square, and *F*-distributions. Most of the time, these distributions are used to support statistical analyses, such as sampling, testing the statistical significance of estimated model parameters, or hypothesis testing. In addition, Student's *t*-distribution is also sometimes used to model asset returns in a manner similar to that of the normal distribution. However, since the *t*-distribution has "longer tails," it may provide a more reliable, more conservative downside risk estimate.

The standard *t*-distribution is a symmetrical probability distribution defined by a single parameter known as **degrees of freedom** (df), the number of independent variables used in defining sample statistics, such as variance, and the probability distributions they measure.

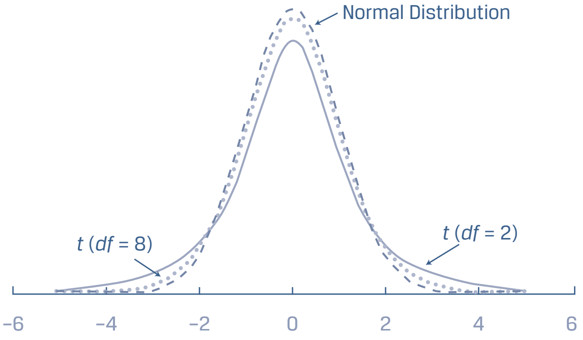
Each value for the number of degrees of freedom defines one distribution in this family of distributions. We will shortly compare *t*-distributions with the standard normal distribution, but first we need to understand the concept of degrees of freedom. We can do so by examining the calculation of the sample variance,

$$s^2 = \frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2}{n-1}. \tag{10}$$

Equation 10 gives the unbiased estimator of the sample variance that we use. The term in the denominator, $n - 1$, which is the sample size minus 1, is the number of degrees of freedom in estimating the population variance when using Equation 10. We also use $n - 1$ as the number of degrees of freedom for determining reliability factors based on the *t*-distribution. The term "degrees of freedom" is used because in a random sample, we assume that observations are selected independently of each other. The numerator of the sample variance, however, uses the sample mean. How does the use of the sample mean affect the number of observations collected independently for the sample variance formula? With a sample size of 10 and a mean of 10%, for example, we can freely select only 9 observations. Regardless of the 9 observations selected, we can always find the value for the 10th observation that gives a mean equal to 10%. From the standpoint of the sample variance formula, then, there are nine degrees of freedom. Given that we must first compute the sample mean from the total of n independent observations, only $n - 1$ observations can be chosen independently for the calculation of the sample variance. The concept of degrees of freedom comes up frequently in statistics, and you will see it often later in the CFA Program curriculum.

Suppose we sample from a normal distribution. The ratio $z = \left(\bar{X} - \mu\right)\Big/\left(\sigma/\sqrt{n}\right)$ is distributed normally with a mean of 0 and standard deviation of 1; however, the ratio $t = \left(\bar{X} - \mu\right)\Big/\left(s/\sqrt{n}\right)$ follows the *t*-distribution with a mean of 0 and $n - 1$ degrees of freedom. The ratio represented by t is not normal because t is the ratio of two random variables, the sample mean and the sample standard deviation. The definition of the standard normal random variable involves only one random variable, the sample mean. As degrees of freedom increase (i.e., as sample size increases), however, the *t*-distribution approaches the standard normal distribution. Exhibit 15 shows the probability density functions for the standard normal distribution and two *t*-distributions, one with df = 2 and one with df = 8.

Exhibit 15 Student's *t*-Distributions vs. Standard Normal Distribution



Of the three distributions shown in Exhibit 15, the standard normal distribution has tails that approach zero faster than the tails of the two *t*-distributions. The *t*-distribution is also symmetrically distributed around its mean value of zero, just like the normal distribution. As the degrees of freedom increase, the *t*-distribution approaches the standard normal distribution. The *t*-distribution with df = 8 is closer to the standard normal distribution than the *t*-distribution with df = 2.

Beyond plus and minus four standard deviations from the mean, the area under the standard normal distribution appears to approach 0; both *t*-distributions, however, continue to show some area under each curve beyond four standard deviations. The *t*-distributions have fatter tails, but the tails of the *t*-distribution with df = 8 more closely resemble the normal distribution's tails. As the degrees of freedom increase, the tails of the *t*-distribution become less fat.

Probabilities for the *t*-distribution can be readily computed with spreadsheets, statistical software, and programming languages. As an example of the latter, see the final sidebar at the end of this section for sample code in the R programming language.

7.2 Chi-Square and *F*-Distribution

o describe the properties of the chi-square distribution and the *F*-distribution, and calculate and interpret their degrees of freedom

The chi-square distribution, unlike the normal and *t*-distributions, is asymmetrical. Like the *t*-distribution, the chi-square distribution is a family of distributions. The chi-square distribution with *k* degrees of freedom is the distribution of the sum of the squares of *k* independent standard normally distributed random variables; hence, this distribution does not take on negative values. A different distribution exists for each possible value of degrees of freedom, $n - 1$ (n is sample size).

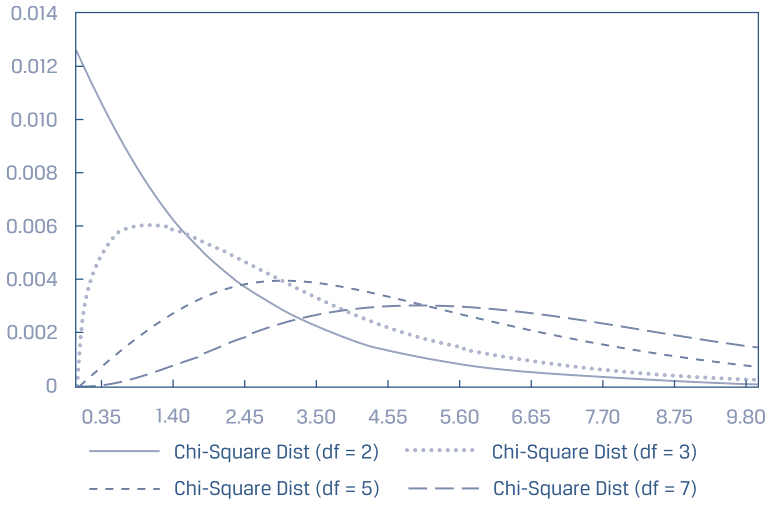
Like the chi-square distribution, the *F*-distribution is a family of asymmetrical distributions bounded from below by 0. Each *F*-distribution is defined by two values of degrees of freedom, called the numerator and denominator degrees of freedom.

The relationship between the chi-square and *F*-distributions is as follows: If χ_1^2 is one chi-square random variable with m degrees of freedom and χ_2^2 is another chi-square random variable with n degrees of freedom, then $F = \left(\chi_1^2/m\right)/\left(\chi_2^2/n\right)$ follows an *F*-distribution with m numerator and n denominator degrees of freedom.

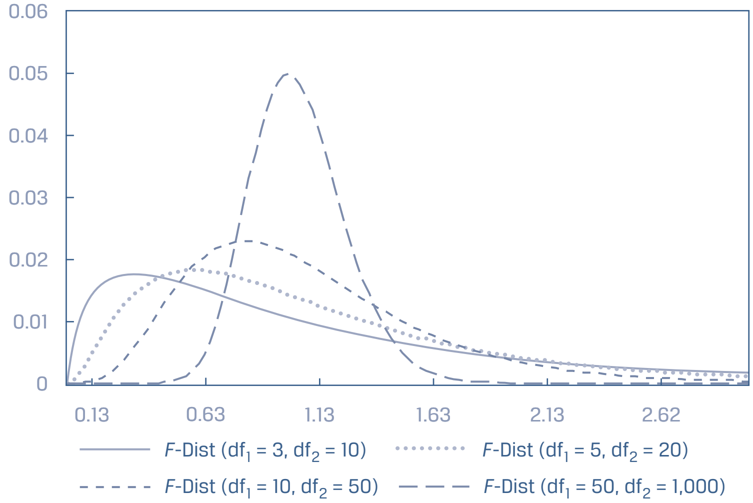
Chi-square and *F*-distributions are asymmetric, and as shown in Exhibit 16, the domain of their pdfs are positive numbers. Like Student's *t*-distribution, as the degrees of freedom of the chi-square distribution increase, the shape of its pdf becomes more similar to a bell curve (see Panel A). For the *F*-distribution, as both the numerator (df_1) and the denominator (df_2) degrees of freedom increase, the density function will also become more bell curve–like (see Panel B).

Exhibit 16 PDFs of Chi-Square and *F*-Distributions

A. Chi-Square Distributions



B. F-Distributions



As for typical investment applications, Student's *t*, chi-square, and *F*-distributions are the basis for test statistics used in performing various types of hypothesis tests on portfolio returns, such as those summarized in Exhibit 17.

Exhibit 17 Student's *t*, Chi-Square, and *F*-Distributions: Basis for Hypothesis Tests of Investment Returns

Distribution	Test Statistic	Hypothesis Tests of Returns
Student's *t*	*t*-Statistic	Tests of a single population mean, of differences between two population means, of mean difference between paired (dependent) populations, and of population correlation coefficient
Chi-square	Chi-square statistic	Test of variance of a normally distributed population
F	*F*-statistic	Test of equality of variances of two normally distributed populations from two independent random samples

EXAMPLE 9

Probabilities Using Student's-*t*, Chi-Square, and *F*-Distributions

1. Of the distributions we have covered in this reading, which can take values that are only positive numbers (i.e., no negative values)?
2. Interpret the degrees of freedom for a chi-square distribution, and describe how a larger value of df affects the shape of the chi-square pdf.
3. Generate cdf tables in Excel for values 1, 2, and 3 for the following distributions: standard normal, Student's *t*- (df = 5), chi-square (df = 5), and *F*-distribution ($df_1 = 5$, $df_2 = 1$). Then, calculate the distance from the mean for probability (p) = 90%, 95%, and 99% for each distribution.
4. You fit a Student's *t*-distribution to historically observed returns of stock market index ABC. Your best fit comes with five degrees of freedom. Compare this Student's *t*-distribution (df = 5) to a standard normal distribution on the basis of your answer to Question 3.

Solution to 1:

Of the probability distributions covered in this reading, the domains of the pdfs of the lognormal, the chi-square, and the *F*-distribution are only positive numbers.

Solution to 2:

A chi-square distribution with *k* degrees of freedom is the distribution of the sum of the squares of *k* independent standard normally distributed random variables. The greater the degrees of freedom, the more symmetrical and bell curve–like the pdf becomes.

Solution to 3:

In Excel, we can calculate cdfs using the NORM.S.DIST(value,1), T.DIST(value,DF,1), CHISQ.DIST(value,DF,1), and F.DIST(value,DF1,DF2,1) functions for the standard normal, Student's *t*-, chi-square, and *F*-distributions, respectively. At the end of this question set, we also show code snippets in the R language for generating cdfs for the requested values. For values 1, 2, and 3, the following are the results using the Excel functions:

CDF Values Using Different Probability Distributions

Value	Normal	Student's *t* (df = 5)	Chi-Square (df = 5)	*F* (df_1 = 5, df_2 = 1)
1	84.1%	81.8%	3.7%	36.3%
2	97.7%	94.9%	15.1%	51.1%
3	99.9%	98.5%	30.0%	58.9%

To calculate distances from the mean given probability *p*, we must use the inverse of the distribution functions: NORM.S.INV(p), T.INV(p,DF), CHISQ.INV(p,DF), and F.INV(p,DF1,DF2), respectively. At the end of this question set, we also show code snippets in the R language for calculating distances from the mean for the requested probabilities. The results using the inverse functions and the requested probabilities are as follows:

Distance from the Mean for a Given Probability (*p*)

Probability	Normal	Student's *t* (df = 5)	Chi-Square (df = 5)	*F* (df_1 = 5, df_2 = 1)
90%	1.28	1.48	9.24	57.24
95%	1.64	2.02	11.07	230.16
99%	2.33	3.36	15.09	5,763.65

Solution to 4:

Student's *t*-distribution with df of 5 has longer tails than the standard normal distribution. For probabilities 90%, 95%, and 99%, such *t*-distributed random variables would fall farther away from their mean (1.48, 2.02, and 3.36 standard deviations, respectively) than a normally distributed random variable (1.28, 1.64, and 2.33 standard deviations, respectively).

R CODE FOR PROBABILITIES INVOLVING STUDENT'S *T*-, CHI-SQUARE, AND *F*-DISTRIBUTIONS

For those of you with a knowledge of (or interest in learning) readily accessible computer code to find probabilities involving Student's *t*-, chi-square, and *F*-distributions, you can try out the following program. Specifically, this program uses code in the R language to solve for the answers to Example 9, which you have just completed. Good luck and have fun!

MONTE CARLO SIMULATION

p describe Monte Carlo simulation

After gaining an understanding of probability distributions, we now learn about a technique in which probability distributions play an integral role. The technique is called **Monte Carlo simulation**, and in finance it involves the use of computer software to represent the operation of a complex financial system. A characteristic feature of Monte Carlo simulation is the generation of a large number of random samples from a specified probability distribution or distributions to represent the role of risk in the system.

Monte Carlo simulation is widely used to estimate risk and return in investment applications. In this setting, we simulate the portfolio's profit and loss performance for a specified time horizon. Repeated trials within the simulation (each trial involving a draw of random observations from a probability distribution) produce a simulated frequency distribution of portfolio returns from which performance and risk measures are derived.

Another important use of Monte Carlo simulation in investments is as a tool for valuing complex securities for which no analytic pricing formula is available. For other securities, such as mortgage-backed securities with complex embedded options, Monte Carlo simulation is also an important modeling resource. Since we control the assumptions when we carry out a simulation, we can run a model for valuing such securities through a Monte Carlo simulation to examine the model's sensitivity to a change in key assumptions.

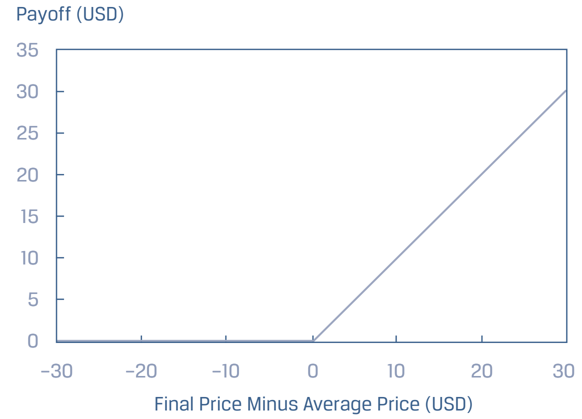
To understand the technique of Monte Carlo simulation, we present the process as a series of steps; these can be viewed as providing an overview rather than a detailed recipe for implementing a Monte Carlo simulation in its many varied applications. To illustrate the steps, we use Monte Carlo simulation to value a **contingent claim** security (a security whose value is based on some other underlying security) for which no analytic pricing formula is available. For our purposes, such a contingent claim security has a value at its maturity equal to the difference between the underlying stock price at that maturity and the average stock price during the life of the contingent claim or \$0, whichever is greater. For instance, if the final underlying stock price is \$34 and the average value over the life of the claim is \$31, the value of the contingent claim at its maturity is \$3 (the greater of \$34 – \$31 = \$3 and \$0).

Assume that the maturity of the claim is one year from today; we will simulate stock prices in monthly steps over the next 12 months and will generate 1,000 scenarios to evaluate this claim. The payoff diagram of this contingent claim security is depicted in Panel A of Exhibit 18, a histogram of simulated average and final stock prices is shown in Panel B, and a histogram of simulated payoffs of the contingent claim is presented in Panel C.

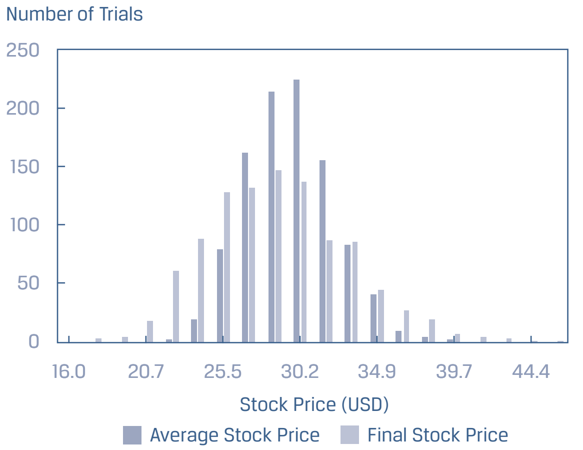
The payoff diagram (Panel A) is a snapshot of the contingent claim at maturity. If the stock's final price is less than or equal to its average over the life of the contingent claim, then the payoff would be zero. However, if the final price exceeds the average price, the payoff is equal to this difference. Panel B shows histograms of the simulated final and average stock prices. Note that the simulated final price distribution is wider than the simulated average price distribution. Also, note that the contingent claim's value depends on the difference between the final and average stock prices, which cannot be directly inferred from these histograms.

Exhibit 18 Payoff Diagram, Histogram of Simulated Average and Final Stock Prices, and Histogram of Simulated Payoffs for Contingent Claim

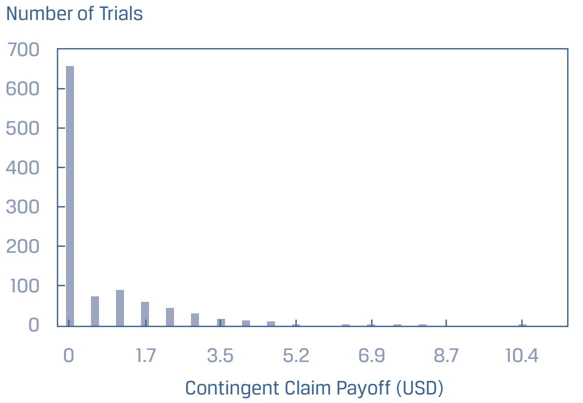
A. Contingent Claim Payoff Diagram



B. Histogram of Simulated Average and Final Stock Prices



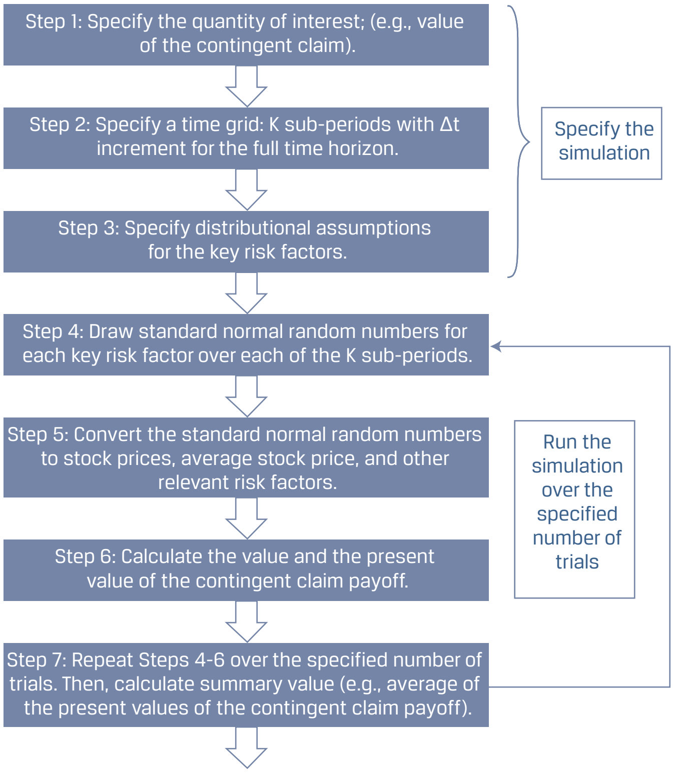
C. Histogram of Simulated Contingent Claim Payoffs



Finally, Panel C shows the histogram of the contingent claim's simulated payoffs. In 654 of 1,000 total trials, the final stock price was less than or equal to the average price, so in 65.4% of the trials the contingent claim paid off zero. In the remaining 34.6% of the trials, however, the claim paid the positive difference between the final and average prices, with the maximum payoff being $11.

The process flowchart in Exhibit 19 shows the steps for implementing the Monte Carlo simulation for valuing this contingent claim. Steps 1 through 3 of the process describe specifying the simulation; Steps 4 through 7 describe running the simulation.

Exhibit 19 Steps in Implementing the Monte Carlo Simulation



Step 1: Specify the quantity of interest; (e.g., value of the contingent claim).
Step 2: Specify a time grid: K sub-periods with Δt increment for the full time horizon.
Step 3: Specify distributional assumptions for the key risk factors.
Specify the simulation
Step 4: Draw standard normal random numbers for each key risk factor over each of the K sub-periods.
Step 5: Convert the standard normal random numbers to stock prices, average stock price, and other relevant risk factors.
Step 6: Calculate the value and the present value of the contingent claim payoff.
Step 7: Repeat Steps 4-6 over the specified number of trials. Then, calculate summary value (e.g., average of the present values of the contingent claim payoff).
Run the simulation over the specified number of trials

The mechanics of implementing the Monte Carlo simulation for valuing the contingent claim using the seven-step process are described as follows:

1 Specify the quantity of interest in terms of underlying variables. Here the quantity of interest is the contingent claim value, and the underlying variable is the stock price. Then, specify the starting value(s) of the underlying variable(s).

We use C_{iT} to represent the value of the claim at maturity, T. The subscript i in C_{iT} indicates that C_{iT} is a value resulting from the ith **simulation trial**, each simulation trial involving a drawing of random values (an iteration of Step 4).

2 Specify a time grid. Take the horizon in terms of calendar time and split it into a number of subperiods—say, K in total. Calendar time divided by the number of subperiods, K, is the time increment, Δt. In our example, calendar time is one year and K is 12, so Δt equals one month.

3 Specify distributional assumptions for the key risk factors that drive the underlying variables. For example, stock price is the underlying variable for the contingent claim, so we need a model for stock price movement. We choose the following model for changes in stock price, where Z_k stands for the standard normal random variable:

$$\Delta\text{Stock price} = (\mu \times \text{Prior stock price} \times \Delta t) + (\sigma \times \text{Prior stock price} \times Z_k).$$

The term Z_k is the key risk factor in the simulation. Through our choice of μ (mean) and σ (standard deviation), we control the distribution of the stock price variable. Although this example has one key risk factor, a given simulation may have multiple key risk factors.

4 Using a computer program or spreadsheet function, draw K random values of each risk factor. In our example, the spreadsheet function would produce a draw of K (= 12) values of the standard normal variable Z_k: $Z_1, Z_2, Z_3, \ldots, Z_K$. We will discuss generating standard normal random numbers (or, in fact, random numbers with any kind of distribution) after describing the sequence of simulation steps.

5 Convert the standard normal random numbers generated in Step 4 into stock price changes (ΔStock price) by using the model of stock price dynamics from Step 3. The result is K observations on possible changes in stock price over the K subperiods (remember, $K = 12$). An additional calculation is needed to convert those changes into a sequence of K stock prices, with the initial stock price as the starting value over the K subperiods. Another calculation produces the average stock price during the life of the contingent claim (the sum of K stock prices divided by K).

6 Compute the value of the contingent claim at maturity, C_{iT}, and then calculate its present value, C_{i0}, by discounting this terminal value using an appropriate interest rate as of today. (The subscript i in C_{i0} stands for the ith simulation trial, as it does in C_{iT}.) We have now completed one simulation trial.

7 Iteratively go back to Step 4 until the specified number of trials, I, is completed. Finally, produce summary values and statistics for the simulation. The quantity of interest in our example is the mean value of C_{i0} for the total number of simulation trials (I = 1,000). This mean value is the Monte Carlo estimate of the value of our contingent claim.

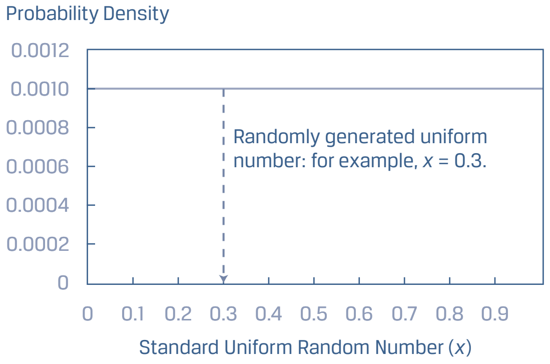
In Step 4 of our example, a computer function produced a set of random observations on a standard normal random variable. Recall that for a uniform distribution, all possible numbers are equally likely. The term **random number generator** refers to an algorithm that produces uniformly distributed random numbers between 0 and 1. In the context of computer simulations, the term **random number** refers to an observation drawn from a uniform distribution. For other distributions, the term "random observation" is used in this context.

It is a remarkable fact that random observations from any distribution can be produced using the uniform random variable with endpoints 0 and 1. The technique for producing random observations is known as the **inverse transformation method**. As a generalist, you do not need to address the technical details of converting random numbers into random observations, but you do need to know that random observations from any distribution can be generated using a uniform random variable.

Exhibit 20 provides a visual representation of the workings of the inverse transformation method. In essence, the randomly generated uniform number (0.30) lying on the continuous uniform probability density function, pdf, bounded by 0 and 1 (Panel A), is mapped onto the inverted cumulative density function, cdf, bounded by 0 and 1, of any distribution from which random observations are desired; here, we use the standard normal distribution (Panel B). The point on the given distribution's cdf is then mapped onto its pdf (Panel C), and the random observation is thereby identified (−0.5244). Note that in actuality, the random observation can be read off the y-axis in Panel B, but we include Panel C here to reinforce the intuition on how inverse transformation works. This method for generating random observations for the standard normal distribution is the same one used in the Monte Carlo simulation–based valuation of the contingent claim just described.

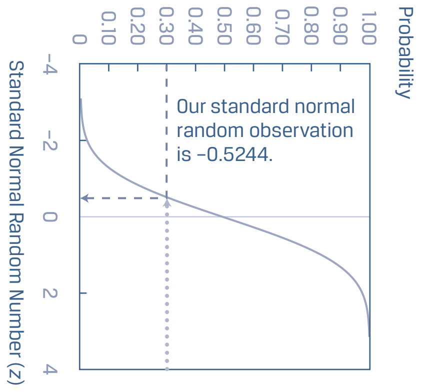
Exhibit 20 Inverse Transformation: Random Number from Uniform Distribution (PDF) Mapped to CDF and PDF of Standard Normal Distribution to Produce Random Observation

A. Uniform Random Number Is Generated



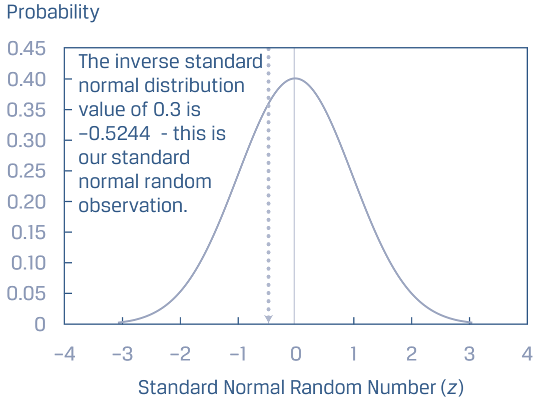
Randomly generated uniform number: for example, $x = 0.3$.

B. Random Number Mapped to Inverted Standard Normal CDF



Our standard normal random observation is −0.5244.

C. Point on Inverted CDF Mapped to Standard Normal PDF



The inverse standard normal distribution value of 0.3 is −0.5244 - this is our standard normal random observation.

In Example 10, we continue with the application of Monte Carlo simulation to value another type of contingent claim.

EXAMPLE 10

Valuing a Lookback Contingent Claim Using Monte Carlo Simulation

A standard lookback contingent claim on stock has a value at maturity equal to (Value of the stock at maturity – Minimum value of stock during the life of the claim prior to maturity) or \$0, whichever is greater. If the minimum value reached prior to maturity was \$20.11 and the value of the stock at maturity is \$23, for example, the contingent claim is worth \$23 – \$20.11 = \$2.89.

Briefly discuss how you might use Monte Carlo simulation in valuing a lookback contingent claim.

Solution:

We previously described how to use Monte Carlo simulation to value a certain type of contingent claim. Just as we can calculate the average value of the stock over a simulation trial to value that claim, for a lookback contingent claim, we can also calculate the minimum value of the stock over a simulation trial. Then, for a given simulation trial, we can calculate the terminal value of the claim, given the minimum value of the stock for the simulation trial. We can then discount this terminal value back to the present to get the value of the claim today (t = 0). The average of these t = 0 values over all simulation trials is the Monte Carlo simulated value of the lookback contingent claim.

Finally, it is important to note that Monte Carlo simulation is a complement to analytical methods. It provides only statistical estimates, not exact results. Analytical methods, where available, provide more insight into cause-and-effect relationships. However, as financial product innovations proceed, the applications for Monte Carlo simulation in investment management continue to grow.

SUMMARY

In this reading, we have presented the most frequently used probability distributions in investment analysis and Monte Carlo simulation.

- A probability distribution specifies the probabilities of the possible outcomes of a random variable.
- The two basic types of random variables are discrete random variables and continuous random variables. Discrete random variables take on at most a countable number of possible outcomes that we can list as $x_1, x_2, \ldots$. In contrast, we cannot describe the possible outcomes of a continuous random variable Z with a list $z_1, z_2, \ldots$, because the outcome $(z_1 + z_2)/2$, not in the list, would always be possible.
- The probability function specifies the probability that the random variable will take on a specific value. The probability function is denoted $p(x)$ for a discrete random variable and $f(x)$ for a continuous random variable. For any probability function $p(x)$, $0 \le p(x) \le 1$, and the sum of $p(x)$ over all values of X equals 1.
- The cumulative distribution function, denoted $F(x)$ for both continuous and discrete random variables, gives the probability that the random variable is less than or equal to x.

- The discrete uniform and the continuous uniform distributions are the distributions of equally likely outcomes.
- The binomial random variable is defined as the number of successes in n Bernoulli trials, where the probability of success, p, is constant for all trials and the trials are independent. A Bernoulli trial is an experiment with two outcomes, which can represent success or failure, an up move or a down move, or another binary (twofold) outcome.
- A binomial random variable has an expected value or mean equal to np and variance equal to $np(1 - p)$.
- A binomial tree is the graphical representation of a model of asset price dynamics in which, at each period, the asset moves up with probability p or down with probability $(1 - p)$. The binomial tree is a flexible method for modeling asset price movement and is widely used in pricing options.
- The normal distribution is a continuous symmetric probability distribution that is completely described by two parameters: its mean, μ, and its variance, σ^2.
- A univariate distribution specifies the probabilities for a single random variable. A multivariate distribution specifies the probabilities for a group of related random variables.
- To specify the normal distribution for a portfolio when its component securities are normally distributed, we need the means, the standard deviations, and all the distinct pairwise correlations of the securities. When we have those statistics, we have also specified a multivariate normal distribution for the securities.
- For a normal random variable, approximately 68% of all possible outcomes are within a one standard deviation interval about the mean, approximately 95% are within a two standard deviation interval about the mean, and approximately 99% are within a three standard deviation interval about the mean.
- A normal random variable, X, is standardized using the expression $Z = (X - \mu)/\sigma$, where μ and σ are the mean and standard deviation of X. Generally, we use the sample mean, $\bar{X}$, as an estimate of μ and the sample standard deviation, s, as an estimate of σ in this expression.
- The standard normal random variable, denoted Z, has a mean equal to 0 and variance equal to 1. All questions about any normal random variable can be answered by referring to the cumulative distribution function of a standard normal random variable, denoted $N(x)$ or $N(z)$.
- Shortfall risk is the risk that portfolio value or portfolio return will fall below some minimum acceptable level over some time horizon.
- Roy's safety-first criterion, addressing shortfall risk, asserts that the optimal portfolio is the one that minimizes the probability that portfolio return falls below a threshold level. According to Roy's safety-first criterion, if returns are normally distributed, the safety-first optimal portfolio P is the one that maximizes the quantity $[E(R_P) - R_L]/\sigma_P$, where R_L is the minimum acceptable level of return.
- A random variable follows a lognormal distribution if the natural logarithm of the random variable is normally distributed. The lognormal distribution is defined in terms of the mean and variance of its associated normal distribution. The lognormal distribution is bounded below by 0 and skewed to the right (it has a long right tail).
- The lognormal distribution is frequently used to model the probability distribution of asset prices because it is bounded below by zero.
- Continuous compounding views time as essentially continuous or unbroken; discrete compounding views time as advancing in discrete finite intervals.

- The continuously compounded return associated with a holding period is the natural log of 1 plus the holding period return, or equivalently, the natural log of ending price over beginning price.
- If continuously compounded returns are normally distributed, asset prices are lognormally distributed. This relationship is used to move back and forth between the distributions for return and price. Because of the central limit theorem, continuously compounded returns need not be normally distributed for asset prices to be reasonably well described by a lognormal distribution.
- Student's *t*-, chi-square, and *F*-distributions are used to support statistical analyses, such as sampling, testing the statistical significance of estimated model parameters, or hypothesis testing.
- The standard *t*-distribution is a symmetrical probability distribution defined by degrees of freedom (df) and characterized by fat tails. As df increase, the *t*-distribution approaches the standard normal distribution.
- The chi-square distribution is asymmetrical, defined by degrees of freedom, and with k df is the distribution of the sum of the squares of k independent standard normally distributed random variables, so it does not take on negative values. A different distribution exists for each value of df, $n - 1$.
- The *F*-distribution is a family of asymmetrical distributions bounded from below by 0. Each *F*-distribution is defined by two values of degrees of freedom, the numerator df and the denominator df. If χ_1^2 is one chi-square random variable with m df and χ_2^2 is another chi-square random variable with n df, then $F = \left(\chi_1^2/m\right)/\left(\chi_2^2/n\right)$ follows an *F*-distribution with m numerator df and n denominator df.
- Monte Carlo simulation involves the use of a computer to represent the operation of a complex financial system. A characteristic feature of Monte Carlo simulation is the generation of a large number of random samples from specified probability distributions to represent the operation of risk in the system. Monte Carlo simulation is used in planning, in financial risk management, and in valuing complex securities. Monte Carlo simulation is a complement to analytical methods but provides only statistical estimates, not exact results.
- Random observations from any distribution can be produced using the uniform random variable with endpoints 0 and 1 via the inverse transformation method. The randomly generated uniform random number is mapped onto the inverted cdf of any distribution from which random observations are desired. The point on the given distribution's cdf is then mapped onto its pdf, and the random observation is identified.

PRACTICE PROBLEMS

1 A European put option on stock conveys the right to sell the stock at a prespecified price, called the exercise price, at the maturity date of the option. The value of this put at maturity is (exercise price – stock price) or \$0, whichever is greater. Suppose the exercise price is \$100 and the underlying stock trades in increments of \$0.01. At any time before maturity, the terminal value of the put is a random variable.

A Describe the distinct possible outcomes for terminal put value. (Think of the put's maximum and minimum values and its minimum price increments.)

B Is terminal put value, at a time before maturity, a discrete or continuous random variable?

C Letting Y stand for terminal put value, express in standard notation the probability that terminal put value is less than or equal to \$24. No calculations or formulas are necessary.

2 Define the term "binomial random variable." Describe the types of problems for which the binomial distribution is used.

3 The value of the cumulative distribution function $F(x)$, where x is a particular outcome, for a discrete uniform distribution:

A sums to 1.

B lies between 0 and 1.

C decreases as x increases.

4 For a binomial random variable with five trials and a probability of success on each trial of 0.50, the distribution will be:

A skewed.

B uniform.

C symmetric.

5 In a discrete uniform distribution with 20 potential outcomes of integers 1–20, the probability that X is greater than or equal to 3 but less than 6, $P(3 \leq X < 6)$, is:

A 0.10.

B 0.15.

C 0.20.

6 Over the last 10 years, a company's annual earnings increased year over year seven times and decreased year over year three times. You decide to model the number of earnings increases for the next decade as a binomial random variable.

A What is your estimate of the probability of success, defined as an increase in annual earnings?

For Parts B, C, and D of this problem, assume the estimated probability is the actual probability for the next decade.

B What is the probability that earnings will increase in exactly 5 of the next 10 years?

C Calculate the expected number of yearly earnings increases during the next 10 years.

© 2017 CFA Institute. All rights reserved.

D Calculate the variance and standard deviation of the number of yearly earnings increases during the next 10 years.

E The expression for the probability function of a binomial random variable depends on two major assumptions. In the context of this problem, what must you assume about annual earnings increases to apply the binomial distribution in Part B? What reservations might you have about the validity of these assumptions?

7 A portfolio manager annually outperforms her benchmark 60% of the time. Assuming independent annual trials, what is the probability that she will outperform her benchmark four or more times over the next five years?

A 0.26

B 0.34

C 0.48

8 You are examining the record of an investment newsletter writer who claims a 70% success rate in making investment recommendations that are profitable over a one-year time horizon. You have the one-year record of the newsletter's seven most recent recommendations. Four of those recommendations were profitable. If all the recommendations are independent and the newsletter writer's skill is as claimed, what is the probability of observing four or fewer profitable recommendations out of seven in total?

9 You are forecasting sales for a company in the fourth quarter of its fiscal year. Your low-end estimate of sales is €14 million, and your high-end estimate is €15 million. You decide to treat all outcomes for sales between these two values as equally likely, using a continuous uniform distribution.

A What is the expected value of sales for the fourth quarter?

B What is the probability that fourth-quarter sales will be less than or equal to €14,125,000?

10 State the approximate probability that a normal random variable will fall within the following intervals:

A Mean plus or minus one standard deviation.

B Mean plus or minus two standard deviations.

C Mean plus or minus three standard deviations.

11 If the probability that a portfolio outperforms its benchmark in any quarter is 0.75, the probability that the portfolio outperforms its benchmark in three or fewer quarters over the course of a year is *closest* to:

A 0.26

B 0.42

C 0.68

12 In futures markets, profits or losses on contracts are settled at the end of each trading day. This procedure is called marking to market or daily resettlement. By preventing a trader's losses from accumulating over many days, marking to market reduces the risk that traders will default on their obligations. A futures markets trader needs a liquidity pool to meet the daily mark to market. If liquidity is exhausted, the trader may be forced to unwind his position at an unfavorable time.

Suppose you are using financial futures contracts to hedge a risk in your portfolio. You have a liquidity pool (cash and cash equivalents) of λ dollars per contract and a time horizon of T trading days. For a given size liquidity pool, λ, Kolb, Gay, and Hunter developed an expression for the probability stating that you will exhaust your liquidity pool within a T-day horizon as a result of the daily marking to market. Kolb et al. assumed that the expected change in futures price is 0 and that futures price changes are normally distributed. With σ representing the standard deviation of daily futures price changes, the standard deviation of price changes over a time horizon to day T is $\sigma\sqrt{T}$, given continuous compounding. With that background, the Kolb et al. expression is

$$\text{Probability of exhausting liquidity pool} = 2[1 - N(x)],$$

where $x = \lambda/\left(\sigma\sqrt{T}\right)$. Here, x is a standardized value of λ. $N(x)$ is the standard normal cumulative distribution function. For some intuition about $1 - N(x)$ in the expression, note that the liquidity pool is exhausted if losses exceed the size of the liquidity pool at any time up to and including T; the probability of that event happening can be shown to be proportional to an area in the right tail of a standard normal distribution, $1 - N(x)$.

Using the Kolb et al. expression, answer the following questions:

A Your hedging horizon is five days, and your liquidity pool is $2,000 per contract. You estimate that the standard deviation of daily price changes for the contract is $450. What is the probability that you will exhaust your liquidity pool in the five-day period?

B Suppose your hedging horizon is 20 days but all the other facts given in Part A remain the same. What is the probability that you will exhaust your liquidity pool in the 20-day period?

13 Which of the following is characteristic of the normal distribution?

A Asymmetry

B Kurtosis of 3

C Definitive limits or boundaries

14 Which of the following assets *most likely* requires the use of a multivariate distribution for modeling returns?

A A call option on a bond

B A portfolio of technology stocks

C A stock in a market index

15 The total number of parameters that fully characterizes a multivariate normal distribution for the returns on two stocks is:

A 3.

B 4.

C 5.

16 A client has a portfolio of common stocks and fixed-income instruments with a current value of £1,350,000. She intends to liquidate £50,000 from the portfolio at the end of the year to purchase a partnership share in a business. Furthermore, the client would like to be able to withdraw the £50,000 without reducing the initial capital of £1,350,000. The following table shows four alternative asset allocations.

Mean and Standard Deviation for Four Allocations (in Percent)

	A	B	C	D
Expected annual return	16	12	10	9
Standard deviation of return	24	17	12	11

Address the following questions (assume normality for Parts B and C):

A Given the client's desire not to invade the £1,350,000 principal, what is the shortfall level, R_L? Use this shortfall level to answer Part B.

B According to the safety-first criterion, which of the allocations is the best?

C What is the probability that the return on the safety-first optimal portfolio will be less than the shortfall level, R_L?

17 A portfolio has an expected mean return of 8% and standard deviation of 14%. The probability that its return falls between 8% and 11% is *closest* to:

A 8.5%.

B 14.8%.

C 58.3%.

18 A portfolio has an expected return of 7%, with a standard deviation of 13%. For an investor with a minimum annual return target of 4%, the probability that the portfolio return will fail to meet the target is *closest* to:

A 33%.

B 41%.

C 59%.

19 **A** Define Monte Carlo simulation, and explain its use in investment management.

B Compared with analytical methods, what are the strengths and weaknesses of Monte Carlo simulation for use in valuing securities?

20 Which of the following is a continuous random variable?

A The value of a futures contract quoted in increments of $0.05

B The total number of heads recorded in 1 million tosses of a coin

C The rate of return on a diversified portfolio of stocks over a three-month period

21 X is a discrete random variable with possible outcomes $X = \{1, 2, 3, 4\}$. Three functions—$f(x)$, $g(x)$, and $h(x)$—are proposed to describe the probabilities of the outcomes in X.

	Probability Function		
$X = x$	**$f(x) = P(X = x)$**	**$g(x) = P(X = x)$**	**$h(x) = P(X = x)$**
1	–0.25	0.20	0.20
2	0.25	0.25	0.25
3	0.50	0.50	0.30
4	0.25	0.05	0.35

The conditions for a probability function are satisfied by:

A $f(x)$.

B $g(x)$.

C $h(x)$.

22 The cumulative distribution function for a discrete random variable is shown in the following table.

$X = x$	Cumulative Distribution Function $F(x) = P(X \leq x)$
1	0.15
2	0.25
3	0.50
4	0.60
5	0.95
6	1.00

The probability that X will take on a value of either 2 or 4 is *closest* to:

A 0.20.

B 0.35.

C 0.85.

23 Which of the following events can be represented as a Bernoulli trial?

A The flip of a coin

B The closing price of a stock

C The picking of a random integer between 1 and 10

24 The weekly closing prices of Mordice Corporation shares are as follows:

Date	Closing Price (€)
1 August	112
8 August	160
15 August	120

The continuously compounded return of Mordice Corporation shares for the period August 1 to August 15 is *closest* to:

A 6.90%.

B 7.14%.

C 8.95%.

25 A stock is priced at $100.00 and follows a one-period binomial process with an up move that equals 1.05 and a down move that equals 0.97. If 1 million Bernoulli trials are conducted and the average terminal stock price is $102.00, the probability of an up move (p) is *closest* to:

A 0.375.

B 0.500.

C 0.625.

26 A call option on a stock index is valued using a three-step binomial tree with an up move that equals 1.05 and a down move that equals 0.95. The current level of the index is $190, and the option exercise price is $200. If the option value is positive when the stock price exceeds the exercise price at expiration and $0 otherwise, the number of terminal nodes with a positive payoff is:

A one.

B two.

C three.

27 A random number between zero and one is generated according to a continuous uniform distribution. What is the probability that the first number generated will have a value of exactly 0.30?

A 0%

B 30%

C 70%

28 A Monte Carlo simulation can be used to:

A directly provide precise valuations of call options.

B simulate a process from historical records of returns.

C test the sensitivity of a model to changes in assumptions—for example, on distributions of key variables.

29 A limitation of Monte Carlo simulation is:

A its failure to do "what if" analysis.

B that it requires historical records of returns.

C its inability to independently specify cause-and-effect relationships.

30 Which parameter equals zero in a normal distribution?

A Kurtosis

B Skewness

C Standard deviation

31 An analyst develops the following capital market projections.

	Stocks	**Bonds**
Mean Return	10%	2%
Standard Deviation	15%	5%

Assuming the returns of the asset classes are described by normal distributions, which of the following statements is correct?

A Bonds have a higher probability of a negative return than stocks.

B On average, 99% of stock returns will fall within two standard deviations of the mean.

C The probability of a bond return less than or equal to 3% is determined using a Z-score of 0.25.

32 A client holding a £2,000,000 portfolio wants to withdraw £90,000 in one year without invading the principal. According to Roy's safety-first criterion, which of the following portfolio allocations is optimal?

	Allocation A	**Allocation B**	**Allocation C**
Expected annual return	6.5%	7.5%	8.5%
Standard deviation of returns	8.35%	10.21%	14.34%

A Allocation A

B Allocation B

C Allocation C

33 In contrast to normal distributions, lognormal distributions:

A are skewed to the left.

B have outcomes that cannot be negative.

C are more suitable for describing asset returns than asset prices.

34 The lognormal distribution is a more accurate model for the distribution of stock prices than the normal distribution because stock prices are:

A symmetrical.

B unbounded.

C non-negative.

35 The price of a stock at $t = 0$ is \$208.25 and at $t = 1$ is \$186.75. The continuously compounded rate of return for the stock from $t = 0$ to $t = 1$ is *closest* to:

A −10.90%.

B −10.32%.

C 11.51%.

36 Which one of the following statements about Student's *t*-distribution is *false*?

A It is symmetrically distributed around its mean value, like the normal distribution.

B It has shorter (i.e., thinner) tails than the normal distribution.

C As its degrees of freedom increase, Student's *t*-distribution approaches the normal distribution.

37 Which one of the following statements concerning chi-square and *F*-distributions is *false*?

A They are both asymmetric distributions.

B As their degrees of freedom increase, the shapes of their pdfs become more bell curve–like.

C The domains of their pdfs are positive and negative numbers.

SOLUTIONS

1 **A** The put's minimum value is \$0. The put's value is \$0 when the stock price is at or above \$100 at the maturity date of the option. The put's maximum value is \$100 = \$100 (the exercise price) – \$0 (the lowest possible stock price). The put's value is \$100 when the stock is worthless at the option's maturity date. The put's minimum price increments are \$0.01. The possible outcomes of terminal put value are thus \$0.00, \$0.01, \$0.02, . . . , \$100.

B The price of the underlying has minimum price fluctuations of \$0.01: These are the minimum price fluctuations for terminal put value. For example, if the stock finishes at \$98.20, the payoff on the put is \$100 – \$98.20 = \$1.80. We can specify that the nearest values to \$1.80 are \$1.79 and \$1.81. With a continuous random variable, we cannot specify the nearest values. So, we must characterize terminal put value as a discrete random variable.

C The probability that terminal put value is less than or equal to \$24 is $P(Y \leq 24)$, or $F(24)$ in standard notation, where F is the cumulative distribution function for terminal put value.

2 A binomial random variable is defined as the number of successes in n Bernoulli trials (a trial that produces one of two outcomes). The binomial distribution is used to make probability statements about a record of successes and failures or about anything with binary (twofold) outcomes.

3 B is correct. The value of the cumulative distribution function lies between 0 and 1 for any x: $0 \leq F(x) \leq 1$.

4 C is correct. The binomial distribution is symmetric when the probability of success on a trial is 0.50, but it is asymmetric or skewed otherwise. Here, it is given that $p = 0.50$.

5 B is correct. The probability of any outcome is 0.05, $P(1) = 1/20 = 0.05$. The probability that X is greater than or equal to 3 but less than 6 is expressed as $P(3 \leq X < 6) = P(3) + P(4) + P(5) = 0.05 + 0.05 + 0.05 = 0.15$.

6 **A** The probability of an earnings increase (success) in a year is estimated as 7/10 = 0.70, or 70%, based on the record of the past 10 years.

B The probability that earnings will increase in 5 of the next 10 years is about 10.3%. Define a binomial random variable X, counting the number of earnings increases over the next 10 years. From Part A, the probability of an earnings increase in a given year is $p = 0.70$ and the number of trials (years) is $n = 10$. Equation 2 gives the probability that a binomial random variable has x successes in n trials, with the probability of success on a trial equal to p:

$$P(X = x) = \binom{n}{x} p^x (1-p)^{n-x} = \frac{n!}{(n-x)!x!} p^x (1-p)^{n-x}.$$

For this example,

$$\begin{aligned}\binom{10}{5} 0.7^5 0.3^{10-5} &= \frac{10!}{(10-5)!5!} 0.7^5 0.3^{10-5} \\ &= 252 \times 0.16807 \times 0.00243 = 0.102919.\end{aligned}$$

We conclude that the probability that earnings will increase in exactly 5 of the next 10 years is 0.1029, or approximately 10.3%.

C The expected number of yearly increases is $E(X) = np = 10 \times 0.70 = 7$.

D The variance of the number of yearly increases over the next 10 years is $\sigma^2 = np(1 - p) = 10 \times 0.70 \times 0.30 = 2.1$. The standard deviation is 1.449 (the positive square root of 2.1).

E You must assume that (1) the probability of an earnings increase (success) is constant from year to year and (2) earnings increases are independent trials. If current and past earnings help forecast next year's earnings, Assumption 2 is violated. If the company's business is subject to economic or industry cycles, neither assumption is likely to hold.

7 B is correct. To calculate the probability of four years of outperformance, use the formula

$$p(x) = P(X = x) = \binom{n}{x} p^x (1 - p)^{n-x} = \frac{n!}{(n - x)!x!} p^x (1 - p)^{n-x}.$$

Using this formula to calculate the probability in four of five years, $n = 5$, $x = 4$, and $p = 0.60$.

Therefore,

$$p(4) = \frac{5!}{(5 - 4)!4!} 0.6^4 (1 - 0.6)^{5-4} = [120/24](0.1296)(0.40) = 0.2592.$$

$$p(5) = \frac{5!}{(5 - 5)!5!} 0.6^5 (1 - 0.6)^{5-5} = [120/120](0.0778)(1) = 0.0778.$$

The probability of outperforming four or more times is $p(4) + p(5) = 0.2592 + 0.0778 = 0.3370$.

8 The observed success rate is 4/7 = 0.571, or 57.1%. The probability of four or fewer successes is $F(4) = p(4) + p(3) + p(2) + p(1) + p(0)$, where $p(4)$, $p(3)$, $p(2)$, $p(1)$, and $p(0)$ are, respectively, the probabilities of 4, 3, 2, 1, and 0 successes, according to the binomial distribution with $n = 7$ and $p = 0.70$. We have the following probabilities:

$p(4) = (7!/4!3!)(0.70^4)(0.30^3) = 35(0.006483) = 0.226895.$

$p(3) = (7!/3!4!)(0.70^3)(0.30^4) = 35(0.002778) = 0.097241.$

$p(2) = (7!/2!5!)(0.70^2)(0.30^5) = 21(0.001191) = 0.025005.$

$p(1) = (7!/1!6!)(0.70^1)(0.30^6) = 7(0.000510) = 0.003572.$

$p(0) = (7!/0!7!)(0.70^0)(0.30^7) = 1(0.000219) = 0.000219.$

Summing all these probabilities, you conclude that $F(4) = 0.226895 + 0.097241 + 0.025005 + 0.003572 + 0.000219 = 0.352931$, or 35.3%.

9 A The expected value of fourth-quarter sales is €14,500,000, calculated as (€14,000,000 + €15,000,000)/2. With a continuous uniform random variable, the mean or expected value is the midpoint between the smallest and largest values.

B The probability that fourth-quarter sales will be less than or equal to €14,125,000 is 0.125, or 12.5%, calculated as (€14,125,000 – €14,000,000)/(€15,000,000 – €14,000,000).

10 A Approximately 68% of all outcomes of a normal random variable fall within plus or minus one standard deviation of the mean.

B Approximately 95% of all outcomes of a normal random variable fall within plus or minus two standard deviations of the mean.

C Approximately 99% of all outcomes of a normal random variable fall within plus or minus three standard deviations of the mean.

11 C is correct. The probability that the performance is at or below the expectation is calculated by finding $F(3) = p(3) + p(2) + p(1) + p(0)$ using the formula:

$$p(x) = P(X = x) = \binom{n}{x} p^x (1 - p)^{n-x} = \frac{n!}{(n - x)!x!} p^x (1 - p)^{n-x}.$$

Using this formula,

$$p(3) = \frac{4!}{(4 - 3)!3!} 0.75^3 (1 - 0.75)^{4-3} = [24/6](0.42)(0.25) = 0.42.$$

$$p(2) = \frac{4!}{(4 - 2)!2!} 0.75^2 (1 - 0.75)^{4-2} = [24/4](0.56)(0.06) = 0.20.$$

$$p(1) = \frac{4!}{(4 - 1)!1!} 0.75^1 (1 - 0.75)^{4-1} = [24/6](0.75)(0.02) = 0.06.$$

$$p(0) = \frac{4!}{(4 - 0)!0!} 0.75^0 (1 - 0.75)^{4-0} = [24/24](1)(0.004) = 0.004.$$

Therefore,

$F(3) = p(3) + p(2) + p(1) + p(0) = 0.42 + 0.20 + 0.06 + 0.004 = 0.684$, or approximately 68%.

12 **A** The probability of exhausting the liquidity pool is 4.7%. First, calculate $x = \lambda/\left(\sigma\sqrt{T}\right) = \$2{,}000/\left(\$450\sqrt{5}\right) = 1.987616$. By using Excel's NORM.S.DIST() function, we get NORM.S.DIST(1.987616) = 0.9766. Thus, the probability of exhausting the liquidity pool is $2[1 - N(1.99)] = 2(1 - 0.9766) = 0.0469$, or about 4.7%.

B The probability of exhausting the liquidity pool is now 32.2%. The calculation follows the same steps as those in Part A. We calculate $x = \lambda/\left(\sigma\sqrt{T}\right) = \$2{,}000/\left(\$450\sqrt{20}\right) = 0.993808$. By using Excel's NORM.S.DIST() function, we get NORM.S.DIST(0.993808)= 0.8398. Thus, the probability of exhausting the liquidity pool is $2[1 - N(0.99)] = 2(1 - 0.8398) = 0.3203$, or about 32.0%. This is a substantial probability that you will run out of funds to meet marking to market.

In their paper, Kolb et al. called the probability of exhausting the liquidity pool the probability of ruin, a traditional name for this type of calculation.

13 B is correct. The normal distribution has a skewness of 0, a kurtosis of 3, and a mean, median, and mode that are all equal.

14 B is correct. Multivariate distributions specify the probabilities for a group of related random variables. A portfolio of technology stocks represents a group of related assets. Accordingly, statistical interrelationships must be considered, resulting in the need to use a multivariate normal distribution.

15 C is correct. A bivariate normal distribution (two stocks) will have two means, two variances, and one correlation. A multivariate normal distribution for the returns on n stocks will have n means, n variances, and $n(n - 1)/2$ distinct correlations.

16 **A** Because £50,000/£1,350,000 is 3.7%, for any return less than 3.7% the client will need to invade principal if she takes out £50,000. So $R_L = 3.7\%$.

B To decide which of the allocations is safety-first optimal, select the alternative with the highest ratio $[\mathrm{E}(R_P) - R_L]/\sigma_P$:

Allocation A: 0.5125 = (16 – 3.7)/24.

Allocation B: 0.488235 = (12 – 3.7)/17.

Allocation C: 0.525 = (10 – 3.7)/12.

Allocation D: 0.481818 = (9 – 3.7)/11.

Allocation C, with the largest ratio (0.525), is the best alternative according to the safety-first criterion.

C To answer this question, note that $P(R_C < 3.7) = N(0.037 - 0.10)/0.12$ $= N(-0.525)$. By using Excel's NORM.S.DIST() function, we get NORM.S.DIST((0.037 – 0.10)/0.12) = 29.98%, or about 30%. The safety-first optimal portfolio has a roughly 30% chance of not meeting a 3.7% return threshold.

17 A is correct. $P(8\% \leq \text{Portfolio return} \leq 11\%) = N(Z \text{ corresponding to } 11\%) - N(Z \text{ corresponding to } 8\%)$. For the first term, NORM.S.DIST((11% – 8%)/14%) = 58.48%. To get the second term immediately, note that 8% is the mean, and for the normal distribution, 50% of the probability lies on either side of the mean. Therefore, $N(Z$ corresponding to 8%) must equal 50%. So, $P(8\% \leq \text{Portfolio return} \leq 11\%) = 0.5848 - 0.50 = 0.0848$, or approximately 8.5%.

18 B is correct. By using Excel's NORM.S.DIST() function, we get NORM.S.DIST((4% – 7%)/13%) = 40.87%. The probability that the portfolio will underperform the target is about 41%.

19 **A** Monte Carlo simulation involves the use of computer software to represent the operation of a complex financial system. A characteristic feature of Monte Carlo simulation is the generation of a large number of random samples from a specified probability distribution (or distributions) to represent the role of risk in the system. Monte Carlo simulation is widely used to estimate risk and return in investment applications. In this setting, we simulate the portfolio's profit and loss performance for a specified time horizon. Repeated trials within the simulation produce a simulated frequency distribution of portfolio returns from which performance and risk measures are derived. Another important use of Monte Carlo simulation in investments is as a tool for valuing complex securities for which no analytic pricing formula is available. It is also an important modeling resource for securities with complex embedded options.

B *Strengths:* Monte Carlo simulation can be used to price complex securities for which no analytic expression is available, particularly European-style options.

Weaknesses: Monte Carlo simulation provides only statistical estimates, not exact results. Analytic methods, when available, provide more insight into cause-and-effect relationships than does Monte Carlo simulation.

20 C is correct. The rate of return is a random variable because the future outcomes are uncertain, and it is continuous because it can take on an unlimited number of outcomes.

21 B is correct. The function $g(x)$ satisfies the conditions of a probability function. All of the values of $g(x)$ are between 0 and 1, and the values of $g(x)$ all sum to 1.

22 A is correct. The probability that X will take on a value of 4 or less is $F(4) = P(X \leq 4) = p(1) + p(2) + p(3) + p(4) = 0.60$. The probability that X will take on a value of 3 or less is $F(3) = P(X \leq 3) = p(1) + p(2) + p(3) = 0.50$. So, the probability that X will take on a value of 4 is $F(4) - F(3) = p(4) = 0.10$. The probability of $X = 2$ can be found using the same logic: $F(2) - F(1) = p(2) = 0.25 - 0.15 = 0.10$. The probability of X taking on a value of 2 or 4 is $p(2) + p(4) = 0.10 + 0.10 = 0.20$.

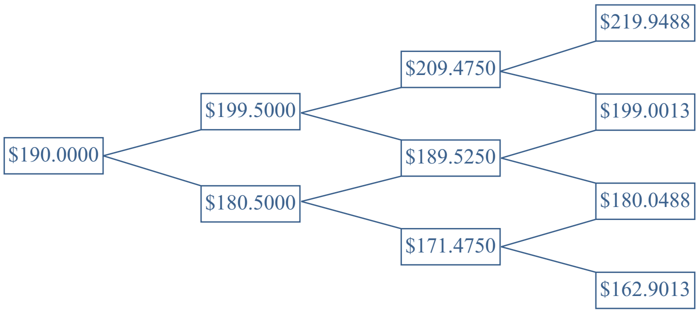
23 A is correct. A trial, such as a coin flip, will produce one of two outcomes. Such a trial is a Bernoulli trial.

24 A is correct. The continuously compounded return of an asset over a period is equal to the natural log of the asset's price change during the period. In this case,

$$\ln(120/112) = 6.90\%.$$

25 C is correct. The probability of an up move (p) can be found by solving the equation $(p)uS + (1 - p)dS = (p)105 + (1 - p)97 = 102$. Solving for p gives $8p = 5$, so $p = 0.625$.

26 A is correct. Only the top node value of \$219.9488 exceeds \$200.



27 A is correct. The probability of generating a random number equal to any fixed point under a continuous uniform distribution is zero.

28 C is correct. A characteristic feature of Monte Carlo simulation is the generation of a large number of random samples from a specified probability distribution or distributions to represent the role of risk in the system. Therefore, it is very useful for investigating the sensitivity of a model to changes in assumptions—for example, on distributions of key variables.

29 C is correct. Monte Carlo simulation is a complement to analytical methods. Monte Carlo simulation provides statistical estimates and not exact results. Analytical methods, when available, provide more insight into cause-and-effect relationships.

30 B is correct. A normal distribution has a skewness of zero (it is symmetrical around the mean). A non-zero skewness implies asymmetry in a distribution.

31 A is correct. The chance of a negative return falls in the area to the left of 0% under a standard normal curve. By standardizing the returns and standard deviations of the two assets, the likelihood of either asset experiencing a negative return may be determined: Z-score (standardized value) = $(X - \mu)/\sigma$.

Z-score for a bond return of 0% = $(0 - 2)/5 = -0.40$.

Z-score for a stock return of 0% = $(0 - 10)/15 = -0.67$.

For bonds, a 0% return falls 0.40 standard deviations below the mean return of 2%. In contrast, for stocks, a 0% return falls 0.67 standard deviations below the mean return of 10%. A standard deviation of 0.40 is less than a standard deviation of 0.67. Negative returns thus occupy more of the left tail of the bond distribution than the stock distribution. Thus, bonds are more likely than stocks to experience a negative return.

32 B is correct. Allocation B has the highest safety-first ratio. The threshold return level, R_L, for the portfolio is £90,000/£2,000,000 = 4.5%;, thus, any return less than R_L = 4.5% will invade the portfolio principal. To compute the allocation that is safety-first optimal, select the alternative with the highest ratio:

$$\frac{\left[\mathrm{E}\left(R_P - R_L\right)\right]}{\sigma_P}.$$

$$\text{Allocation A} = \frac{6.5 - 4.5}{8.35} = 0.240.$$

$$\text{Allocation B} = \frac{7.5 - 4.5}{10.21} = 0.294.$$

$$\text{Allocation C} = \frac{8.5 - 4.5}{14.34} = 0.279.$$

33 B is correct. By definition, lognormal random variables cannot have negative values.

34 C is correct. A lognormal distributed variable has a lower bound of zero. The lognormal distribution is also right skewed, which is a useful property in describing asset prices.

35 A is correct. The continuously compounded return from $t = 0$ to $t = 1$ is $r_{0,1} = \ln(S_1/S_0) = \ln(186.75/208.25) = -0.10897 = -10.90\%$.

36 A is correct, since it is false. Student's t-distribution has longer (fatter) tails than the normal distribution and, therefore, it may provide a more reliable, more conservative downside risk estimate.

37 C is correct, since it is false. Both chi-square and F-distributions are bounded from below by zero, so the domains of their pdfs are restricted to positive numbers.

Sampling and Estimation

by Richard A. DeFusco, PhD, CFA, Dennis W. McLeavey, CFA, Jerald E. Pinto, PhD, CFA, and David E. Runkle, PhD, CFA

Richard A. DeFusco, PhD, CFA, is at the University of Nebraska-Lincoln (USA). Dennis W. McLeavey, DBA, CFA, is at the University of Rhode Island (USA). Jerald E. Pinto, PhD, CFA, is at CFA Institute (USA). David E. Runkle, PhD, CFA, is at Jacobs Levy Equity Management (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** compare and contrast probability samples with non-probability samples and discuss applications of each to an investment problem;
☐	**b.** explain sampling error;
☐	**c.** compare and contrast simple random, stratified random, cluster, convenience, and judgmental sampling;
☐	**d.** explain the central limit theorem and its importance;
☐	**e.** calculate and interpret the standard error of the sample mean;
☐	**f.** identify and describe desirable properties of an estimator;
☐	**g.** contrast a point estimate and a confidence interval estimate of a population parameter;
☐	**h.** calculate and interpret a confidence interval for a population mean, given a normal distribution with 1) a known population variance, 2) an unknown population variance, or 3) an unknown population variance and a large sample size;
☐	**i.** describe the use of resampling (bootstrap, jackknife) to estimate the sampling distribution of a statistic.
☐	**j.** describe the issues regarding selection of the appropriate sample size, data snooping bias, sample selection bias, survivorship bias, look-ahead bias, and time-period bias.

CFA Institute would like to thank Jian Wu, PhD, at State Street (USA), for this major revision of Sampling & Estimation, including new visuals, graphics, Excel functions and related text content throughout the reading.

1 INTRODUCTION

Each day, we observe the high, low, and close of stock market indexes from around the world. Indexes such as the S&P 500 Index and the Nikkei 225 Stock Average are samples of stocks. Although the S&P 500 and the Nikkei do not represent the populations of US or Japanese stocks, we view them as valid indicators of the whole population's behavior. As analysts, we are accustomed to using this sample information to assess how various markets from around the world are performing. Any statistics that we compute with sample information, however, are only estimates of the underlying population parameters. A sample, then, is a subset of the population—a subset studied to infer conclusions about the population itself.

We introduce and discuss **sampling**—the process of obtaining a sample. In investments, we continually make use of the mean as a measure of central tendency of random variables, such as return and earnings per share. Even when the probability distribution of the random variable is unknown, we can make probability statements about the population mean using the central limit theorem. We discuss and illustrate this key result. Following that discussion, we turn to statistical estimation. Estimation seeks precise answers to the question "What is this parameter's value?"

The central limit theorem and estimation, the core of the body of methods presented in the sections that follow, may be applied in investment applications. We often interpret the results for the purpose of deciding what works and what does not work in investments. We will also discuss the interpretation of statistical results based on financial data and the possible pitfalls in this process.

2 SAMPLING METHODS

a compare and contrast probability samples with non-probability samples and discuss applications of each to an investment problem

b explain sampling error

c compare and contrast simple random, stratified random, cluster, convenience, and judgmental sampling

In this section, we present the various methods for obtaining information on a population (all members of a specified group) through samples (part of the population). The information on a population that we try to obtain usually concerns the value of a **parameter**, a quantity computed from or used to describe a population of data. When we use a sample to estimate a parameter, we make use of sample statistics (statistics, for short). A statistic is a quantity computed from or used to describe a sample of data.

We take samples for one of two reasons. In some cases, we cannot possibly examine every member of the population. In other cases, examining every member of the population would not be economically efficient. Thus, savings of time and money are two primary factors that cause an analyst to use sampling to answer a question about a population.

There are two types of sampling methods: **probability sampling** and **non-probability sampling** Probability sampling gives every member of the population an equal chance of being selected. Hence it can create a sample that is representative of the population. In contrast, non-probability sampling depends on factors other than probability considerations, such as a sampler's judgment or the convenience to access data. Consequently, there is a significant risk that non-probability sampling might generate a non-representative sample. In general, all else being equal, probability sampling can yield more accuracy and reliability compared with non-probability sampling.

We first focus on probability sampling, particularly the widely used **simple random sampling** and **stratified random sampling**. We then turn our attention to non-probability sampling.

2.1 Simple Random Sampling

Suppose a telecommunications equipment analyst wants to know how much major customers will spend on average for equipment during the coming year. One strategy is to survey the population of telecom equipment customers and inquire what their purchasing plans are. In statistical terms, the characteristics of the population of customers' planned expenditures would then usually be expressed by descriptive measures such as the mean and variance. Surveying all companies, however, would be very costly in terms of time and money.

Alternatively, the analyst can collect a representative sample of companies and survey them about upcoming telecom equipment expenditures. In this case, the analyst will compute the sample mean expenditure, $\overline{X}$, a statistic. This strategy has a substantial advantage over polling the whole population because it can be accomplished more quickly and at lower cost.

Sampling, however, introduces error. The error arises because not all the companies in the population are surveyed. The analyst who decides to sample is trading time and money for sampling error.

When an analyst chooses to sample, he must formulate a sampling plan. A **sampling plan** is the set of rules used to select a sample. The basic type of sample from which we can draw statistically sound conclusions about a population is the **simple random sample** (random sample, for short).

- **Definition of Simple Random Sample.** A simple random sample is a subset of a larger population created in such a way that each element of the population has an equal probability of being selected to the subset.

The procedure of drawing a sample to satisfy the definition of a simple random sample is called **simple random sampling**. How is simple random sampling carried out? We need a method that ensures randomness—the lack of any pattern—in the selection of the sample. For a finite (limited) population, the most common method for obtaining a random sample involves the use of random numbers (numbers with assured properties of randomness). First, we number the members of the population in sequence. For example, if the population contains 500 members, we number them in sequence with three digits, starting with 001 and ending with 500. Suppose we want a simple random sample of size 50. In that case, using a computer random-number generator or a table of random numbers, we generate a series of three-digit random numbers. We then match these random numbers with the number codes of the population members until we have selected a sample of size 50. Simple random sampling is particularly useful when data in the population is homogeneous—that is, the characteristics of the data or observations (e.g., size or region) are broadly similar. We will see that if this condition is not satisfied other types of sampling may be more appropriate.

Sometimes we cannot code (or even identify) all the members of a population. We often use **systematic sampling** in such cases. With systematic sampling, we select every *k*th member until we have a sample of the desired size. The sample that results from this procedure should be approximately random. Real sampling situations may require that we take an approximately random sample.

Suppose the telecommunications equipment analyst polls a random sample of telecom equipment customers to determine the average equipment expenditure. The sample mean will provide the analyst with an estimate of the population mean expenditure. The mean obtained from the sample this way will differ from the population mean that we are trying to estimate. It is subject to error. An important part of this error is known as **sampling error**, which comes from sampling variation and occurs because we have data on only a subset of the population.

- **Definition of Sampling Error.** Sampling error is the difference between the observed value of a statistic and the quantity it is intended to estimate as a result of using subsets of the population.

A random sample reflects the properties of the population in an unbiased way, and sample statistics, such as the sample mean, computed on the basis of a random sample are valid estimates of the underlying population parameters.

A sample statistic is a random variable. In other words, not only do the original data from the population have a distribution but so does the sample statistic.

This distribution is the statistic's **sampling distribution**.

- **Definition of Sampling Distribution of a Statistic.** The sampling distribution of a statistic is the distribution of all the distinct possible values that the statistic can assume when computed from samples of the same size randomly drawn from the same population.

In the case of the sample mean, for example, we refer to the "sampling distribution of the sample mean" or the distribution of the sample mean. We will have more to say about sampling distributions later in this reading. Next, however, we look at another sampling method that is useful in investment analysis.

2.2 Stratified Random Sampling

The simple random sampling method just discussed may not be the best approach in all situations. One frequently used alternative is stratified random sampling.

- **Definition of Stratified Random Sampling.** In stratified random sampling, the population is divided into subpopulations (strata) based on one or more classification criteria. Simple random samples are then drawn from each stratum in sizes proportional to the relative size of each stratum in the population. These samples are then pooled to form a stratified random sample.

In contrast to simple random sampling, stratified random sampling guarantees that population subdivisions of interest are represented in the sample. Another advantage is that estimates of parameters produced from stratified sampling have greater precision—that is, smaller variance or dispersion—than estimates obtained from simple random sampling.

Bond indexing is one area in which stratified sampling is frequently applied. **Indexing** is an investment strategy in which an investor constructs a portfolio to mirror the performance of a specified index. In pure bond indexing, also called the full-replication approach, the investor attempts to fully replicate an index by owning all the bonds in the index in proportion to their market value weights. Many bond indexes consist of thousands of issues, however, so pure bond indexing is difficult to implement. In addition, transaction costs would be high because many bonds do not have liquid markets. Although a simple random sample could be a solution to the cost problem, the sample would probably not match the index's major risk factors—interest rate sensitivity, for example. Because the major risk factors of fixed-income portfolios are well known and quantifiable, stratified sampling offers a more effective approach. In this approach, we divide the population of index bonds into groups of similar duration (interest rate sensitivity), cash flow distribution, sector, credit quality, and call exposure. We refer to each group as a stratum or cell (a term frequently used in this context). Then, we choose a sample from each stratum proportional to the relative market weighting of the stratum in the index to be replicated.

EXAMPLE 1

Bond Indexes and Stratified Sampling

Suppose you are the manager of a portfolio of bonds indexed to the Bloomberg Barclays US Government/Credit Index, meaning that the portfolio returns should be similar to those of the index. You are exploring several approaches to indexing, including a stratified sampling approach. You first distinguish among agency bonds, US Treasury bonds, and investment-grade corporate bonds. For each of these three groups, you define 10 maturity intervals—1 to 2 years, 2 to 3 years, 3 to 4 years, 4 to 6 years, 6 to 8 years, 8 to 10 years, 10 to 12 years, 12 to 15 years, 15 to 20 years, and 20 to 30 years—and also separate the bonds with coupons (annual interest rates) of 6% or less from the bonds with coupons of more than 6%.

1 How many cells or strata does this sampling plan entail?

2 If you use this sampling plan, what is the minimum number of issues the indexed portfolio can have?

3 Suppose that in selecting among the securities that qualify for selection within each cell, you apply a criterion concerning the liquidity of the security's market. Is the sample obtained random? Explain your answer.

Solution to 1:

We have 3 issuer classifications, 10 maturity classifications, and 2 coupon classifications. So, in total, this plan entails 3(10)(2) = 60 different strata or cells.

Solution to 2:

One cannot have less than 1 issue for each cell, so the portfolio must include at least 60 issues.

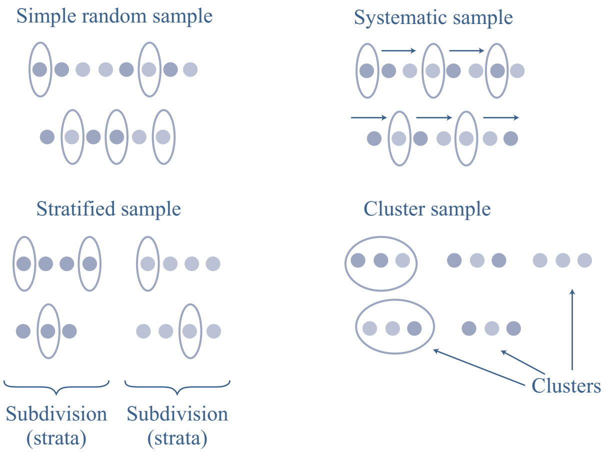
Solution to 3:

Applying any additional criteria to the selection of securities for the cells, not every security that might be included has an equal probability of being selected. As a result, the sampling is not random. In practice, indexing using stratified sampling usually does not strictly involve random sampling because the selection of bond issues within cells is subject to various additional criteria. Because the purpose of sampling in this application is not to make an inference about a population parameter but rather to index a portfolio, lack of randomness is not in itself a problem in this application of stratified sampling.

2.3 Cluster Sampling

Another sampling method, **cluster sampling**, also requires the division or classification of the population into subpopulation groups, called clusters. In this method, the population is divided into clusters, each of which is essentially a mini-representation of the entire populations. Then certain clusters are chosen as a whole using simple random sampling. If all the members in each sampled cluster are sampled, this sample plan is referred to as one-stage cluster sampling. If a subsample is randomly selected from each selected cluster, then the plan is referred as two-stage cluster sampling. Exhibit 1 (bottom right panel) shows how cluster sampling works and how it compares with the other probability sampling methods.

Exhibit 1 Probability Sampling



A major difference between cluster and stratified random samples is that in cluster sampling, a whole cluster is regarded as a sampling unit and only sampled clusters are included. In stratified random sampling, however, all the strata are included and only specific elements within each stratum are then selected as sampling units.

Cluster sampling is commonly used for market survey, and the most popular version identifies clusters based on geographic parameters. For example, a research institute is looking to survey if individual investors in the United States are bullish, bearish, or neutral on the stock market. It would be impossible to carry out the research by surveying all the individual investors in the country. The two-stage cluster sampling is a good solution in this case. At the first stage, a researcher can group the population by states and all the individual investors of each state represent a cluster. A handful of the clusters are then randomly selected. At the second stage, a simple random sample of individual investors is selected from each sampled cluster to conduct the survey.

Compared with other probability sampling methods, given equal sample size, cluster sampling usually yields lower accuracy because a sample from a cluster might be less representative of the entire population. Its major advantage, however, is offering the most time-efficient and cost-efficient probability sampling plan for analyzing a vast population.

2.4 Non-Probability Sampling

Non-probability sampling methods rely not on a fixed selection process but instead on a researcher's sample selection capabilities. We introduce two major types of non-probability sampling methods here.

- **Convenience Sampling:** In this method, an element is selected from the population based on whether or not it is accessible to a researcher or on how easy it is for a researcher to access the element. Because the samples are selected conveniently, they are not necessarily representative of the entire population, and hence the level of the sampling accuracy could be limited. But the advantage of **convenience sampling** is that data can be collected quickly at a low cost. In situations such as the preliminary stage of research or in circumstances subject to cost constraints, convenience sampling is often used as a time-efficient and cost-effective sampling plan for a small-scale pilot study before testing a large-scale and more representative sample.

- **Judgmental Sampling:** This sampling process involves selectively handpicking elements from the population based on a researcher's knowledge and professional judgment. Sample selection under **judgmental sampling** could be affected by the bias of the researcher and might lead to skewed results that do not represent the whole population. In circumstances where there is a time constraint, however, or when the specialty of researchers is critical to select a more representative sample than by using other probability or non-probability sampling methods, judgmental sampling allows researchers to go directly to the target population of interest. For example, when auditing financial statements, seasoned auditors can apply their sound judgment to select accounts or transactions that can provide sufficient audit coverage. Example 2 illustrates an application of these sampling methods.

EXAMPLE 2

Demonstrating the Power of Sampling

To demonstrate the power of sampling, we conduct two sampling experiments on a large dataset. The full dataset is the "population," representing daily returns of the fictitious Euro-Asia-Africa (EAA) Equity Index. This dataset spans a five-year period and consists of 1,258 observations of daily returns with a minimum value of −4.1% and a maximum value of 5.0%.

First, we calculate the mean daily return of the EAA Equity Index (using the population).

By taking the average of all the data points, the mean of the entire daily return series is computed as 0.035%.

First Experiment: Random Sampling

The sample size m is set to 5, 10, 20, 50, 100, 200, 500, and 1,000. At each sample size, we run random sampling multiple times (N = 100) to collect 100 samples to compute mean absolute error. The aim is to compute and plot the mean error versus the sample size.

For a given sample size m, we use the following procedure to compute mean absolute error in order to measure sampling error:

1. Randomly draw m observations from the entire daily return series to form a sample.
2. Compute the mean of this sample.
3. Compute the absolute error, the difference between the sample's mean and the population mean. Because we treat the whole five-year daily return series as a population, the population mean is 0.035% as we computed in Solution 1.
4. We repeat the previous three steps a hundred times (N =100) to collect 100 samples of the same size m and compute the absolute error of each sample.
5. Compute the mean of the 100 absolute errors as the mean absolute error for the sample size m.

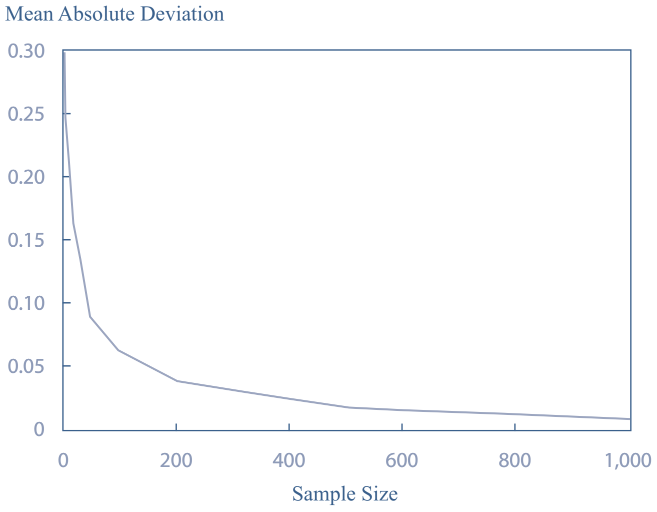
By applying this procedure, we compute mean absolute errors for eight different sample sizes: m = 5, 10, 20, 50, 100, 200, 500, and 1000. Exhibit 2 summarizes the results.

Exhibit 2 Mean Absolute Error of Random Sampling

Sample size	5	10	20	50	100	200	500	1,000
Mean absolute error	0.297%	0.218%	0.163%	0.091%	0.063%	0.039%	0.019%	0.009%

Mean absolute errors are plotted against sample size in Exhibit 3. The plot shows that the error quickly shrinks as the sample size increases. It also indicates that a minimum sample size is needed to limit sample error and achieve a certain level of accuracy. After a certain size, however (e.g., 200 to 400 in this case), there is little incremental benefit from adding more observations.

Exhibit 3 Mean Absolute Error of Random Sampling vs. Sample Size



Second Experiment: Stratified Random Sampling

We now conduct stratified random sampling by dividing daily returns into groups by year. The sample size m is again set to 5, 10, 20, 50, 100, 200, 500, and 1,000. At each sample size, run random sampling multiple times (N = 100) to collect 100 samples to compute mean absolute error.

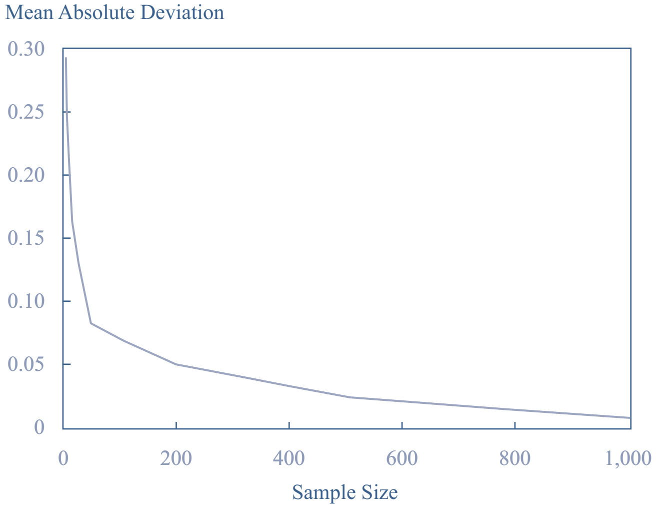
We follow the same steps as before, except for the first step. Rather than running a simple random sampling, we conduct stratified random sampling—that is, randomly selecting subsamples of equal number from daily return groups by year to generate a full sample. For example, for a sample of 50, 10 data points are randomly selected from daily returns of each year from 2014 to 2018, respectively. Exhibit 4 summarizes the results.

Exhibit 4 Mean Absolute Error of Stratified Random Sampling

Sample size	5	10	20	50	100	200	500	1,000
Mean absolute error	0.294%	0.205%	0.152%	0.083%	0.071%	0.051%	0.025%	0.008%

Mean absolute errors are plotted against sample size in Exhibit 5. Similar to random sampling, the plot shows rapid shrinking of errors with increasing sample size, but this incremental benefit diminishes after a certain sample size is reached.

Exhibit 5 Mean Absolute Error of Stratified Random Sampling vs. Sample Size



The sampling methods introduced here are summarized in the diagram in Exhibit 6.

Judgment Sampling

EXAMPLE 3

An analyst is studying research and development (R&D) spending by pharmaceutical companies around the world. She considers three sampling methods for understanding a company's level of R&D. Method 1 is to simply use all the data available to her from an internal database that she and her colleagues built while researching several dozen representative stocks in the sector. Method 2 involves relying on a commercial database provided by a data vendor. She would select every fifth pharmaceutical company on the list to pull the data. Method 3 is to first divide pharmaceutical companies in the commercial database into three groups according to the region where a company is headquartered (e.g., Asia, Europe, or North America) and then randomly select a subsample of companies from each group, with the sample size proportional to the size of its associated group in order to form a complete sample.

1 Method 1 is an example of:

- **A** simple random sampling.
- **B** stratified random sampling.
- **C** convenience sampling.

2 Method 2 is an example of:

- **A** judgmental sampling.
- **B** systematic sampling.
- **C** cluster sampling.

3 Method 3 is an example of:

- **A** simple random sampling.

B stratified random sampling.

C cluster sampling.

Solution to 1:

C is correct. The analyst selects the data from the internal database because they are easy and convenient to access.

Solution to 2:

B is correct. The sample elements are selected with a fixed interval ($k = 5$) from the large population provided by data vendor.

Solution to 3:

B is correct. The population of pharmaceutical companies is divided into three strata by region to perform random sampling individually.

2.5 Sampling from Different Distributions

In practice, other than selecting appropriate sampling methods, we also need to be careful when sampling from a population that is not under one single distribution. Example 4 illustrates the problems that can arise when sampling from more than one distribution.

EXAMPLE 4

Calculating Sharpe Ratios: One or Two Years of Quarterly Data

Analysts often use the Sharpe ratio to evaluate the performance of a managed portfolio. The **Sharpe ratio** is the average return in excess of the risk-free rate divided by the standard deviation of returns. This ratio measures the return of a fund or a security over and above the risk-free rate (the excess return) earned per unit of standard deviation of return.

To compute the Sharpe ratio, suppose that an analyst collects eight quarterly excess returns (i.e., total return in excess of the risk-free rate). During the first year, the investment manager of the portfolio followed a low-risk strategy, and during the second year, the manager followed a high-risk strategy. For each of these years, the analyst also tracks the quarterly excess returns of some benchmark against which the manager will be evaluated. For each of the two years, the Sharpe ratio for the benchmark is 0.21. Exhibit 7 gives the calculation of the Sharpe ratio of the portfolio.

Exhibit 7 Calculation of Sharpe Ratios: Low-Risk and High-Risk Strategies

Quarter/Measure	Year 1 Excess Returns	Year 2 Excess Returns
Quarter 1	−3%	−12%
Quarter 2	5	20
Quarter 3	−3	−12
Quarter 4	5	20
Quarterly average	1%	4%

(continued)

Exhibit 7 (Continued)

Quarter/Measure	Year 1 Excess Returns	Year 2 Excess Returns
Quarterly standard deviation	4.62%	18.48%
Sharpe ratio = 0.22 = 1/4.62 = 4/18.48		

For the first year, during which the manager followed a low-risk strategy, the average quarterly return in excess of the risk-free rate was 1% with a standard deviation of 4.62%. The Sharpe ratio is thus 1/4.62 = 0.22. The second year's results mirror the first year except for the higher average return and volatility. The Sharpe ratio for the second year is 4/18.48 = 0.22. The Sharpe ratio for the benchmark is 0.21 during the first and second years. Because larger Sharpe ratios are better than smaller ones (providing more return per unit of risk), the manager appears to have outperformed the benchmark.

Now, suppose the analyst believes a larger sample to be superior to a small one. She thus decides to pool the two years together and calculate a Sharpe ratio based on eight quarterly observations. The average quarterly excess return for the two years is the average of each year's average excess return. For the two-year period, the average excess return is (1 + 4)/2 = 2.5% per quarter. The standard deviation for all eight quarters measured from the sample mean of 2.5% is 12.57%. The portfolio's Sharpe ratio for the two-year period is now 2.5/12.57 = 0.199; the Sharpe ratio for the benchmark remains 0.21. Thus, when returns for the two-year period are pooled, the manager appears to have provided less return per unit of risk than the benchmark and less when compared with the separate yearly results.

The problem with using eight quarters of return data is that the analyst has violated the assumption that the sampled returns come from the same population. As a result of the change in the manager's investment strategy, returns in Year 2 followed a different distribution than returns in Year 1. Clearly, during Year 1, returns were generated by an underlying population with lower mean and variance than the population of the second year. Combining the results for the first and second years yielded a sample that was representative of no population. Because the larger sample did not satisfy model assumptions, any conclusions the analyst reached based on the larger sample are incorrect. For this example, she was better off using a smaller sample than a larger sample because the smaller sample represented a more homogeneous distribution of returns.

3 DISTRIBUTION OF THE SAMPLE MEAN AND THE CENTRAL LIMIT THEOREM

d explain the central limit theorem and its importance

e calculate and interpret the standard error of the sample mean

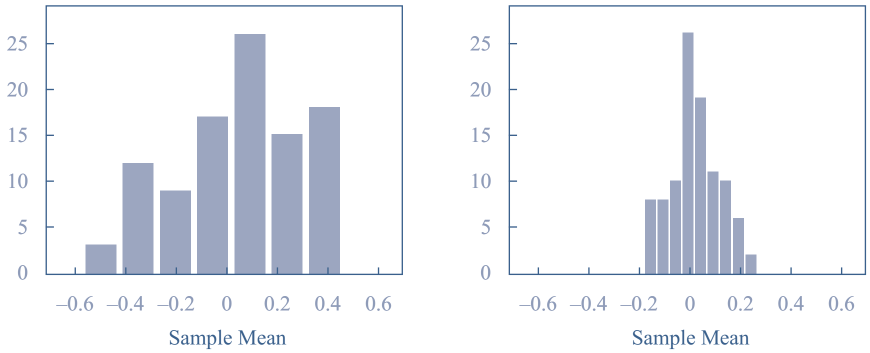
Earlier we presented a telecommunications equipment analyst who decided to sample in order to estimate mean planned capital expenditures by the customers of telecom equipment vendors. Supposing that the sample is representative of the underlying population, how can the analyst assess the sampling error in estimating the population mean? Viewed as a formula that takes a function of the random outcomes of a random variable, the sample mean is itself a random variable with a probability distribution. That probability distribution is called the statistic's sampling distribution. To estimate how closely the sample mean can be expected to match the underlying population mean, the analyst needs to understand the sampling distribution of the mean. Fortunately, we have a result, the central limit theorem, that helps us understand the sampling distribution of the mean for many of the estimation problems we face.

3.1 The Central Limit Theorem

To explain the central limit theorem, we will revisit the daily returns of the fictitious Euro-Asia-Africa Equity Index shown earlier. The dataset (the population) consists of daily returns of the index over a five-year period. The 1,258 return observations have a population mean of 0.035%.

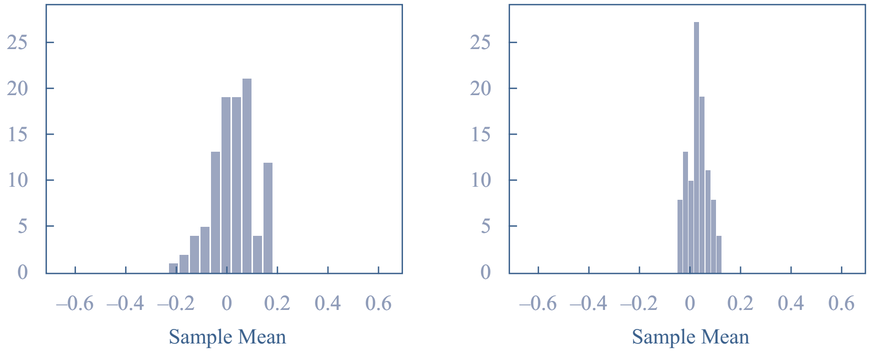
We conduct four different sets of random sampling from the population. We first draw a random sample of 10 daily returns and obtain a sample mean. We repeat this exercise 99 more times, drawing a total of 100 samples of 10 daily returns. We plot the sample mean results in a histogram, as shown in the top left panel of Exhibit 8. We then repeat the process with a larger sample size of 50 daily returns. We draw 100 samples of 50 daily returns and plot the results (the mean returns) in the histogram shown in the top right panel of Exhibit 8. We then repeat the process for sample sizes of 100 and 300 daily returns, respectively, again drawing 100 samples in each case. These results appear in the bottom left and bottom right panels of Exhibit 8. Looking at all four panels together, we observe that the larger the sample size, the more closely the histogram follows the shape of normal distribution.

Exhibit 8 Sampling Distribution with Increasing Sample Size



A. Sample Size $n = 10$

B. Sample Size $n = 50$



C. Sample Size $n = 100$

D. Sample Size $n = 300$

The results of this exercise show that as we increase the size of a random sample, the distribution of the sample means tends towards a normal distribution. This is a significant outcome and brings us to the central limit theorem concept, one of the most practically useful theorems in probability theory. It has important implications for how we construct confidence intervals and test hypotheses. Formally, it is stated as follows:

- **The Central Limit Theorem.** Given a population described by any probability distribution having mean μ and finite variance σ^2, the sampling distribution of the sample mean $\overline{X}$ computed from random samples of size n from this population will be approximately normal with mean μ (the population mean) and variance σ^2/n (the population variance divided by n) when the sample size n is large.

Consider what the expression σ^2/n signifies. Variance (σ^2) stays the same, but as n increases, the size of the fraction decreases. This dynamic suggests that it becomes progressively less common to obtain a sample mean that is far from the population mean with a larger sample size. For example, if we randomly pick returns of five stocks (trading on a market that features more than 1,000 stocks) on a particular day, their mean return is likely to be quite different from the market return. If we pick 100 stocks, the sample mean will be much closer to the market return. If we pick 1,000 stocks, the sample mean will likely be very close to the market return.

The central limit theorem allows us to make quite precise probability statements about the population mean by using the sample mean, *whatever the distribution of the population* (so long as it has finite variance), because the sample mean follows an approximate normal distribution for large-size samples. The obvious question is, "When is a sample's size large enough that we can assume the sample mean is normally distributed?" In general, when sample size n is greater than or equal to 30, we can assume that the sample mean is approximately normally distributed. When the underlying population is very non-normal, a sample size well in excess of 30 may be required for the normal distribution to be a good description of the sampling distribution of the mean.

EXAMPLE 5

A research analyst makes two statements about repeated random sampling:

1 When repeatedly drawing large samples from datasets, the sample means are approximately normally distributed.

2 The underlying population from which samples are drawn must be normally distributed in order for the sample mean to be normally distributed.

Which of the following best describes the analyst's statements?

A Statement 1 is false; Statement 2 is true.

B Both statements are true.

C Statement 1 is true; Statement 2 is false.

Solution:

C is correct. According to the central limit theorem, Statement 1 is true. Statement 2 is false because the underlying population does not need to be normally distributed in order for the sample mean to be normally distributed.

3.2 Standard Error of the Sample Mean

The central limit theorem states that the variance of the distribution of the sample mean is σ^2/n. The positive square root of variance is standard deviation. The standard deviation of a sample statistic is known as the standard error of the statistic. The standard error of the sample mean is an important quantity in applying the central limit theorem in practice.

- **Definition of the Standard Error of the Sample Mean.** For sample mean $\overline{X}$ calculated from a sample generated by a population with standard deviation σ, the standard error of the sample mean is given by one of two expressions:

$$\sigma_{\overline{X}} = \frac{\sigma}{\sqrt{n}} \tag{1}$$

when we know σ, the population standard deviation, or by

$$s_{\overline{X}} = \frac{s}{\sqrt{n}} \tag{2}$$

when we do not know the population standard deviation and need to use the sample standard deviation, s, to estimate it.

In practice, we almost always need to use Equation 2. The estimate of s is given by the square root of the sample variance, s^2, calculated as follows:

$$s^2 = \frac{\sum_{i=1}^{n}\left(X_i - \overline{X}\right)^2}{n-1} \tag{3}$$

It is worth noting that although the standard error is the standard deviation of the sampling distribution of the parameter, "standard deviation" in general and "standard error" are two distinct concepts, and the terms are not interchangeable. Simply put, standard deviation measures the dispersion of the data from the mean, whereas standard error measures how much inaccuracy of a population parameter estimate comes from sampling. The contrast between standard deviation and standard error reflects the distinction between data description and inference. If we want to draw conclusions about how spread out the data are, standard deviation is the term to quote. If we want to find out how precise the estimate of a population parameter from sampled data is relative to its true value, standard error is the metric to use.

We will soon see how we can use the sample mean and its standard error to make probability statements about the population mean by using the technique of confidence intervals. First, however, we provide an illustration of the central limit theorem's force.

EXAMPLE 6

The Central Limit Theorem

It is remarkable that the sample mean for large sample sizes will be distributed normally regardless of the distribution of the underlying population. To illustrate the central limit theorem in action, we specify in this example a distinctly non-normal distribution and use it to generate a large number of random samples of size 100. We then calculate the sample mean for each sample and observe the frequency distribution of the calculated sample means. Does that sampling distribution look like a normal distribution?

We return to the telecommunications analyst studying the capital expenditure plans of telecom businesses. Suppose that capital expenditures for communications equipment form a continuous uniform random variable with a **lower bound** equal to \$0 and an upper bound equal to \$100—for short, call this a uniform (0, 100) random variable. The probability function of this continuous uniform random variable has a rather simple shape that is anything but normal. It is a horizontal line with a vertical intercept equal to 1/100. Unlike a normal random variable, for which outcomes close to the mean are most likely, all possible outcomes are equally likely for a uniform random variable.

To illustrate the power of the central limit theorem, we conduct a Monte Carlo simulation to study the capital expenditure plans of telecom businesses. In this simulation, we collect 200 random samples of the capital expenditures of 100 companies (200 random draws, each consisting of the capital expenditures of 100 companies with $n = 100$). In each simulation trial, 100 values for capital expenditure are generated from the uniform (0, 100) distribution. For each random sample, we then compute the sample mean. We conduct 200 simulation trials in total. Because we have specified the continuous random distribution generating the samples, we know that the population mean capital expenditure is equal to (\$0 + \$100 million)/2 = \$50 million (i.e., $\mu = (a + b)/2$) ; the population variance of capital expenditures is equal to $(100 - 0)^2/12 = 833.33$ (i.e., $\sigma^2 = (b - a)^2/12$); thus, the standard deviation is \$28.87 million and the standard error is $28.87/\sqrt{100} = 2.887$ under the central limit theorem.

The results of this Monte Carlo experiment are tabulated in Exhibit 9 in the form of a frequency distribution. This distribution is the estimated sampling distribution of the sample mean.

Exhibit 9 Frequency Distribution: 200 Random Samples of a Uniform (0,100) Random Variable

Range of Sample Means ($ million)	Absolute Frequency
$42.5 \leq \overline{X} < 44$	1
$44 \leq \overline{X} < 45.5$	6
$45.5 \leq \overline{X} < 47$	22
$47 \leq \overline{X} < 48.5$	39
$48.5 \leq \overline{X} < 50$	41
$50 \leq \overline{X} < 51.5$	39
$51.5 \leq \overline{X} < 53$	23
$53 \leq \overline{X} < 54.5$	12
$54.5 \leq \overline{X} < 56$	12
$56 \leq \overline{X} < 57.5$	5

Note: $\overline{X}$ is the mean capital expenditure for each sample.

The frequency distribution can be described as bell-shaped and centered close to the population mean of 50. The most frequent, or modal, range, with 41 observations, is 48.5 to 50. The overall average of the sample means is $49.92, with a standard error equal to $2.80. The calculated standard error is close to the value of 2.887 given by the central limit theorem. The discrepancy between calculated and expected values of the mean and standard deviation under the central limit theorem is a result of random chance (sampling error).

In summary, although the distribution of the underlying population is very non-normal, the simulation has shown that a normal distribution well describes the estimated sampling distribution of the sample mean, with mean and standard error consistent with the values predicted by the central limit theorem.

To summarize, according to the central limit theorem, when we sample from any distribution, the distribution of the sample mean will have the following properties as long as our sample size is large:

- The distribution of the sample mean $\overline{X}$ will be approximately normal.

- The mean of the distribution of $\overline{X}$ will be equal to the mean of the population from which the samples are drawn.
- The variance of the distribution of $\overline{X}$ will be equal to the variance of the population divided by the sample size.

We next discuss the concepts and tools related to estimating the population parameters, with a special focus on the population mean. We focus on the population mean because analysts are more likely to meet interval estimates for the population mean than any other type of interval estimate.

4

POINT ESTIMATES OF THE POPULATION MEAN

f identify and describe desirable properties of an estimator

Statistical inference traditionally consists of two branches, hypothesis testing and estimation. Hypothesis testing addresses the question "Is the value of this parameter (say, a population mean) equal to some specific value (0, for example)?" In this process, we have a hypothesis concerning the value of a parameter, and we seek to determine whether the evidence from a sample supports or does not support that hypothesis. The topic of hypothesis testing will be discussed later.

The second branch of statistical inference, and what we focus on now, is estimation. Estimation seeks an answer to the question "What is this parameter's (for example, the population mean's) value?" In estimating, unlike in hypothesis testing, we do not start with a hypothesis about a parameter's value and seek to test it. Rather, we try to make the best use of the information in a sample to form one of several types of estimates of the parameter's value. With estimation, we are interested in arriving at a rule for best calculating a single number to estimate the unknown population parameter (a point estimate). In addition to calculating a point estimate, we may also be interested in calculating a range of values that brackets the unknown population parameter with some specified level of probability (a confidence interval). We first discuss point estimates of parameters and then turn our attention to the formulation of confidence intervals for the population mean.

4.1 Point Estimators

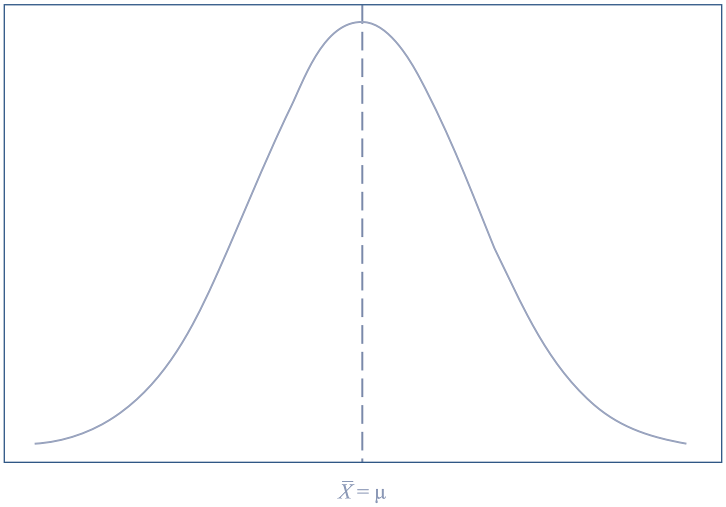
An important concept introduced here is that sample statistics viewed as formulas involving random outcomes are random variables. The formulas that we use to compute the sample mean and all the other sample statistics are examples of estimation formulas or **estimators**. The particular value that we calculate from sample observations using an estimator is called an **estimate**. An estimator has a sampling distribution; an estimate is a fixed number pertaining to a given sample and thus has no sampling distribution. To take the example of the mean, the calculated value of the sample mean in a given sample, used as an estimate of the population mean, is called a **point estimate** of the population mean. As we have seen earlier, the formula for the sample mean can and will yield different results in repeated samples as different samples are drawn from the population.

In many applications, we have a choice among a number of possible estimators for estimating a given parameter. How do we make our choice? We often select estimators because they have one or more desirable statistical properties. Following is a brief description of three desirable properties of estimators: unbiasedness (lack of bias), efficiency, and consistency.

- **Unbiasedness.** An unbiased estimator is one whose expected value (the mean of its sampling distribution) equals the parameter it is intended to estimate.

For example, as shown in Exhibit 10 of the sampling distribution of the sample mean, the expected value of the sample mean, $\overline{X}$, equals μ, the population mean, so we say that the sample mean is an unbiased estimator (of the population mean). The sample variance, s^2, calculated using a divisor of $n - 1$ (Equation 3), is an unbiased estimator of the population variance, σ^2. If we were to calculate the sample variance using a divisor of *n,* the estimator would be biased: Its expected value would be smaller than the population variance. We would say that sample variance calculated with a divisor of *n* is a biased estimator of the population variance.

Exhibit 10 Unbiasedness of an Estimator

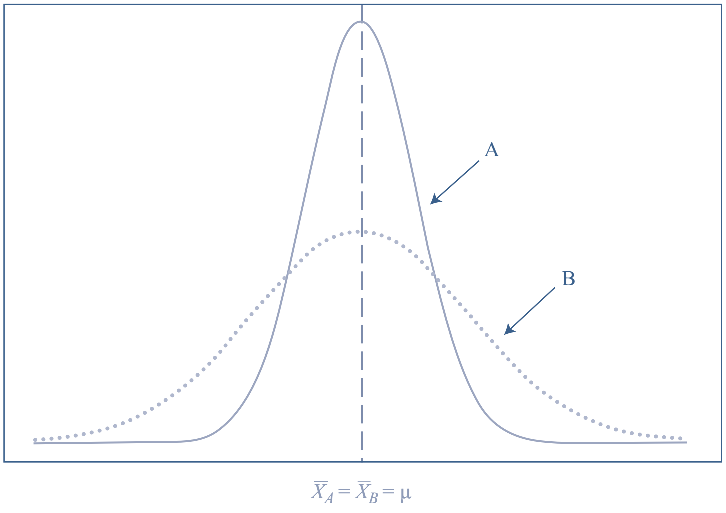


Whenever one unbiased estimator of a parameter can be found, we can usually find a large number of other unbiased estimators. How do we choose among alternative unbiased estimators? The criterion of efficiency provides a way to select from among unbiased estimators of a parameter.

- **Efficiency.** An unbiased estimator is efficient if no other unbiased estimator of the same parameter has a sampling distribution with smaller variance.

To explain the definition, in repeated samples we expect the estimates from an efficient estimator to be more tightly grouped around the mean than estimates from other unbiased estimators. For example, Exhibit 11 shows the sampling distributions of two different estimators of the population mean. Both estimators A and B are unbiased because their expected values are equal to the population mean ($\overline{X}_A = \overline{X}_B = \mu$), but estimator A is more efficient because it shows smaller variance. Efficiency is an important property of an estimator. Sample mean $\overline{X}$ is an efficient estimator of the population mean; sample variance s^2 is an efficient estimator of σ^2.

Exhibit 11 Efficiency of an Estimator

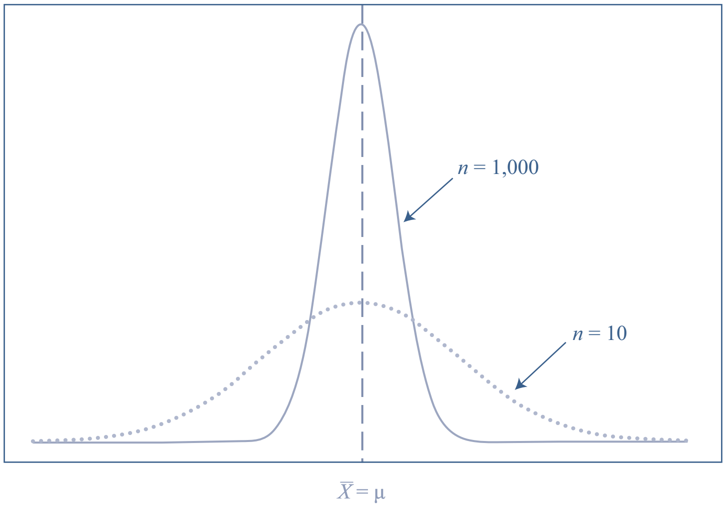


Recall that a statistic's sampling distribution is defined for a given sample size. Different sample sizes define different sampling distributions. For example, the variance of sampling distribution of the sample mean is smaller for larger sample sizes. Unbiasedness and efficiency are properties of an estimator's sampling distribution that hold for any size sample. An unbiased estimator is unbiased equally in a sample of size 100 and in a sample of size 1,000. In some problems, however, we cannot find estimators that have such desirable properties as unbiasedness in small samples. In this case, statisticians may justify the choice of an estimator based on the properties of the estimator's sampling distribution in extremely large samples, the estimator's so-called asymptotic properties. Among such properties, the most important is consistency.

- **Consistency.** A consistent estimator is one for which the probability of estimates close to the value of the population parameter increases as sample size increases.

Somewhat more technically, we can define a consistent estimator as an estimator whose sampling distribution becomes concentrated on the value of the parameter it is intended to estimate as the sample size approaches infinity. The sample mean, in addition to being an efficient estimator, is also a consistent estimator of the population mean: As sample size n goes to infinity, its standard error, $\sigma/\sqrt{n}$, goes to 0 and its sampling distribution becomes concentrated right over the value of population mean, μ. Exhibit 12 illustrates the consistency of the sample mean, in which the standard error of the estimator narrows as the sample size increases. To summarize, we can think of a consistent estimator as one that tends to produce more and more accurate estimates of the population parameter as we increase the sample's size. If an estimator is consistent, we may attempt to increase the accuracy of estimates of a population parameter by calculating estimates using a larger sample. For an inconsistent estimator, however, increasing sample size does not help to increase the probability of accurate estimates.

Exhibit 12 Consistency of an Estimator



It is worth noting that in a Big Data world, consistency is much more crucial than efficiency, because the accuracy of a population parameter's estimates can be increasingly improved with the availability of more sample data. In addition, given a big dataset, a biased but consistent estimator can offer considerably reduced error. For example, s^2/n is a biased estimator of variance. As n goes to infinity, the distinction between s^2/n and the unbiased estimator $s^2/(n - 1)$ diminish to zero.

EXAMPLE 7

Exhibit 13 plots several sampling distributions of an estimator for the population mean, and the vertical dash line represents the true value of population mean.

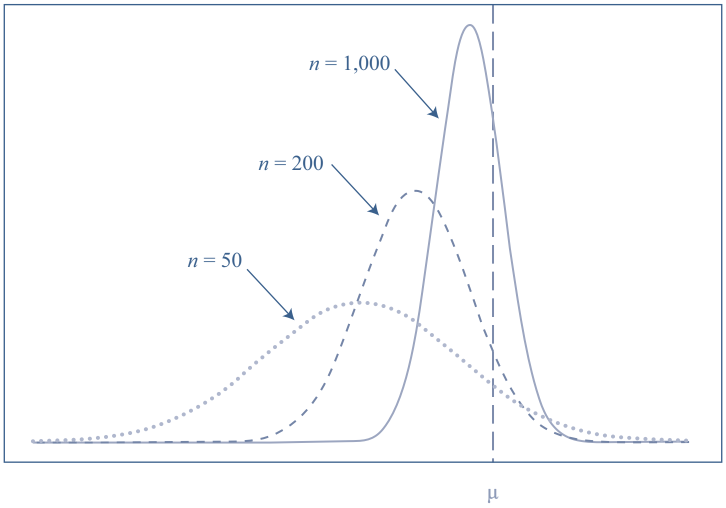
Which of the following statements *best* describes the estimator's properties?

A The estimator is unbiased.

B The estimator is biased and inconsistent.

C The estimator is biased but consistent.

Exhibit 13 Sampling Distributions of an Estimator



Solution:

C is correct. The chart shows three sampling distributions of the estimator at different sample sizes (n = 50, 200, and 1,000). We can observe that the means of each sampling distribution—that is, the expected value of the estimator—deviates from the population mean, so the estimator is biased. As the sample size increases, however, the mean of the sampling distribution draws closer to the population mean with smaller variance. So, it is a consistent estimator.

5

CONFIDENCE INTERVALS FOR THE POPULATION MEAN AND SELECTION OF SAMPLE SIZE

g contrast a point estimate and a confidence interval estimate of a population parameter

h calculate and interpret a confidence interval for a population mean, given a normal distribution with 1) a known population variance, 2) an unknown population variance, or 3) an unknown population variance and a large sample size

When we need a single number as an estimate of a population parameter, we make use of a point estimate. However, because of sampling error, the point estimate is not likely to equal the population parameter in any given sample. Often, a more useful approach than finding a point estimate is to find a range of values that we expect to bracket the parameter with a specified level of probability—an interval estimate of the parameter. A confidence interval fulfills this role.

- **Definition of Confidence Interval.** A confidence interval is a range for which one can assert with a given probability 1 − α, called the **degree of confidence**, that it will contain the parameter it is intended to estimate. This interval is often referred to as the 100(1 − α)% confidence interval for the parameter.

The endpoints of a confidence interval are referred to as the lower and upper confidence limits. In this reading, we are concerned only with two-sided confidence intervals—confidence intervals for which we calculate both lower and upper limits.

Confidence intervals are frequently given either a probabilistic interpretation or a practical interpretation. In the probabilistic interpretation, we interpret a 95% confidence interval for the population mean as follows. In repeated sampling, 95% of such confidence intervals will, in the long run, include or bracket the population mean. For example, suppose we sample from the population 1,000 times, and based on each sample, we construct a 95% confidence interval using the calculated sample mean. Because of random chance, these confidence intervals will vary from each other, but we expect 95%, or 950, of these intervals to include the unknown value of the population mean. In practice, we generally do not carry out such repeated sampling. Therefore, in the practical interpretation, we assert that we are 95% confident that a single 95% confidence interval contains the population mean. We are justified in making this statement because we know that 95% of all possible confidence intervals constructed in the same manner will contain the population mean. The confidence intervals that we discuss in this reading have structures similar to the following basic structure:

- **Construction of Confidence Intervals.** A $100(1 - \alpha)\%$ confidence interval for a parameter has the following structure:

  Point estimate ± Reliability factor × Standard error

  where

  Point estimate = a point estimate of the parameter (a value of a sample statistic)
  Reliability factor = a number based on the assumed distribution of the point estimate and the degree of confidence $(1 - \alpha)$ for the confidence interval
  Standard error = the standard error of the sample statistic providing the point estimate

  The quantity "Reliability factor × Standard error" is sometimes called the precision of the estimator; larger values of the product imply lower precision in estimating the population parameter.

The most basic confidence interval for the population mean arises when we are sampling from a normal distribution with known variance. The reliability factor in this case is based on the standard normal distribution, which has a mean of 0 and a variance of 1. A standard normal random variable is conventionally denoted by Z. The notation z_α denotes the point of the standard normal distribution such that α of the probability remains in the right tail. For example, 0.05 or 5% of the possible values of a standard normal random variable are larger than $z_{0.05} = 1.65$. Similarly, 0.025 or 2.5% of the possible values of a standard normal random variable are larger than $z_{0.025} = 1.96$.

Suppose we want to construct a 95% confidence interval for the population mean and, for this purpose, we have taken a sample of size 100 from a normally distributed population with known variance of $\sigma^2 = 400$ (so, $\sigma = 20$). We calculate a sample mean of $\overline{X} = 25$. Our point estimate of the population mean is, therefore, 25. If we move 1.96 standard deviations above the mean of a normal distribution, 0.025 or 2.5% of the probability remains in the right tail; by symmetry of the normal distribution, if we move 1.96 standard deviations below the mean, 0.025 or 2.5% of the probability remains in the left tail. In total, 0.05 or 5% of the probability is in the two tails and 0.95 or 95% lies in between. So, $z_{0.025} = 1.96$ is the reliability factor for this 95% confidence interval. Note the relationship $100(1 - \alpha)\%$ for the confidence interval and the $z_{\alpha/2}$ for the reliability factor. The standard error of the sample mean, given by Equation 1, is $\sigma_{\overline{X}} = 20/\sqrt{100} = 2$. The confidence interval, therefore, has a lower limit of $\overline{X} - 1.96\sigma_{\overline{X}}$

= 25 − 1.96(2) = 25 − 3.92 = 21.08. The upper limit of the confidence interval is $\overline{X} + 1.96\sigma_{\overline{X}}$ = 25 + 1.96(2) = 25 + 3.92 = 28.92. The 95% confidence interval for the population mean spans 21.08 to 28.92.

- **Confidence Intervals for the Population Mean (Normally Distributed Population with Known Variance).** A 100(1 − α)% confidence interval for population mean μ when we are sampling from a normal distribution with known variance σ^2 is given by

$$\overline{X} \pm z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \tag{4}$$

The reliability factors for the most frequently used confidence intervals are as follows.

- **Reliability Factors for Confidence Intervals Based on the Standard Normal Distribution.** We use the following reliability factors when we construct confidence intervals based on the standard normal distribution:
  - 90% confidence intervals: Use $z_{0.05} = 1.65$
  - 95% confidence intervals: Use $z_{0.025} = 1.96$
  - 99% confidence intervals: Use $z_{0.005} = 2.58$

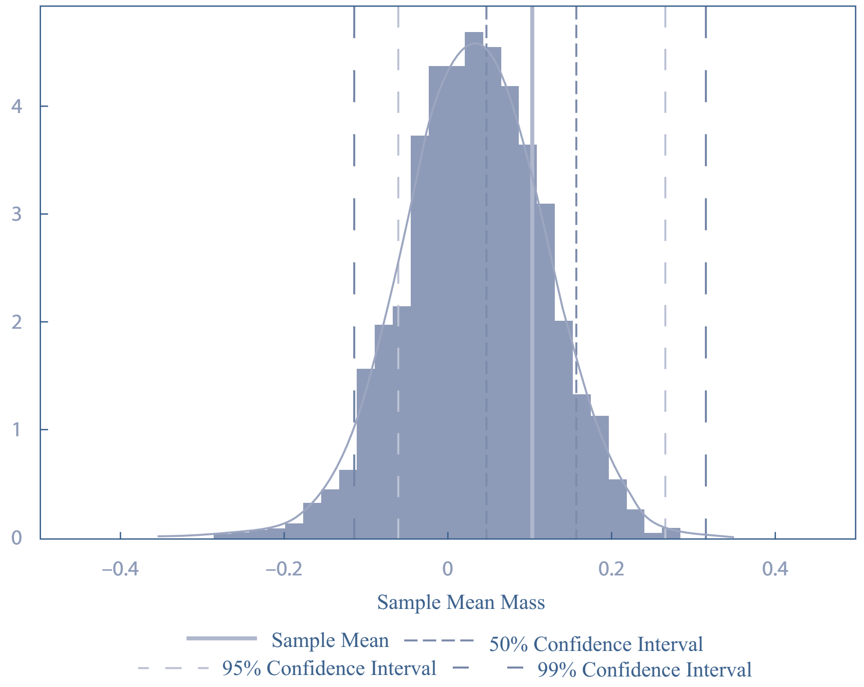
These reliability factors highlight an important fact about all confidence intervals. As we increase the degree of confidence, the confidence interval becomes wider and gives us less precise information about the quantity we want to estimate.

Exhibit 14 demonstrates how a confidence interval works. We again use the daily returns of the fictitious Euro-Asia-Africa Equity Index shown earlier. The dataset consists of 1,258 observations with a population mean of 0.035% and a population standard deviation of 0.834%. We conduct random sampling from the population 1,000 times, drawing a sample of a hundred daily returns (n = 100) each time.

We construct a histogram of the sample means, shown in Exhibit 14. The shape appears to be that of a normal distribution, in line with the central limit theorem. We next pick one random sample to construct confidence intervals around its sample mean. The mean of the selected sample is computed to be 0.103% (as plotted with a solid line). Next we construct 99%, 95%, and 50% confidence intervals around that sample mean. We use Equation 4, to compute the upper and lower bounds of each pair of confidence intervals and plot these bounds in dashed lines.

The resulting chart shows that confidence intervals narrow with decreasing confidence level, and vice versa. For example, the narrowest confidence interval in the chart corresponds to the lowest confidence level of 50%—that is, we are only 50% confident that the population mean falls within the 50% confidence interval around the sample mean. Importantly, as shown by Equation 4, given a fixed confidence level, the confidence interval narrows with smaller population deviation and greater sample size, indicating higher estimate accuracy.

Exhibit 14 Illustration of Confidence Intervals



In practice, the assumption that the sampling distribution of the sample mean is at least approximately normal is frequently reasonable, either because the underlying distribution is approximately normal or because we have a large sample and the central limit theorem applies. Rarely do we know the population variance in practice, however. When the population variance is unknown but the sample mean is at least approximately normally distributed, we have two acceptable ways to calculate the confidence interval for the population mean. We will soon discuss the more conservative approach, which is based on Student's *t*-distribution (the *t*-distribution, for short and covered earlier). In investment literature, it is the most frequently used approach in both estimation and hypothesis tests concerning the mean when the population variance is not known, whether sample size is small or large.

A second approach to confidence intervals for the population mean, based on the standard normal distribution, is the *z*-alternative. It can be used only when sample size is large. (In general, a sample size of 30 or larger may be considered large.) In contrast to the confidence interval given in Equation 4, this confidence interval uses the sample standard deviation, *s*, in computing the standard error of the sample mean (Equation 2).

- **Confidence Intervals for the Population Mean—The *z*-Alternative (Large Sample, Population Variance Unknown).** A 100(1 − α)% confidence interval for population mean μ when sampling from any distribution with unknown variance and when sample size is large is given by

$$\overline{X} \pm z_{\alpha/2}\frac{s}{\sqrt{n}} \tag{5}$$

Because this type of confidence interval appears quite often, we illustrate its calculation in Example 8.

EXAMPLE 8

Confidence Interval for the Population Mean of Sharpe Ratios—*z*-Statistic

Suppose an investment analyst takes a random sample of US equity mutual funds and calculates the average Sharpe ratio. The sample size is 100, and the average Sharpe ratio is 0.45. The sample has a standard deviation of 0.30. Calculate and interpret the 90% confidence interval for the population mean of all US equity mutual funds by using a reliability factor based on the standard normal distribution.

The reliability factor for a 90% confidence interval, as given earlier, is $z_{0.05} = 1.65$. The confidence interval will be

$$\overline{X} \pm z_{0.05}\frac{s}{\sqrt{n}} = 0.45 \pm 1.65\frac{0.30}{\sqrt{100}} = 0.45 \pm 1.65(0.03) = 0.45 \pm 0.0495$$

The confidence interval spans 0.4005 to 0.4995, or 0.40 to 0.50, carrying two decimal places. The analyst can say with 90% confidence that the interval includes the population mean.

In this example, the analyst makes no specific assumption about the probability distribution describing the population. Rather, the analyst relies on the central limit theorem to produce an approximate normal distribution for the sample mean.

As Example 8 shows, even if we are unsure of the underlying population distribution, we can still construct confidence intervals for the population mean as long as the sample size is large because we can apply the central limit theorem.

We now turn to the conservative alternative, using the *t*-distribution, for constructing confidence intervals for the population mean when the population variance is not known. For confidence intervals based on samples from normally distributed populations with unknown variance, the theoretically correct reliability factor is based on the *t*-distribution. Using a reliability factor based on the *t*-distribution is essential for a small sample size. Using a *t* reliability factor is appropriate when the population variance is unknown, even when we have a large sample and could use the central limit theorem to justify using a *z* reliability factor. In this large sample case, the *t*-distribution provides more-conservative (wider) confidence intervals.

Suppose we sample from a normal distribution. The ratio $z = \left(\overline{X} - \mu\right)\big/\left(\sigma/\sqrt{n}\right)$ is distributed normally with a mean of 0 and standard deviation of 1; however, the ratio $t = \left(\overline{X} - \mu\right)\big/\left(s/\sqrt{n}\right)$ follows the *t*-distribution with a mean of 0 and $n - 1$ degrees of freedom. The ratio represented by *t* is not normal because *t* is the ratio of two random variables, the sample mean and the sample standard deviation. The definition of the standard normal random variable involves only one random variable, the sample mean.

Values for the *t*-distribution are available from Excel, using the function T.INV(p,DF). For each degree of freedom, five values are given: $t_{0.10}$, $t_{0.05}$, $t_{0.025}$, $t_{0.01}$, and $t_{0.005}$. The values for $t_{0.10}$, $t_{0.05}$, $t_{0.025}$, $t_{0.01}$, and $t_{0.005}$ are such that, respectively, 0.10, 0.05, 0.025, 0.01, and 0.005 of the probability remains in the right tail, for the specified number of degrees of freedom. For example, for df = 30, $t_{0.10} = 1.310$, $t_{0.05} = 1.697$, $t_{0.025} = 2.042$, $t_{0.01} = 2.457$, and $t_{0.005} = 2.750$.

We now give the form of confidence intervals for the population mean using the t-distribution.

- **Confidence Intervals for the Population Mean (Population Variance Unknown)—*t*-Distribution.** If we are sampling from a population with unknown variance and either of the conditions below holds:
  - the sample is large, or
  - the sample is small, but the population is normally distributed, or approximately normally distributed,

  then a 100(1 − α)% confidence interval for the population mean μ is given by

  $$\overline{X} \pm t_{\alpha/2}\frac{s}{\sqrt{n}} \tag{6}$$

  where the number of degrees of freedom for $t_{\alpha/2}$ is $n - 1$ and n is the sample size.

Example 9 reprises the data of Example 8 but uses the t-statistic rather than the z-statistic to calculate a confidence interval for the population mean of Sharpe ratios.

EXAMPLE 9

Confidence Interval for the Population Mean of Sharpe Ratios—*t*-Statistic

As in Example 8, an investment analyst seeks to calculate a 90% confidence interval for the population mean Sharpe ratio of US equity mutual funds based on a random sample of 100 US equity mutual funds. The sample mean Sharpe ratio is 0.45, and the sample standard deviation of the Sharpe ratios is 0.30. Now recognizing that the population variance of the distribution of Sharpe ratios is unknown, the analyst decides to calculate the confidence interval using the theoretically correct t-statistic.

Because the sample size is 100, df = 99. Using the Excel function T.INV(0.05,99), $t_{0.05} = 1.66$. This reliability factor is slightly larger than the reliability factor $z_{0.05} = 1.65$ that was used in Example 8. The confidence interval will be

$$\overline{X} \pm t_{0.05}\frac{s}{\sqrt{n}} = 0.45 \pm 1.66\frac{0.30}{\sqrt{100}} = 0.45 \pm 1.66(0.03) = 0.45 \pm 0.0498$$

The confidence interval spans 0.4002 to 0.4998, or 0.40 to 0.50, carrying two decimal places. To two decimal places, the confidence interval is unchanged from the one computed in Example 8.

Exhibit 15 summarizes the various reliability factors that we have used.

5.1 Selection of Sample Size

What choices affect the width of a confidence interval? To this point we have discussed two factors that affect width: the choice of statistic (*t* or *z*) and the choice of degree of confidence (affecting which specific value of *t* or *z* we use). These two choices determine the reliability factor. (Recall that a confidence interval has the structure Point estimate ± Reliability factor × Standard error.)

The choice of sample size also affects the width of a confidence interval. All else equal, a larger sample size decreases the width of a confidence interval. Recall the expression for the standard error of the sample mean:

$$\text{Standard error of the sample mean} = \frac{\text{Sample standard deviation}}{\sqrt{\text{Sample size}}}$$

We see that the standard error varies inversely with the square root of sample size. As we increase sample size, the standard error decreases and consequently the width of the confidence interval also decreases. The larger the sample size, the greater precision with which we can estimate the population parameter.

At a given degree of confidence (1 − α), we can determine the sample size needed to obtain a desired width for a confidence interval. Define E = Reliability factor × Standard error; then $2E$ is the confidence interval's width. The smaller E is, the smaller the width of the confidence interval. Accordingly, the sample size to obtain a desired value of E at a given degree of confidence (1 − α) can be derived as $n = [(t \times s)/E]^2$. It is worth noting that appropriate sample size is also needed for performing a valid power analysis and determining the minimum detectable effect in hypothesis testing, concepts that will be covered at a later stage.

All else equal, larger samples are good, in that sense. In practice, however, two considerations may operate against increasing sample size. First, as we saw earlier concerning the Sharpe ratio, increasing the size of a sample may result in sampling from more than one population. Second, increasing sample size may involve additional expenses that outweigh the value of additional precision. Thus three issues that the analyst should weigh in selecting sample size are the need for precision, the risk of sampling from more than one population, and the expenses of different sample sizes.

EXAMPLE 10

A Money Manager Estimates Net Client Inflows

A money manager wants to obtain a 95% confidence interval for fund inflows and outflows over the next six months for his existing clients. He begins by calling a random sample of 10 clients and inquiring about their planned additions to and withdrawals from the fund. The manager then computes the change in cash flow for each client sampled as a percentage change in total funds placed with the manager. A positive percentage change indicates a net cash inflow to the client's account, and a negative percentage change indicates a net cash outflow from the client's account. The manager weights each response by the relative size of the account within the sample and then computes a weighted average.

As a result of this process, the money manager computes a weighted average of 5.5%. Thus, a point estimate is that the total amount of funds under management will increase by 5.5% in the next six months. The standard deviation of the observations in the sample is 10%. A histogram of past data looks fairly close to normal, so the manager assumes the population is normal.

1 Calculate a 95% confidence interval for the population mean and interpret your findings.

2 The manager decides to see what the confidence interval would look like if he had used a sample size of 20 or 30 and found the same mean (5.5%) and standard deviation (10%).

Compute the confidence interval for sample sizes of 20 and 30. For the sample size of 30, use Equation 6.

3 Interpret your results from Parts 1 and 2.

Solution to 1:

Because the population variance is unknown and the sample size is small, the manager must use the t-statistic in Equation 6 to calculate the confidence interval. Based on the sample size of 10, df = n − 1 = 10 − 1 = 9. For a 95% confidence interval, he needs to use the value of $t_{0.025}$ for df = 9. This value is 2.262, using Excel function T.INV(0.025,9). Therefore, a 95% confidence interval for the population mean is

$$\begin{aligned}\overline{X} \pm t_{0.025}\frac{s}{\sqrt{n}} &= 5.5\% \pm 2.262\frac{10\%}{\sqrt{10}}\\ &= 5.5\% \pm 2.262(3.162)\\ &= 5.5\% \pm 7.15\%\end{aligned}$$

The confidence interval for the population mean spans −1.65% to +12.65%. The manager can be confident at the 95% level that this range includes the population mean.

Solution to 2:

Exhibit 17 gives the calculations for the three sample sizes.

Exhibit 17 The 95% Confidence Interval for Three Sample Sizes

Distribution	95% Confidence Interval	Lower Bound	Upper Bound	Relative Size
$t(n = 10)$	5.5% ± 2.262(3.162)	−1.65%	12.65%	100.0%
$t(n = 20)$	5.5% ± 2.093(2.236)	0.82	10.18	65.5
$t(n = 30)$	5.5% ± 2.045(1.826)	1.77	9.23	52.2

Solution to 3:

The width of the confidence interval decreases as we increase the sample size. This decrease is a function of the standard error becoming smaller as n increases. The reliability factor also becomes smaller as the number of degrees of freedom increases. The last column of Exhibit 17 shows the relative size of the width of confidence intervals based on n = 10 to be 100%. Using a sample size of 20 reduces the confidence interval's width to 65.5% of the interval width for a sample size of 10. Using a sample size of 30 cuts the width of the interval almost in half. Comparing these choices, the money manager would obtain the most precise results using a sample of 30.

6 RESAMPLING

i. Describe the use of resampling (bootstrap, jackknife) to estimate the sampling distribution of a statistic

Earlier, we demonstrated how to find the standard error of the sample mean, which can be computed using Equation 4 based on the central limit theorem. We now introduce a computational tool called **resampling**, which repeatedly draws samples from the original observed data sample for the statistical inference of population parameters. **Bootstrap**, one of the most popular resampling methods, uses computer simulation for statistical inference without using an analytical formula such as a z-statistic or t-statistic.

The idea behind bootstrap is to mimic the process of performing random sampling from a population, similar to what we have shown earlier, to construct the sampling distribution of the sample mean. The difference lies in the fact that we have no knowledge of what the population looks like, except for a sample with size *n* drawn from the population. Because a random sample offers a good representation of the population, we can simulate sampling from the population by sampling from the observed sample. In other words, the bootstrap mimics the process by treating the randomly drawn sample as if it were the population.

The right-hand side of Exhibit 18 illustrates the process. In bootstrap, we repeatedly draw samples from the original sample, and each resample is of the same size as the original sample. Note that each item drawn is replaced for the next draw (i.e., the identical element is put back into the group so that it can be drawn more than once). Assuming we are looking to find the standard error of sample mean, we take many resamples and then compute the mean of each resample. Note that although some items may appear several times in the resamples, other items may not appear at all.

True Sampling Distribution
Bootstrap Sampling Distribution

Subsequently, we construct a sampling distribution with these resamples. The bootstrap sampling distribution (right-hand side of Exhibit 18) will approximate the true sampling distribution. We estimate the standard error of the sample mean using Equation 7. Note that to distinguish the foregoing resampling process from other types of resampling, it is often called model-free resampling or non-parametric resampling.

$$s_{\overline{X}} = \sqrt{\frac{1}{B-1}\sum_{b=1}^{B}(\hat{\theta}_b - \overline{\theta})^2} \tag{7}$$

where

$S_{\overline{X}}$ is the estimate of the standard error of the sample mean

B denotes the number of resamples drawn from the original sample.

$\hat{\theta}_b$ denotes the mean of a resample

$\overline{\theta}$ denotes the mean across all the resample means

Bootstrap is one of the most powerful and widely used tools for statistical inference. As we have explained, it can be used to estimate the standard error of sample mean. Similarly, bootstrap can be used to find the standard error or construct confidence intervals for the statistic of other population parameters, such as the median, which does not apply to the previously discussed methodologies. Compared with conventional statistical methods, bootstrap does not rely on an analytical formula to estimate the distribution of the estimators. It is a simple but powerful method for any complicated estimators and particularly useful when no analytical formula is available. In addition, bootstrap has potential advantages in accuracy. Given these advantages, bootstrap can be applied widely in finance, such as for historical simulations in asset allocation or in gauging an investment strategy's performance against a benchmark.

EXAMPLE 11

Bootstrap Resampling Illustration

The following table displays a set of 12 monthly returns of a rarely traded stock, shown in Column A. Our aim is to calculate the standard error of the sample mean. Using the bootstrap resampling method, a series of bootstrap samples, labelled as "resamples" (with replacement) are drawn from the sample of 12 returns. Notice how some of the returns from data sample in Column A feature more than once in some of the resamples (for example, 0.055 features twice in Resample 1).

Column A	Resample 1	Resample 2	Resample 3		Resample 1,000
−0.096	0.055	−0.096	−0.033	.....	−0.072

0.055	−0.132	−0.132	0.296	.....	0.055
−0.072	−0.096	0.055	−0.096	.....	−0.096
0.255	0.055	−0.072	0.055	.....	−0.191
−0.157	−0.157	−0.053	−0.157	.....	0.055
Sample mean	−0.019	−0.060	0.001	.....	0.040

Drawing 1,000 such samples, we obtain 1,000 sample means. The mean across all resample means is −0.01367. The sum of squares of the differences between each sample mean and the mean across all resample means ($\sum_{b=1}^{B}(\hat{\theta}_b - \bar{\theta})^2$) is 1.94143. Using Equation 7, we calculate an estimate of the standard error of the sample mean:

$$s_{\bar{X}} = \sqrt{\frac{1}{B-1}\sum_{b=1}^{B}(\hat{\theta}_b - \bar{\theta})^2} = \sqrt{\frac{1}{999} \times 1.94143} = 0.04408$$

Jackknife is another resampling technique for statistical inference of population parameters. Unlike bootstrap, which repeatedly draws samples with replacement, jackknife samples are selected by taking the original observed data sample and leaving out one observation at a time from the set (and not replacing it). Jackknife method is often used to reduce the bias of an estimator, and other applications include finding the standard error and confidence interval of an estimator. According to its computation procedure, we can conclude that jackknife produces similar results for every run, whereas bootstrap usually gives different results because bootstrap resamples are randomly drawn. For a sample of size *n*, jackknife usually requires *n* repetitions, whereas with bootstrap, we are left to determine how many repetitions are appropriate.

EXAMPLE 12

An analyst in a real estate investment company is researching the housing market of the Greater Boston area. From a sample of collected house sale price data in the past year, she estimates the median house price of the area. To find the standard error of the estimated median, she is considering two options:

Option 1 The standard error of the sample median can be given by $\frac{s}{\sqrt{n}}$, where s denotes the sample standard deviation and n denotes the sample size.

Option 2 Apply the bootstrap method to construct the sampling distribution of the sample median, and then compute the standard error by using Equation 7.

Which of the following statements is accurate?

A Option 1 is suitable to find the standard error of the sample median.

B Option 2 is suitable to find the standard error of the sample median.

C Both options are suitable to find the standard error of the sample median.

Solution:

B is correct. Option 1 is valid for estimating the standard error of the sample mean but not for that of the sample median, which is not based on the given formula. Thus, both A and C are incorrect. The bootstrap method is a simple way to find the standard error of an estimator even if no analytical formula is available or it is too complicated.

Having covered many of the fundamental concepts of sampling and estimation, we are in a good position to focus on sampling issues of special concern to analysts. The quality of inferences depends on the quality of the data as well as on the quality of the sampling plan used. Financial data pose special problems, and sampling plans frequently reflect one or more biases. The next section discusses these issues.

7 DATA SNOOPING BIAS, SAMPLE SELECTION BIAS, LOOK-AHEAD BIAS, AND TIME-PERIOD BIAS

j describe the issues regarding selection of the appropriate sample size, data snooping bias, sample selection bias, survivorship bias, look-ahead bias, and time-period bias

We have already seen that the selection of sample period length may raise the issue of sampling from more than one population. There are, in fact, a range of challenges to valid sampling that arise in working with financial data. In this section we discuss several such sampling-related issues: data snooping bias, sample selection group of biases (including survivorship bias), look-ahead bias, and time-period bias. All of these issues are important for point and interval estimation and hypothesis testing. As we will see, if the sample is biased in any way, then point and interval estimates and any other conclusions that we draw from the sample will be in error.

7.1 Data Snooping Bias

Data snooping relates to overuse of the same or related data in ways that we shall describe shortly. Data snooping bias refers to the errors that arise from such misuse of data. Investment strategies that reflect data snooping biases are often not successful if applied in the future. Nevertheless, both investment practitioners and researchers in general have frequently engaged in data snooping. Analysts thus need to understand and guard against this problem.

Data snooping is the practice of determining a model by extensive searching through a dataset for statistically significant patterns (that is, repeatedly “drilling” in the same data until finding something that appears to work). In exercises involving statistical significance, we set a significance level, which is the probability of rejecting the hypothesis we are testing when the hypothesis is in fact correct. Because rejecting a true hypothesis is undesirable, the investigator often sets the significance level at a relatively small number, such as 0.05 or 5%.

Suppose we test the hypothesis that a variable does not predict stock returns, and we test in turn 100 different variables. Let us also suppose that in truth, none of the 100 variables has the ability to predict stock returns. Using a 5% significance level in our tests, we would still expect that 5 out of 100 variables would appear to be significant predictors of stock returns because of random chance alone. We have mined the data to find some apparently significant variables. In essence, we have explored the same data again and again until we found some after-the-fact pattern or patterns in the dataset. This is the sense in which data snooping involves overuse of data. If we were to report only the significant variables without also reporting the total number of variables tested that were unsuccessful as predictors, we would be presenting a very misleading picture of our findings. Our results would appear to be far more significant than they actually were, because a series of tests such as the one just described invalidates the conventional interpretation of a given significance level (such as 5%), according to the theory of inference. Datasets in the Big Data space are often blindly used to make statistical inferences without a proper hypothesis testing framework, which may lead to inferring higher-than-justified significance.

How can we investigate the presence of data snooping bias? Typically we can split the data into three separate datasets: the training dataset, the validation dataset, and the test dataset. The training dataset is used to build a model and fit the model parameters. The validation dataset is used to evaluate the model fit while tuning the model parameters. The test dataset is to provide an **out-of-sample test** to evaluate the final model fit. If a variable or investment strategy is the result of data snooping, it should generally not be significant in out-of-sample tests.

A variable or investment strategy that is statistically and economically significant in out-of-sample tests, and that has a plausible economic basis, may be the basis for a valid investment strategy. Caution is still warranted, however. The most crucial out-of-sample test is future investment success. It should be noted that if the strategy becomes known to other investors, prices may adjust so that the strategy, however well tested, does not work in the future. To summarize, the analyst should be aware that many apparently profitable investment strategies may reflect data snooping bias and thus be cautious about the future applicability of published investment research results.

UNTANGLING THE EXTENT OF DATA SNOOPING

To assess the significance of an investment strategy, we need to know how many unsuccessful strategies were tried not only by the current investigator but also by *previous* investigators using the same or related datasets. Much research, in practice, closely builds on what other investigators have done, and so reflects intergenerational data mining (McQueen and Thorley, 1999) that involves using information developed by previous researchers using a dataset to guide current research using the same or a related dataset. Analysts have accumulated many observations about the peculiarities of many financial datasets, and other analysts may develop models or investment strategies that will tend to be supported within a dataset based on their familiarity with the prior experience of other analysts. As a consequence, the importance of those new results may be overstated. Research has suggested that the magnitude of this type of data-mining bias may be considerable.

McQueen and Thorley (1999) explored data mining in the context of the popular Motley Fool “Foolish Four” investment strategy, a version of the Dow Dividend Strategy tuned by its developers to exhibit an even higher arithmetic mean return than the original Dow Dividend Strategy. The Foolish Four strategy claimed to show significant investment returns over 20 years starting in 1973, and its proponents claimed that the strategy should have similar returns in the future. McQueen and Thorley highlighted the data-mining issues in that research and presented two signs that can warn analysts about the potential existence of data mining:

- *Too much digging/too little confidence*. The testing of many variables by the researcher is the “too much digging” warning sign of a data-mining problem. Although the number of variables examined may not be reported, we should look closely for verbal hints that the researcher searched over many variables. The use of terms such as “we noticed (or noted) that” or “someone noticed (or noted) that,” with respect to a pattern in a dataset, should raise suspicions that the researchers were trying out variables based on their own or others’ observations of the data.
- *No story/no future*. The absence of an explicit economic rationale for a variable or trading strategy is the “no story” warning sign of a data-mining problem. Without a plausible economic rationale or story for why a variable should work, the variable is unlikely to have predictive power. What if we do have a plausible economic explanation for a significant variable? McQueen and Thorley caution that a plausible economic rationale is a necessary but not a sufficient condition for a trading strategy to have value. As we mentioned earlier, if the strategy is publicized, market prices may adjust to reflect the new information as traders seek to exploit it; as a result, the strategy may no longer work.

7.2 Sample Selection Bias

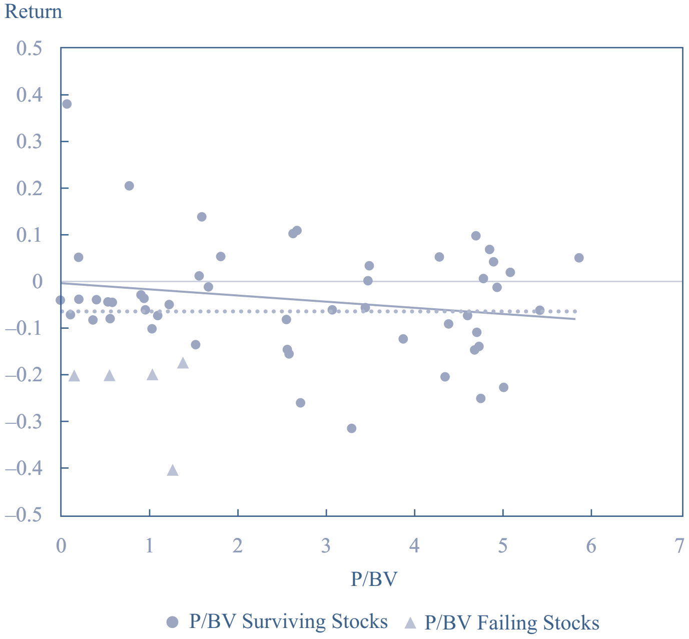
When researchers look into questions of interest to analysts or portfolio managers, they may exclude certain stocks, bonds, portfolios, or periods from the analysis for various reasons—perhaps because of data availability. When data availability leads to certain assets being excluded from the analysis, we call the resulting problem **sample selection bias**. For example, you might sample from a database that tracks only companies currently in existence. Many mutual fund databases, for instance, provide historical information about only those funds that currently exist. Databases that report historical balance sheet and income statement information suffer from the same sort of bias as the mutual fund databases: Funds or companies that are no longer in business do not appear there. So, a study that uses these types of databases suffers from a type of sample selection bias known as **survivorship bias**.

The issue of survivorship bias has also been raised in relation to international indexes, particularly those representing less established markets. Some of these markets have suffered complete loss of value as a result of hyperinflation, nationalization or confiscation of industries, or market failure. Measuring the performance of markets or particular investments that survive over time will overstate returns from investing. There is, of course, no way of determining in advance which markets will fail or survive.

Survivorship bias sometimes appears when we use both stock price and accounting data. For example, many studies in finance have used the ratio of a company's market price to book equity per share (i.e., the price-to-book ratio, P/B) and found that P/B is inversely related to a company's returns. P/B is also used to create many popular value and growth indexes. The "value" indexes, for example, would include companies trading on relatively low P/B. If the database that we use to collect accounting data excludes failing companies, however, a survivorship bias might result. It can be argued that failing stocks would be expected to have low returns and low P/Bs. If we exclude failing stocks, then those stocks with low P/Bs that are included in the index will have returns that are higher on average than if all stocks with low P/Bs were included. As shown in Exhibit 19, without failing stocks (shown in the bottom left part), we can fit a line with a negative slope indicating that P/B is inversely related to a company's stock return. With all the companies included, however, the fitted line (horizontal, dotted) shows an insignificant slope coefficient.

This bias would then be responsible for some of the traditional findings of an inverse relationship between average return and P/B. Researchers should be aware of any biases potentially inherent in a sample.

Exhibit 19 Survivorship Bias



DELISTINGS AND BIAS

A sample can also be biased because of the removal (or delisting) of a company's stock from an exchange. For example, the Center for Research in Security Prices at the University of Chicago is a major provider of return data used in academic research. When a delisting occurs, CRSP attempts to collect returns for the delisted company. Many times, however, it cannot do so because of the difficulty involved; CRSP must simply list delisted company returns as missing. A study in the *Journal of Finance* by Shumway and Warther (1999) documented the bias caused by delisting for CRSP NASDAQ return data. The authors showed that delistings associated with poor company performance (e.g., bankruptcy) are missed more often than delistings associated with good or neutral company performance (e.g., merger or moving to another exchange). In addition, delistings occur more frequently for small companies.

Sample selection bias occurs even in markets where the quality and consistency of the data are quite high. Newer asset classes such as hedge funds may present even greater problems of sample selection bias. Hedge funds are a heterogeneous group of investment vehicles typically organized so as to be free from regulatory oversight. In general, hedge funds are not required to publicly disclose performance (in contrast to, say, mutual funds). Hedge funds themselves decide whether they want to be included in one of the various databases of hedge fund performance. Hedge funds with poor track records clearly may not wish to make their records public, creating a problem of self-selection bias in hedge fund databases. Further, as pointed out by Fung and Hsieh (2002), because only hedge funds with good records will volunteer to enter a database, in general, overall past hedge fund industry performance will tend to appear better than it really is. Furthermore, many hedge fund databases drop funds that go out of business, creating survivorship bias in the database. Even if the database does not drop defunct hedge funds, in the attempt to eliminate survivorship bias, the problem remains of hedge funds that stop reporting performance because of poor results or because successful funds no longer want new cash inflows. In some circumstances, **implicit selection bias** may exist because of a threshold enabling self-selection. For example, compared with smaller exchanges, the NYSE has higher stock listing requirements. Choosing NYSE-listed stocks may introduce an implicit quality bias into the analysis. Although the bias is less obvious, it is important for generalizing findings.

A variation of selection bias is **backfill bias**. For example, when a new hedge fund is added to a given index, the fund's past performance may be backfilled into the index's database, even though the fund was not included in the database in the previous year. Usually a new fund starts contributing data after a period of good performance, so adding the fund's instant history into the index database may inflate the index performance.

7.3 Look-Ahead Bias

A test design is subject to **look-ahead bias** if it uses information that was not available on the test date. For example, tests of trading rules that use stock market returns and accounting balance sheet data must account for look-ahead bias. In such tests, a company's book value per share is commonly used to construct the P/B variable. Although the market price of a stock is available for all market participants at the same point in time, fiscal year-end book equity per share might not become publicly available until sometime in the following quarter. One solution to mitigate the look-ahead bias is to use point-in-time (PIT) data when possible. PIT data is stamped with the date when it was recorded or released. In the previous example, the PIT data of P/B would be accompanied with the date of company filing date or press release date, rather than the end date of the fiscal quarter the P/B data represents. It is worth noting that the look-ahead bias could also be implicitly introduced. For example, when normalizing input data by deducting the mean and dividing it by standard deviation, we must ensure that the standard deviation of the training data is used as the proxy for standard deviation in validation and test data sets. Using standard deviation of validation or test data to normalize them will implicitly introduce a look-ahead bias as the variance of future data is inappropriately used.

7.4 Time-Period Bias

A test design is subject to **time-period bias** if it is based on a period that may make the results period specific. A short time series is likely to give period-specific results that may not reflect a longer period. A long time series may give a more accurate picture of true investment performance; its disadvantage lies in the potential for a structural change occurring during the time frame that would result in two different return distributions. In this situation, the distribution that would reflect conditions before the change differs from the distribution that would describe conditions after the change. Regime changes, such as low versus high volatility regimes or low versus high interest rate regimes, are highly influential to asset classes. Inferences based on data influenced by one regime, and thus not appropriately distributed, should account for how the regime may bias the inferences.

EXAMPLE 13

Biases in Investment Research

An analyst is reviewing the empirical evidence on historical equity returns in the Eurozone (European countries that use the euro). She finds that value stocks (i.e., those with low P/Bs) outperformed growth stocks (i.e., those with high P/Bs) in recent periods. After reviewing the Eurozone market, the analyst wonders whether value stocks might be attractive in the United Kingdom. She investigates the performance of value and growth stocks in the UK market for a 10-year period. To conduct this research, the analyst does the following:

- obtains the current composition of the Financial Times Stock Exchange (FTSE) All Share Index, a market-capitalization-weighted index;
- eliminates the companies that do not have December fiscal year-ends;
- uses year-end book values and market prices to rank the remaining universe of companies by P/Bs at the end of the year;
- based on these rankings, divides the universe into 10 portfolios, each of which contains an equal number of stocks;
- calculates the equal-weighted return of each portfolio and the return for the FTSE All Share Index for the 12 months following the date each ranking was made; and
- subtracts the FTSE returns from each portfolio's returns to derive excess returns for each portfolio.

She discusses the research process with her supervisor, who makes two comments:

- The proposed process may introduce survivorship bias into her analysis.
- The proposed research should cover a longer period.

1 Which of the following best describes the supervisor's first comment?

A The comment is false. The proposed method is designed to avoid survivorship bias.

B The comment is true, because she is planning to use the current list of FTSE stocks rather than the actual list of stocks that existed at the start of each year.

C The comment is true, because the test design uses information unavailable on the test date.

2 What bias is the supervisor concerned about when making the second comment?

A Time period bias, because the results may be period specific

B Look-ahead bias, because the bias could be reduced or eliminated if one uses a longer period

C Survivorship bias, because the bias would become less relevant over longer periods

Solution to 1:

B is correct because the research design is subject to survivorship bias if it fails to account for companies that have gone bankrupt, merged, or otherwise departed the database. Using the current list of FTSE stocks rather than the actual list of stocks that existed at the start of each year means that the computation of returns excluded companies removed from the index. The performance of the portfolios with the lowest P/B is subject to survivorship bias and may be overstated. At some time during the testing period, those companies not currently in existence were eliminated from testing. They would probably have had low prices (and low P/Bs) and poor returns.

A is incorrect because the method is not designed to avoid survivorship bias. C is incorrect because the fact that the test design uses information unavailable on the test date relates to look-ahead bias. A test design is subject to look-ahead bias if it uses information unavailable on the test date. This bias would make a strategy based on the information appear successful, but it assumes perfect forecasting ability.

Solution to 2:

A is correct. A test design is subject to time-period bias if it is based on a period that may make the results period specific. Although the research covered a period of 10 years, that period may be too short for testing an anomaly. Ideally, an analyst should test market anomalies over several market cycles to ensure that results are not period specific. This bias can favor a proposed strategy if the period chosen was favorable to the strategy.

SUMMARY

In this reading, we have presented basic concepts and results in sampling and estimation. We have also emphasized the challenges faced by analysts in appropriately using and interpreting financial data. As analysts, we should always use a critical eye when evaluating the results from any study. The quality of the sample is of the utmost importance: If the sample is biased, the conclusions drawn from the sample will be in error.

- To draw valid inferences from a sample, the sample should be random.
- In simple random sampling, each observation has an equal chance of being selected. In stratified random sampling, the population is divided into subpopulations, called strata or cells, based on one or more classification criteria; simple random samples are then drawn from each stratum.
- Stratified random sampling ensures that population subdivisions of interest are represented in the sample. Stratified random sampling also produces more-precise parameter estimates than simple random sampling.
- Convenience sampling selects an element from the population on the basis of whether or not it is accessible to a researcher or how easy it is to access. Because convenience sampling presents the advantage of collecting data quickly at a low cost, it is a suitable sampling plan for small-scale pilot studies.
- Judgmental sampling may yield skewed results because of the bias of researchers, but its advantages lie in the fact that in some circumstances, the specialty of researchers and their judgmental can lead them directly to the target population of interest within time constraints.
- The central limit theorem states that for large sample sizes, for any underlying distribution for a random variable, the sampling distribution of the sample mean for that variable will be approximately normal, with mean equal to the population mean for that random variable and variance equal to the population variance of the variable divided by sample size.
- Based on the central limit theorem, when the sample size is large, we can compute confidence intervals for the population mean based on the normal distribution regardless of the distribution of the underlying population. In general, a sample size of 30 or larger can be considered large.

- An estimator is a formula for estimating a parameter. An estimate is a particular value that we calculate from a sample by using an estimator.
- Because an estimator or statistic is a random variable, it is described by some probability distribution. We refer to the distribution of an estimator as its sampling distribution. The standard deviation of the sampling distribution of the sample mean is called the standard error of the sample mean.
- The desirable properties of an estimator are *unbiasedness* (the expected value of the estimator equals the population parameter), *efficiency* (the estimator has the smallest variance), and *consistency* (the probability of accurate estimates increases as sample size increases).
- The two types of estimates of a parameter are point estimates and interval estimates. A point estimate is a single number that we use to estimate a parameter. An interval estimate is a range of values that brackets the population parameter with some probability.
- A confidence interval is an interval for which we can assert with a given probability $1 - \alpha$, called the degree of confidence, that it will contain the parameter it is intended to estimate. This measure is often referred to as the $100(1 - \alpha)\%$ confidence interval for the parameter.
- A $100(1 - \alpha)\%$ confidence interval for a parameter has the following structure: Point estimate ± Reliability factor × Standard error, where the reliability factor is a number based on the assumed distribution of the point estimate and the degree of confidence $(1 - \alpha)$ for the confidence interval and where standard error is the standard error of the sample statistic providing the point estimate.
- A $100(1 - \alpha)\%$ confidence interval for population mean μ when sampling from a normal distribution with known variance σ^2 is given by $\overline{X} \pm z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$, where $z_{\alpha/2}$ is the point of the standard normal distribution such that $\alpha/2$ remains in the right tail.
- A random sample of size n is said to have $n - 1$ degrees of freedom for estimating the population variance, in the sense that there are only $n - 1$ independent deviations from the mean on which to base the estimate.
- A $100(1 - \alpha)\%$ confidence interval for the population mean μ when sampling from a normal distribution with unknown variance (a *t*-distribution confidence interval) is given by $\overline{X} \pm t_{\alpha/2}\left(s/\sqrt{n}\right)$, where $t_{\alpha/2}$ is the point of the t-distribution such that $\alpha/2$ remains in the right tail and s is the sample standard deviation. This confidence interval can also be used, because of the central limit theorem, when dealing with a large sample from a population with unknown variance that may not be normal.
- We may use the confidence interval $\overline{X} \pm z_{\alpha/2}\left(s/\sqrt{n}\right)$ as an alternative to the t-distribution confidence interval for the population mean when using a large sample from a population with unknown variance. The confidence interval based on the z-statistic is less conservative (narrower) than the corresponding confidence interval based on a t-distribution.
- Bootstrap and jackknife are simple but powerful methods for statistical inference, and they are particularly useful when no analytical formula is available. Bootstrap constructs the sampling distribution of an estimator by repeatedly drawing samples from the original sample to find standard error and confidence interval. Jackknife draws repeated samples while leaving out one observation at a time from the set, without replacing it.

- Three issues in the selection of sample size are the need for precision, the risk of sampling from more than one population, and the expenses of different sample sizes.
- *Data snooping bias* comes from finding models by repeatedly searching through databases for patterns.
- *Sample selection bias* occurs when data availability leads to certain assets being excluded from the analysis, we call the resulting problem
- *Survivorship bias* is a subset of sample selection bias and occurs if companies are excluded from the analysis because they have gone out of business or because of reasons related to poor performance.
- *Self-selection* bias reflects the ability of entities to decide whether or not they wish to report their attributes or results and be included in databases or samples. *Implicit selection bias* is one type of selection bias introduced through the presence of a threshold that filters out some unqualified members. A subset of selection bias is *backfill bias*, in which past data, not reported or used before, is backfilled into an existing database.
- *Look-ahead bias* exists if the model uses data not available to market participants at the time the market participants act in the model.
- *Time-period bias* is present if the period used makes the results period specific or if the period used includes a point of structural change.

PRACTICE PROBLEMS

1 Perkiomen Kinzua, a seasoned auditor, is auditing last year's transactions for Conemaugh Corporation. Unfortunately, Conemaugh had a very large number of transactions last year, and Kinzua is under a time constraint to finish the audit. He decides to audit only the small subset of the transaction population that is of interest and to use sampling to create that subset.

The most appropriate sampling method for Kinzua to use is:

A judgmental sampling.

B systematic sampling.

C convenience sampling.

2 Which one of the following statements is true about non-probability sampling?

A There is significant risk that the sample is not representative of the population.

B Every member of the population has an equal chance of being selected for the sample.

C Using judgment guarantees that population subdivisions of interest are represented in the sample.

3 The *best* approach for creating a stratified random sample of a population involves:

A drawing an equal number of simple random samples from each subpopulation.

B selecting every *k*th member of the population until the desired sample size is reached.

C drawing simple random samples from each subpopulation in sizes proportional to the relative size of each subpopulation.

4 Although he knows security returns are not independent, a colleague makes the claim that because of the central limit theorem, if we diversify across a large number of investments, the portfolio standard deviation will eventually approach zero as n becomes large. Is he correct?

5 Why is the central limit theorem important?

6 What is wrong with the following statement of the central limit theorem?

> *Central Limit Theorem.* "If the random variables $X_1, X_2, X_3, \ldots, X_n$ are a random sample of size n from any distribution with finite mean μ and variance σ^2, then the distribution of $\overline{X}$ will be approximately normal, with a standard deviation of $\sigma/\sqrt{n}$."

7 Peter Biggs wants to know how growth managers performed last year. Biggs assumes that the population cross-sectional standard deviation of growth manager returns is 6% and that the returns are independent across managers.

A How large a random sample does Biggs need if he wants the standard deviation of the sample means to be 1%?

B How large a random sample does Biggs need if he wants the standard deviation of the sample means to be 0.25%?

© 2021 CFA Institute. All rights reserved.

8 Petra Munzi wants to know how value managers performed last year. Munzi estimates that the population cross-sectional standard deviation of value manager returns is 4% and assumes that the returns are independent across managers.

A Munzi wants to build a 95% confidence interval for the population mean return. How large a random sample does Munzi need if she wants the 95% confidence interval to have a total width of 1%?

B Munzi expects a cost of about $10 to collect each observation. If she has a $1,000 budget, will she be able to construct the confidence interval she wants?

9 Find the reliability factors based on the *t*-distribution for the following confidence intervals for the population mean (df = degrees of freedom, n = sample size):

A A 99% confidence interval, df = 20

B A 90% confidence interval, df = 20

C A 95% confidence interval, $n = 25$

D A 95% confidence interval, $n = 16$

10 Assume that monthly returns are normally distributed with a mean of 1% and a sample standard deviation of 4%. The population standard deviation is unknown. Construct a 95% confidence interval for the sample mean of monthly returns if the sample size is 24.

11 Explain the differences between constructing a confidence interval when sampling from a normal population with a known population variance and sampling from a normal population with an unknown variance.

12 Suppose we take a random sample of 30 companies in an industry with 200 companies. We calculate the sample mean of the ratio of cash flow to total debt for the prior year. We find that this ratio is 23%. Subsequently, we learn that the population cash flow to total debt ratio (taking account of all 200 companies) is 26%. What is the explanation for the discrepancy between the sample mean of 23% and the population mean of 26%?

A Sampling error.

B Bias.

C A lack of consistency.

13 Alcorn Mutual Funds is placing large advertisements in several financial publications. The advertisements prominently display the returns of 5 of Alcorn's 30 funds for the past 1-, 3-, 5-, and 10-year periods. The results are indeed impressive, with all of the funds beating the major market indexes and a few beating them by a large margin. Is the Alcorn family of funds superior to its competitors?

14 Julius Spence has tested several predictive models in order to identify undervalued stocks. Spence used about 30 company-specific variables and 10 market-related variables to predict returns for about 5,000 North American and European stocks. He found that a final model using eight variables applied to telecommunications and computer stocks yields spectacular results. Spence wants you to use the model to select investments. Should you? What steps would you take to evaluate the model?

15 A population has a non-normal distribution with mean μ and variance σ^2. The sampling distribution of the sample mean computed from samples of large size from that population will have:

A the same distribution as the population distribution.

B its mean approximately equal to the population mean.

C its variance approximately equal to the population variance.

16 A sample mean is computed from a population with a variance of 2.45. The sample size is 40. The standard error of the sample mean is *closest* to:

A 0.039.

B 0.247.

C 0.387.

17 An estimator with an expected value equal to the parameter that it is intended to estimate is described as:

A efficient.

B unbiased.

C consistent.

18 If an estimator is consistent, an increase in sample size will increase the:

A accuracy of estimates.

B efficiency of the estimator.

C unbiasedness of the estimator.

19 For a two-sided confidence interval, an increase in the degree of confidence will result in:

A a wider confidence interval.

B a narrower confidence interval.

C no change in the width of the confidence interval.

20 For a sample size of 17, with a mean of 116.23 and a variance of 245.55, the width of a 90% confidence interval using the appropriate t-distribution is *closest to*:

A 13.23.

B 13.27.

C 13.68.

21 For a sample size of 65 with a mean of 31 taken from a normally distributed population with a variance of 529, a 99% confidence interval for the population mean will have a lower limit *closest* to:

A 23.64.

B 25.41.

C 30.09.

22 An increase in sample size is *most likely* to result in a:

A wider confidence interval.

B decrease in the standard error of the sample mean.

C lower likelihood of sampling from more than one population.

23 Otema Chi has a spreadsheet with 108 monthly returns for shares in Marunou Corporation. He writes a software program that uses bootstrap resampling to create 200 resamples of this Marunou data by sampling with replacement. Each resample has 108 data points. Chi's program calculates the mean of each of the 200 resamples, and then it calculates that the mean of these 200 resample means is 0.0261. The program subtracts 0.0261 from each of the 200 resample means, squares each of these 200 differences, and adds the squared differences together. The result is 0.835. The program then calculates an estimate of the standard error of the sample mean.

The estimated standard error of the sample mean is closest to:

A 0.0115

B 0.0648

C 0.0883

24 Compared with bootstrap resampling, jackknife resampling:

A is done with replacement.

B usually requires that the number of repetitions is equal to the sample size.

C produces dissimilar results for every run because resamples are randomly drawn.

25 A report on long-term stock returns focused exclusively on all currently publicly traded firms in an industry is *most likely* susceptible to:

A look-ahead bias.

B survivorship bias.

C intergenerational data mining.

26 Which sampling bias is *most likely* investigated with an out-of-sample test?

A Look-ahead bias

B Data-mining bias

C Sample selection bias

27 Which of the following characteristics of an investment study *most likely* indicates time-period bias?

A The study is based on a short time-series.

B Information not available on the test date is used.

C A structural change occurred prior to the start of the study's time series.

SOLUTIONS

1. A is correct. With judgmental sampling, Kinzua will use his knowledge and professional judgment as a seasoned auditor to select transactions of interest from the population. This approach will allow Kinzua to create a sample that is representative of the population and that will provide sufficient audit coverage. Judgmental sampling is useful in cases that have a time constraint or in which the specialty of researchers is critical to select a more representative sample than by using other probability or non-probability sampling methods. Judgement sampling, however, entails the risk that Kinzua is biased in his selections, leading to skewed results that are not representative of the whole population.
2. A is correct. Because non-probability sampling is dependent on factors other than probability considerations, such as a sampler's judgment or the convenience to access data, there is a significant risk that non-probability sampling might generate a non-representative sample
3. C is correct. Stratified random sampling involves dividing a population into subpopulations based on one or more classification criteria. Then, simple random samples are drawn from each subpopulation in sizes proportional to the relative size of each subpopulation. These samples are then pooled to form a stratified random sample.
4. No. First the conclusion on the limit of zero is wrong; second, the support cited for drawing the conclusion (i.e., the central limit theorem) is not relevant in this context.
5. In many instances, the distribution that describes the underlying population is not normal or the distribution is not known. The central limit theorem states that if the sample size is large, regardless of the shape of the underlying population, the distribution of the sample mean is approximately normal. Therefore, even in these instances, we can still construct confidence intervals (and conduct tests of inference) as long as the sample size is large (generally $n \geq 30$).
6. The statement makes the following mistakes:
   - Given the conditions in the statement, the distribution of $\overline{X}$ will be approximately normal only for large sample sizes.
   - The statement omits the important element of the central limit theorem that the distribution of $\overline{X}$ will have mean μ.
7. **A** The standard deviation or standard error of the sample mean is $\sigma_{\overline{X}} = \sigma/\sqrt{n}$. Substituting in the values for $\sigma_{\overline{X}}$ and σ, we have $1\% = 6\%/\sqrt{n}$, or $\sqrt{n} = 6$. Squaring this value, we get a random sample of $n = 36$.

   B As in Part A, the standard deviation of sample mean is $\sigma_{\overline{X}} = \sigma/\sqrt{n}$. Substituting in the values for $\sigma_{\overline{X}}$ and σ, we have $0.25\% = 6\%/\sqrt{n}$, or $\sqrt{n} = 24$. Squaring this value, we get a random sample of $n = 576$, which is substantially larger than for Part A of this question.

8 **A** Assume the sample size will be large and thus the 95% confidence interval for the population mean of manager returns is $\overline{X} \pm 1.96 s_{\overline{X}}$, where $s_{\overline{X}} = s/\sqrt{n}$. Munzi wants the distance between the upper limit and lower limit in the confidence interval to be 1%, which is

$$\left(\overline{X} + 1.96 s_{\overline{X}}\right) - \left(\overline{X} - 1.96 s_{\overline{X}}\right) = 1\%$$

Simplifying this equation, we get $2\left(1.96 s_{\overline{X}}\right) = 1\%$. Finally, we have $3.92 s_{\overline{X}} =$ 1%, which gives us the standard deviation of the sample mean, $s_{\overline{X}} = 0.255\%$. The distribution of sample means is $s_{\overline{X}} = s/\sqrt{n}$. Substituting in the values for $s_{\overline{X}}$ and s, we have $0.255\% = 4\%/\sqrt{n}$, or $\sqrt{n} = 15.69$. Squaring this value, we get a random sample of $n = 246$.

B With her budget, Munzi can pay for a sample of up to 100 observations, which is far short of the 246 observations needed. Munzi can either proceed with her current budget and settle for a wider confidence interval or she can raise her budget (to around $2,460) to get the sample size for a 1% width in her confidence interval.

9 **A** For a 99% confidence interval, the reliability factor we use is $t_{0.005}$; for df = 20, this factor is 2.845.

B For a 90% confidence interval, the reliability factor we use is $t_{0.05}$; for df = 20, this factor is 1.725.

C Degrees of freedom equals $n - 1$, or in this case $25 - 1 = 24$. For a 95% confidence interval, the reliability factor we use is $t_{0.025}$; for df = 24, this factor is 2.064.

D Degrees of freedom equals $16 - 1 = 15$. For a 95% confidence interval, the reliability factor we use is $t_{0.025}$; for df = 15, this factor is 2.131.

10 Because this is a small sample from a normal population and we have only the sample standard deviation, we use the following model to solve for the confidence interval of the population mean:

$$\overline{X} \pm t_{\alpha/2} \frac{s}{\sqrt{n}}$$

where we find $t_{0.025}$ (for a 95% confidence interval) for df = $n - 1 = 24 - 1 = 23$; this value is 2.069. Our solution is $1\% \pm 2.069(4\%)/\sqrt{24} = 1\% \pm 2.069(0.8165) =$ $1\% \pm 1.69$. The 95% confidence interval spans the range from −0.69% to +2.69%.

11 If the population variance is known, the confidence interval is

$$\overline{X} \pm z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$$

The confidence interval for the population mean is centered at the sample mean, $\overline{X}$. The population standard deviation is σ, and the sample size is n. The population standard deviation divided by the square root of n is the standard error of the estimate of the mean. The value of z depends on the desired degree of confidence. For a 95% confidence interval, $z_{0.025} = 1.96$ and the confidence interval estimate is

$$\overline{X} \pm 1.96 \frac{\sigma}{\sqrt{n}}$$

If the population variance is not known, we make two changes to the technique used when the population variance is known. First, we must use the sample standard deviation instead of the population standard deviation. Second, we use the *t*-distribution instead of the normal distribution. The critical *t*-value will depend on degrees of freedom $n - 1$. If the sample size is large, we have the alternative of using the *z*-distribution with the sample standard deviation.

12 A is correct. The discrepancy arises from sampling error. Sampling error exists whenever one fails to observe every element of the population, because a sample statistic can vary from sample to sample. As stated in the reading, the sample mean is an unbiased estimator, a consistent estimator, and an efficient estimator of the population mean. Although the sample mean is an unbiased estimator of the population mean—the expected value of the sample mean equals the population mean—because of sampling error, we do not expect the sample mean to exactly equal the population mean in any one sample we may take.

13 No, we cannot say that Alcorn Mutual Funds as a group is superior to competitors. Alcorn Mutual Funds' advertisement may easily mislead readers because the advertisement does not show the performance of all its funds. In particular, Alcorn Mutual Funds is engaging in sample selection bias by presenting the investment results from its best-performing funds only.

14 Spence may be guilty of data mining. He has used so many possible combinations of variables on so many stocks, it is not surprising that he found some instances in which a model worked. In fact, it would have been more surprising if he had not found any. To decide whether to use his model, you should do two things: First, ask that the model be tested on out-of-sample data—that is, data that were not used in building the model. The model may not be successful with out-of-sample data. Second, examine his model to make sure that the relationships in the model make economic sense, have a story, and have a future.

15 B is correct. Given a population described by any probability distribution (normal or non-normal) with finite variance, the central limit theorem states that the sampling distribution of the sample mean will be approximately normal, with the mean approximately equal to the population mean, when the sample size is large.

16 B is correct. Taking the square root of the known population variance to determine the population standard deviation (σ) results in

$$\sigma = \sqrt{2.45} = 1.565$$

The formula for the standard error of the sample mean (σ_X), based on a known sample size (n), is

$$\sigma_X = \frac{\sigma}{\sqrt{n}}$$

Therefore,

$$\sigma_X = \frac{1.565}{\sqrt{40}} = 0.247$$

17 B is correct. An unbiased estimator is one for which the expected value equals the parameter it is intended to estimate.

18 A is correct. A consistent estimator is one for which the probability of estimates close to the value of the population parameter increases as sample size increases. More specifically, a consistent estimator's sampling distribution becomes concentrated on the value of the parameter it is intended to estimate as the sample size approaches infinity.

19 A is correct. As the degree of confidence increases (e.g., from 95% to 99%), a given confidence interval will become wider. A confidence interval is a range for which one can assert with a given probability 1 – α, called the degree of confidence, that it will contain the parameter it is intended to estimate.

20 B is correct. The confidence interval is calculated using the following equation:

$$\overline{X} \pm t_{\alpha/2} \frac{s}{\sqrt{n}}$$

Sample standard deviation (s) = $\sqrt{245.55}$ = 15.670.

For a sample size of 17, degrees of freedom equal 16, so $t_{0.05}$ = 1.746.

The confidence interval is calculated as

$$116.23 \pm 1.746 \frac{15.67}{\sqrt{17}} = 116.23 \pm 6.6357$$

Therefore, the interval spans 109.5943 to 122.8656, meaning its width is equal to approximately 13.271. (This interval can be alternatively calculated as 6.6357 × 2.)

21 A is correct. To solve, use the structure of Confidence interval = Point estimate ± Reliability factor × Standard error, which, for a normally distributed population with known variance, is represented by the following formula:

$$\overline{X} \pm z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$$

For a 99% confidence interval, use $z_{0.005}$ = 2.58.

Also, σ = $\sqrt{529}$ = 23.

Therefore, the lower limit = $31 - 2.58 \frac{23}{\sqrt{65}} = 23.6398$.

22 B is correct. All else being equal, as the sample size increases, the standard error of the sample mean decreases and the width of the confidence interval also decreases.

23 B is correct.

The estimate of the standard error of the sample mean with bootstrap resampling is calculated as follows:

$$s_{\overline{X}} = \sqrt{\frac{1}{B-1} \sum_{b=1}^{B} \left(\hat{,}_{b} - \bar{,}\right)^2} = \sqrt{\frac{1}{200-1} \sum_{b=1}^{200} \left(\hat{,}_{b} - 0.0261\right)^2} = \sqrt{\frac{1}{199} \times 0.835}$$

$$s_{\overline{X}} = 0.0648$$

24 B is correct. For a sample of size n, jackknife resampling usually requires n repetitions. In contrast, with bootstrap resampling, we are left to determine how many repetitions are appropriate.

25 B is correct. A report that uses a current list of stocks does not account for firms that failed, merged, or otherwise disappeared from the public equity market in previous years. As a consequence, the report is biased. This type of bias is known as survivorship bias.

26 B is correct. An out-of-sample test is used to investigate the presence of data-mining bias. Such a test uses a sample that does not overlap the time period of the sample on which a variable, strategy, or model was developed.

27 A is correct. A short time series is likely to give period-specific results that may not reflect a longer time period.

Hypothesis Testing

by Pamela Peterson Drake, PhD, CFA

Pamela Peterson Drake, PhD, CFA, is at James Madison University (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** define a hypothesis, describe the steps of hypothesis testing, and describe and interpret the choice of the null and alternative hypotheses;
☐	**b.** compare and contrast one-tailed and two-tailed tests of hypotheses;
☐	**c.** explain a test statistic, Type I and Type II errors, a significance level, how significance levels are used in hypothesis testing, and the power of a test;
☐	**d.** explain a decision rule and the relation between confidence intervals and hypothesis tests, and determine whether a statistically significant result is also economically meaningful.
☐	**e.** explain and interpret the *p*-value as it relates to hypothesis testing;
☐	**f.** describe how to interpret the significance of a test in the context of multiple tests;
☐	**g.** identify the appropriate test statistic and interpret the results for a hypothesis test concerning the population mean of both large and small samples when the population is normally or approximately normally distributed and the variance is (1) known or (2) unknown;
☐	**h.** identify the appropriate test statistic and interpret the results for a hypothesis test concerning the equality of the population means of two at least approximately normally distributed populations based on independent random samples with equal assumed variances;
☐	**i.** identify the appropriate test statistic and interpret the results for a hypothesis test concerning the mean difference of two normally distributed populations;

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**j.** identify the appropriate test statistic and interpret the results for a hypothesis test concerning (1) the variance of a normally distributed population and (2) the equality of the variances of two normally distributed populations based on two independent random samples;
☐	**k.** compare and contrast parametric and nonparametric tests, and describe situations where each is the more appropriate type of test;
☐	**l.** explain parametric and nonparametric tests of the hypothesis that the population correlation coefficient equals zero, and determine whether the hypothesis is rejected at a given level of significance;
☐	**m.** explain tests of independence based on contingency table data.

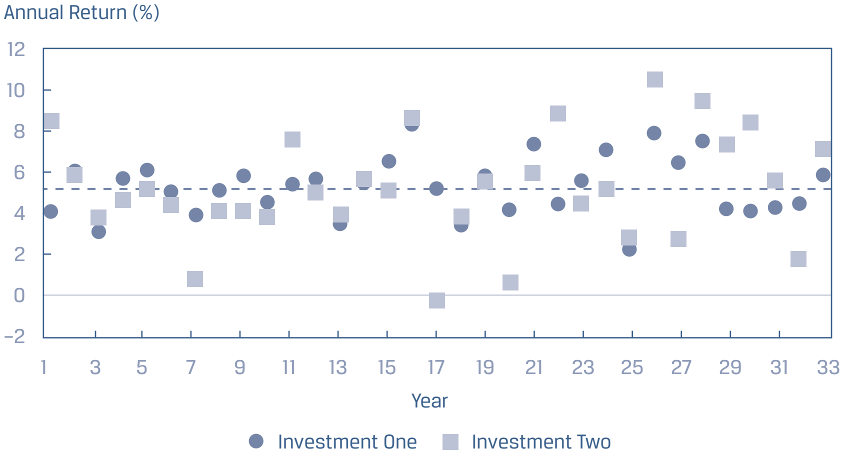
1 INTRODUCTION

a define a hypothesis, describe the steps of hypothesis testing, and describe and interpret the choice of the null and alternative hypotheses

1.1 Why Hypothesis Testing?

Faced with an overwhelming amount of data, analysts must deal with the task of wrangling those data into something that provides a clearer picture of what is going on. Consider an analyst evaluating the returns on two investments over 33 years, as we show in Exhibit 1.

Exhibit 1 Returns for Investments One and Two over 33 Years



Although "a picture is worth a thousand words," what can we actually glean from this plot? Can we tell if each investment's returns are different from an average of 5%? Can we tell whether the returns are different for Investment One and Investment Two? Can we tell whether the standard deviations of the two investments are each different from 2%? Can we tell whether the variability is different for the two investments? For these questions, we need to have more precise tools than simply a plot over time. What we need is a set of tools that aid us in making decisions based on the data.

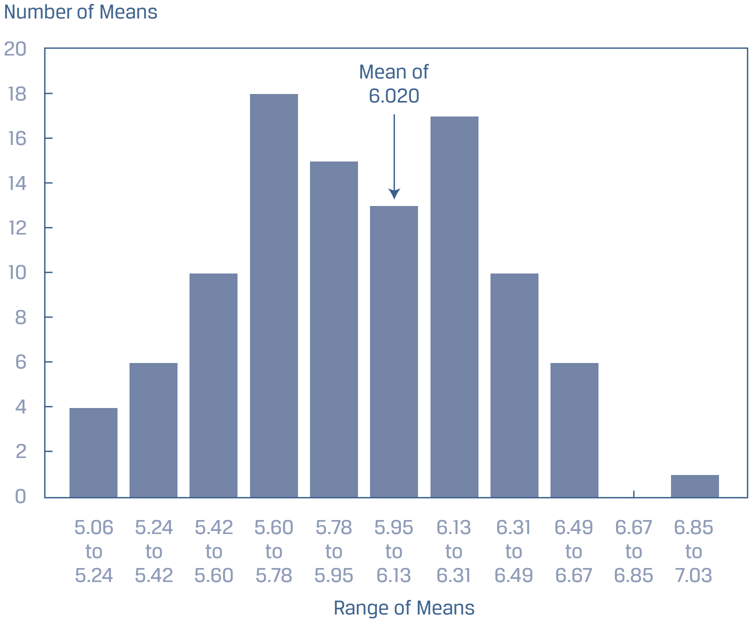
We use the concepts and tools of **hypothesis testing** to address these questions. Hypothesis testing is part of statistical inference, the process of making judgments about a larger group (a population) based on a smaller group of observations (that is, a sample).

1.2 Implications from a Sampling Distribution

Consider a set of 1,000 asset returns with a mean of 6% and a standard deviation of 2%. If we draw a sample of returns from this population, what is the chance that the mean of this sample will be 6%? What we know about sampling distributions is that how close any given sample mean will be to the population mean depends on the sample size, the variability within the population, and the quality of our sampling methodology.

For example, suppose we draw a sample of 30 observations and the sample mean is 6.13%. Is this close enough to 6% to alleviate doubt that the sample is drawn from a population with a mean of 6%? Suppose we draw another sample of 30 and find a sample mean of 4.8%. Does this bring into doubt whether the population mean is 6%? If we keep drawing samples of 30 observations from this population, we will get a range of possible sample means, as we show in Exhibit 2 for 100 different samples of size 30 from this population, with a range of values from 5.06 to 7.03%. All these sample means are a result of sampling from the 1,000 asset returns.

Exhibit 2 Distribution of Sample Means of 100 Samples Drawn from a Population of 1,000 Returns



As you can see in Exhibit 2, a sample mean that is quite different from the population mean can occur; this situation is not as likely as drawing a sample with a mean closer to the population mean, but it can still happen. *In hypothesis testing, we test to see whether a sample statistic is likely to come from a population with the hypothesized value of the population parameter.*

The concepts and tools of hypothesis testing provide an objective means to gauge whether the available evidence supports the hypothesis. After applying a statistical test of a hypothesis, we should have a clearer idea of the probability that a hypothesis is true or not, although our conclusion always stops short of certainty.

The main focus of this reading is on the framework of hypothesis testing and tests concerning mean, variance, and correlation, three quantities frequently used in investments.

2

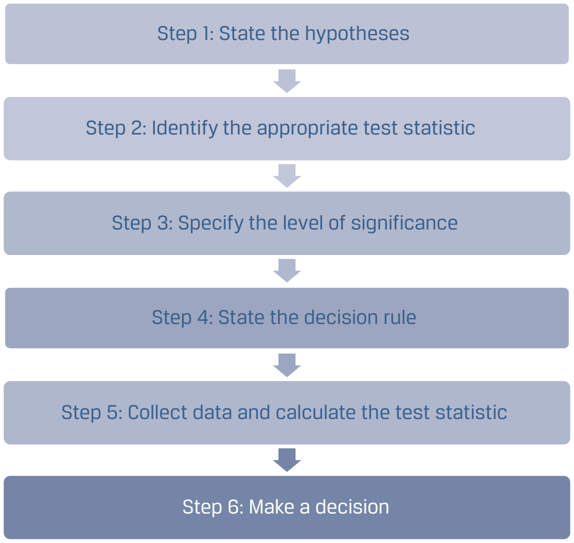
THE PROCESS OF HYPOTHESIS TESTING

Hypothesis testing is part of the branch of statistics known as statistical inference. In statistical inference, there is estimation and hypothesis testing. Estimation involves point estimates and interval estimates. Consider a sample mean, which is a point estimate, that we can use to form a confidence interval. In hypothesis testing, the focus is examining how a sample statistic informs us about a population parameter. A **hypothesis** is a statement about one or more populations that we test using sample statistics.

The process of hypothesis testing begins with the formulation of a theory to organize and explain observations. We judge the correctness of the theory by its ability to make accurate predictions—for example, to predict the results of new observations. If the predictions are correct, we continue to maintain the theory as a possibly correct explanation of our observations. Risk plays a role in the outcomes of observations in finance, so we can only try to make unbiased, probability-based judgments about whether the new data support the predictions. Statistical hypothesis testing fills that key role of testing hypotheses when there is uncertainty. When an analyst correctly formulates the question into a testable hypothesis and carries out a test of hypotheses, the use of well-established scientific methods supports the conclusions and decisions made on the basis of this test.

We organize this introduction to hypothesis testing around the six steps in Exhibit 3, which illustrate the standard approach to hypothesis testing.

Exhibit 3 The Process of Hypothesis Testing



Step 1: State the hypotheses
Step 2: Identify the appropriate test statistic
Step 3: Specify the level of significance
Step 4: State the decision rule
Step 5: Collect data and calculate the test statistic
Step 6: Make a decision

2.1 Stating the Hypotheses

For each hypothesis test, we always state two hypotheses: the **null hypothesis** (or null), designated H_0, and the **alternative hypothesis**, designated H_a. For example, our null hypothesis may concern the value of a population mean, μ, in relation to one possible value of the mean, μ_0. As another example, our null hypothesis may concern the population variance, σ^2, compared with a possible value of this variance, $\sigma_0{}^2$. The null hypothesis is a statement concerning a population parameter or parameters considered to be true unless the sample we use to conduct the hypothesis test gives convincing evidence that the null hypothesis is false. In fact, the null hypothesis is what we want to reject. If there is sufficient evidence to indicate that the null hypothesis is not true, we reject it in favor of the alternative hypothesis.

Importantly, the null and alternative hypotheses are stated in terms of population parameters, and we use sample statistics to test these hypotheses.

2.2 Two-Sided vs. One-Sided Hypotheses

b compare and contrast one-tailed and two-tailed tests of hypotheses

Suppose we want to test whether the population mean return is equal to 6%. We would state the hypotheses as

H_0: $\mu = 6$

and the alternative as

H_a: $\mu \neq 6$.

What we just created was a **two-sided hypothesis test**. We are testing whether the mean is equal to 6%; it could be greater than or less than that because we are simply asking whether the mean is different from 6%. If we find that the sample mean is far enough away from the hypothesized value, considering the risk of drawing a sample that is not representative of the population, then we would reject the null in favor of the alternative hypothesis.

What if we wanted to test whether the mean is greater than 6%. This presents us with a **one-sided hypothesis test**, and we specify the hypotheses as follows:

H_0: $\mu \leq 6$.

H_a: $\mu > 6$.

If we find that the sample mean is greater than the hypothesized value of 6 by a sufficient margin, then we would reject the null hypothesis. Why is the null hypothesis stated with a "≤" sign? First, if the sample mean is less than or equal to 6%, this would not support the alternative. Second, the null and alternative hypotheses must be mutually exclusive and collectively exhaustive; in other words, all possible values are contained in either the null or the alternative hypothesis.

Despite the different ways to formulate hypotheses, we always conduct a test of the null hypothesis at the point of equality; for example, $\mu = \mu_0$. Whether the null is H_0: $\mu = \mu_0$, H_0: $\mu \leq \mu_0$, or H_0: $\mu \geq \mu_0$, we actually test $\mu = \mu_0$. The reasoning is straightforward: Suppose the hypothesized value of the mean is 6. Consider H_0: $\mu \leq 6$, with a "greater than" alternative hypothesis, H_a: $\mu > 6$. If we have enough evidence to reject H_0: $\mu = 6$ in favor of H_a: $\mu > 6$, we definitely also have enough evidence to reject the hypothesis that the parameter μ is some smaller value, such as 4.5 or 5.

Using hypotheses regarding the population mean as an example, the three possible formulations of hypotheses are as follows:

Two-sided alternative: H_0: $\mu = \mu_0$ versus H_a: $\mu \neq \mu_0$

One-sided alternative (right side): $H_{0:}$ $\mu \leq \mu_0$ versus $H_{a:}$ $\mu > \mu_0$

One-sided alternative (left side): $H_{0:}$ $\mu \geq \mu_0$ versus $H_{a:}$ $\mu < \mu_0$

The reference to the side (right or left) refers to where we reject the null in the probability distribution. For example, if the alternative is H_a: $\mu > 6$, this means that we will reject the null hypothesis if the sample mean is sufficiently higher than (or on the right side of the distribution of) the hypothesized value.

Importantly, the calculation to test the null hypothesis is the same for all three formulations. What is different for the three formulations is how the calculation is evaluated to decide whether to reject the null.

2.3 Selecting the Appropriate Hypotheses

How do we choose the null and alternative hypotheses? The null is what we are hoping to reject. The most common alternative is the "not equal to" hypothesis. However, economic or financial theory may suggest a one-sided alternative hypothesis. For example, if the population parameter is the mean risk premium, financial theory may argue that this risk premium is positive. Following the principle of stating the alternative as the "hoped for" condition and using μ_{rp} for the population mean risk premium, we formulate the following hypotheses:

H_0: $\mu_{rp} \leq 0$ versus H_a: $\mu_{rp} > 0$

Note that the sign in the alternative hypotheses reflects the belief of the researcher more strongly than a two-sided alternative hypothesis. However, the researcher may sometimes select a two-sided alternative hypothesis to emphasize an attitude of neutrality when a one-sided alternative hypothesis is also reasonable. Typically, the easiest way to formulate the hypotheses is to specify the alternative hypothesis first and then specify the null.

EXAMPLE 1

Specifying the Hypotheses

An analyst suspects that in the most recent year excess returns on stocks have fallen below 5%. She wants to study whether the excess returns are less than 5%. Designating the population mean as μ, which hypotheses are most appropriate for her analysis?

A H_0: $\mu = 5$ versus H_a: $\mu \neq 5$

B H_0: $\mu \geq 5$ versus H_a: $\mu < 5$

C H_0: $\mu \leq 5$ versus H_a: $\mu > 5$

Solution

B is correct. The null hypothesis is what she wants to reject in favor of the alternative, which is that population mean excess return is less than 5%. This is a one-sided (left-side) alternative hypothesis.

IDENTIFY THE APPROPRIATE TEST STATISTIC

3

c explain a test statistic, Type I and Type II errors, a significance level, how significance levels are used in hypothesis testing, and the power of a test

A test statistic is a value calculated on the basis of a sample that, when used in conjunction with a decision rule, is the basis for deciding whether to reject the null hypothesis.

3.1 Test Statistics

The focal point of our statistical decision is the value of the test statistic. The test statistic that we use depends on what we are testing. As an example, let us examine the test of a population mean risk premium. Consider the sample mean, $\overline{X}$, calculated from a sample of returns drawn from the population. If the population standard deviation is known, the standard error of the distribution of sample means, $\sigma_{\overline{X}}$, is the ratio of the population standard deviation to the square root of the sample size:

$$\sigma_{\overline{X}} = \frac{\sigma}{\sqrt{n}}. \tag{1}$$

The test statistic for the test of the mean when the population variance is known is a z-distributed (that is, normally distributed) test statistic:

$$z = \frac{\overline{X}_{rp} - \mu_0}{\sigma/\sqrt{n}}. \tag{2}$$

If the hypothesized value of the mean population risk premium is 6 (that is, $\mu_0 = 6$), we calculate this as $z = \frac{\overline{X}_{rp} - 6}{\sigma/\sqrt{n}}$. If, however, the hypothesized value of the mean risk premium is zero (that is, $\mu_0 = 0$), we can simplify this test statistic as

$$z = \frac{\overline{X}_{rp}}{\sigma/\sqrt{n}}.$$

Notably, the key to hypothesis testing is identifying the appropriate test statistic for the hypotheses and the underlying distribution of the population.

3.2 Identifying the Distribution of the Test Statistic

Following the identification of the appropriate test statistic, we must be concerned with the distribution of the test statistic. We show examples of the test statistics and their corresponding distributions in Exhibit 4.

Exhibit 4 Test Statistics and Their Distributions

What We Want to Test	Test Statistic	Probability Distribution of the Statistic	Degrees of Freedom
Test of a single mean	$t = \dfrac{\bar{X} - \mu_0}{s/\sqrt{n}}$	*t*-Distributed	$n - 1$
Test of the difference in means	$t = \dfrac{(\bar{X}_1 - \bar{X}_2) - (\mu_1 - \mu_2)}{\sqrt{\dfrac{s_p^2}{n_1} + \dfrac{s_p^2}{n_2}}}$	*t*-Distributed	$n_1 + n_2 - 2$
Test of the mean of differences	$t = \dfrac{\bar{d} - \mu_{d0}}{s_{\bar{d}}}$	*t*-Distributed	$n - 1$
Test of a single variance	$\chi^2 = \dfrac{s^2(n-1)}{\sigma_0^2}$	Chi-square distributed	$n - 1$
Test of the difference in variances	$F = \dfrac{s_1^2}{s_2^2}$	*F*-distributed	$n_1 - 1, n_2 - 1$
Test of a correlation	$t = \dfrac{r\sqrt{n-2}}{\sqrt{1-r^2}}$	*t*-Distributed	$n - 2$
Test of independence (categorical data)	$\chi^2 = \sum_{i=1}^{m} \dfrac{(O_{ij} - E_{ij})^2}{E_{ij}}$	Chi-square distributed	$(r - 1)(c - 1)$

Note: μ_0, μ_{d0}, and σ_0^2 denote hypothesized values of the mean, mean difference, and variance, respectively. The $\bar{x}$, $\bar{d}$, s^2, s, and r denote for a sample the mean, mean of the differences, variance, standard deviation, and correlation, respectively, with subscripts indicating the sample, if appropriate. The sample size is indicated as n, and the subscript indicates the sample, if appropriate. O_{ij} and E_{ij} are observed and expected frequencies, respectively, with r indicating the number of rows and c indicating the number of columns in the contingency table.

4

SPECIFY THE LEVEL OF SIGNIFICANCE

The level of significance reflects how much sample evidence we require to reject the null hypothesis. The required standard of proof can change according to the nature of the hypotheses and the seriousness of the consequences of making a mistake. There are four possible outcomes when we test a null hypothesis, as shown in Exhibit 5. A **Type I error** is a false positive (reject when the null is true), whereas a **Type II error** is a false negative (fail to reject when the null is false).

Exhibit 5 Correct and Incorrect Decisions in Hypothesis Testing

	True Situation	
Decision	**H_0 True**	**H_0 False**
Fail to reject H_0	Correct decision: Do not reject a true null hypothesis.	Type II error: Fail to reject a false null hypothesis. False negative
Reject H_0	Type I error: Reject a true null hypothesis. False positive	Correct decision: Reject a false null hypothesis.

When we make a decision in a hypothesis test, we run the risk of making either a Type I or a Type II error. As you can see in Exhibit 5, these errors are mutually exclusive: If we mistakenly reject the true null, we can only be making a Type I error; if we mistakenly fail to reject the false null, we can only be making a Type II error.

Consider a test of a hypothesis of whether the mean return of a population is equal to 6%. How far away from 6% could a sample mean be before we believe it to be different from 6%, the hypothesized population mean? We are going to tolerate sample means that are close to 6%, but we begin doubting that the population mean is equal to 6% when we calculate a sample mean that is much different from 0.06. How do we determine "much different"? We do this by setting a risk tolerance for a Type I error and determining the critical value or values at which we believe that the sample mean is much different from the population mean. These critical values depend on (1) the alternative hypothesis, whether one sided or two sided, and (2) the probability distribution of the test statistic, which, in turn, depends on the sample size and the level of risk tolerance in making a Type I error.

The probability of a Type I error in testing a hypothesis is denoted by the lowercase Greek letter alpha, α. This probability is also known as the **level of significance** of the test, and its complement, $(1 - \alpha)$, is the **confidence level**. For example, a level of significance of 5% for a test means that there is a 5% probability of rejecting a true null hypothesis and corresponds to the 95% confidence level.

Controlling the probabilities of the two types of errors involves a trade-off. All else equal, if we decrease the probability of a Type I error by specifying a smaller significance level (say, 1% rather than 5%), we increase the probability of making a Type II error because we will reject the null less frequently, including when it is false. Both Type I and Type II errors are risks of being wrong. Whether to accept more of one type versus the other depends on the consequences of the errors, such as costs. The only way to reduce the probabilities of both types of errors simultaneously is to increase the sample size, n.

Quantifying the trade-off between the two types of errors in practice is challenging because the probability of a Type II error is itself difficult to quantify because there may be many different possible false hypotheses. Because of this, we specify only α, the probability of a Type I error, when we conduct a hypothesis test.

Whereas the significance level of a test is the probability of incorrectly rejecting the true null, the **power of a test** is the probability of *correctly* rejecting the null—that is, the probability of rejecting the null when it is false. The power of a test is, in fact, the complement of the Type II error. The probability of a Type II error is often denoted by the lowercase Greek letter beta, β. We can classify the different probabilities in Exhibit 6 to reflect the notation that is often used.

Exhibit 6 Probabilities Associated with Hypothesis Testing Decisions

	True Situation	
Decision	**H_0 True**	**H_0 False**
Fail to reject H_0	Confidence level (1 − α)	β
Reject H_0	Level of significance α	Power of the test (1 − β)

The standard approach to hypothesis testing involves choosing the test statistic with the most power and then specifying a level of significance. It is more appropriate to specify this significance level prior to calculating the test statistic because if we specify it after calculating the test statistic, we may be influenced by the result of the calculation. The researcher is free to specify the probability of a Type I error, but the most common are 10%, 5%, and 1%.

EXAMPLE 2

Significance Level

If a researcher selects a 5% level of significance for a hypothesis test, the confidence level is:

A 2.5%.

B 5%.

C 95%.

Solution

C is correct. The 5% level of significance (i.e., probability of a Type I error) corresponds to 1 − 0.05 = 0.95, or a 95% confidence level (i.e., probability of not rejecting a true null hypothesis). The level of significance is the complement to the confidence level; in other words, they sum to 1.00, or 100%.

5 STATE THE DECISION RULE

d explain a decision rule and the relation between confidence intervals and hypothesis tests, and determine whether a statistically significant result is also economically meaningful

The fourth step in hypothesis testing is stating the decision rule. Before any sample is drawn and before a test statistic is calculated, we need to set up a decision rule: When do we reject the null hypothesis, and when do we not? The action we take is based on comparing the calculated test statistic with a specified value or values, which we refer to as **critical values**. The critical value or values we choose are based on the level of significance and the probability distribution associated with the test statistic. If we find that the calculated value of the test statistic is more extreme than the critical value or values, then we reject the null hypothesis; we say the result is **statistically significant**. Otherwise, we fail to reject the null hypothesis; there is not sufficient evidence to reject the null hypothesis.

5.1 Determining Critical Values

For a two-tailed test, we indicate two critical values, splitting the level of significance, α, equally between the left and right tails of the distribution. Using a z-distributed (standard normal) test statistic, for example, we would designate these critical values as $\pm z_{\alpha/2}$. For a one-tailed test, we indicate a single rejection point using the symbol for the test statistic with a subscript indicating the specified probability of a Type I error— for example, z_{α}.

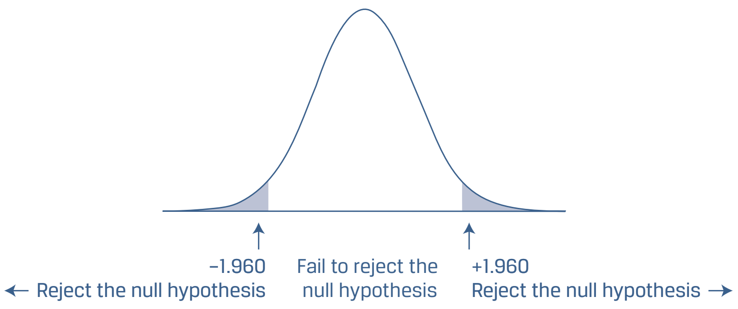
As we noted in our discussion of Exhibit 2, it is possible to draw a sample that has a mean different from the true population mean. In fact, it is likely that a given sample mean is different from the population mean because of sampling error. The issue becomes whether a given sample mean is far enough away from what is hypothesized to be the population mean that there is doubt about whether the hypothesized population mean is true. Therefore, we need to decide how far is too far for a sample mean in comparison to a population mean. That is where the critical values come into the picture.

Suppose we are using a z-test and have chosen a 5% level of significance. In Exhibit 7, we illustrate two tests at the 5% significance level using a z-statistic: A two-sided alternative hypothesis test in Panel A and a one-sided alternative hypothesis test in Panel B, with the white area under the curve indicating the confidence level and the shaded areas indicating the significance level. In Panel A, if the null hypothesis that $\mu = \mu_0$ is true, the test statistic has a 2.5% chance of falling in the left rejection region and a 2.5% chance of falling in the right rejection region. Any calculated value of the test statistic that falls in either of these two regions causes us to reject the null hypothesis at the 5% significance level.

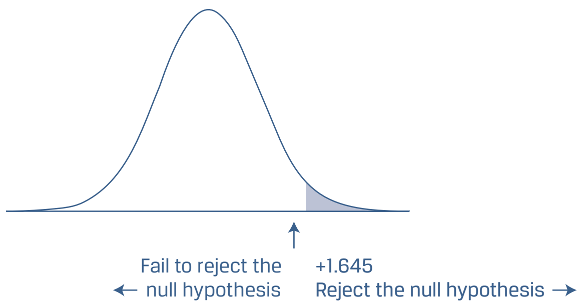
We determine the cut-off values for the reject and fail-to-reject regions on the basis of the distribution of the test statistic. For a test statistic that is normally distributed, we determine these cut-off points on the basis of the area under the normal curve; with a Type I error (i.e., level of significance, α) of 5% and a two-sided test, there is 2.5% of the area on either side of the distribution. This results in rejection points of −1.960 and +1.960, dividing the distribution between the rejection and fail-to-reject regions. Similarly, if we have a one-sided test involving a normal distribution, we would have 5% area under the curve with a demarcation of 1.645 for a right-side test, as we show in Exhibit 7 (or −1.645 for a left-side test).

Exhibit 7 Decision Criteria Using a 5% Level of Significance

A. H_0: $\mu = \mu_0$ versus H_a: $\mu \neq \mu_0$



B. H_0: $\mu \leq \mu_0$ versus H_a: $\mu > \mu_0$



Determining the cut-off points using programming

The programs in Microsoft Excel, Python, and R differ slightly, depending on whether the user specifies the area to the right or the left of the cut-off in the code:

Cut-off for . . .	Excel	Python	R
Right tail, 2.5%	NORM.S.INV(0.975)	norm.ppf(.975)	qnorm(.025,lower.tail=FALSE)
Left tail, 2.5%	NORM.S.INV(0.025)	norm.ppf(.025)	qnorm(.025,lower.tail=TRUE)
Right tail, 5%	NORM.S.INV(0.95)	norm.ppf(.95)	qnorm(.05,lower.tail=FALSE)
Left tail, 5%	NORM.S.INV(0.05)	norm.ppf(.05)	qnorm(.05,lower.tail=TRUE)

For Python, install scipy.stats and import: from scipy.stats import norm.

5.2 Decision Rules and Confidence Intervals

Exhibit 7 provides an opportunity to highlight the relationship between confidence intervals and hypothesis tests. A 95% confidence interval for the population mean, μ, based on sample mean, $\overline{X}$, is given by:

$$\left\{\overline{X} - 1.96\frac{\sigma}{\sqrt{n}}, \overline{X} + 1.96\frac{\sigma}{\sqrt{n}}\right\}, \tag{3}$$

or, more compactly, $\overline{X} \pm 1.96\frac{\sigma}{\sqrt{n}}$.

Now consider the conditions for rejecting the null hypothesis:

$$\frac{\bar{X} - \mu_0}{\sigma/\sqrt{n}} < -1.96 \text{ or } \frac{\bar{X} - \mu_0}{\sigma/\sqrt{n}} > 1.96, \text{ where } z = \frac{\bar{X} - \mu_0}{\sigma/\sqrt{n}}.$$

As you can see by comparing these conditions with the confidence interval, we can address the question of whether $\bar{X}$ is far enough away from μ_0 by either comparing the calculated test statistic with the critical values or comparing the hypothesized population parameter ($\mu = \mu_0$) with the bounds of the confidence interval, as we show in Exhibit 8. Thus, a significance level in a two-sided hypothesis test can be interpreted in the same way as a $(1 - \alpha)$ confidence interval.

Exhibit 8 Making a Decision Based on Critical Values and Confidence Intervals for a Two-Sided Alternative Hypothesis

Method	Procedure	Decision
1	Compare the calculated test statistic with the critical values.	If the calculated test statistic is less than the lower critical value or greater than the upper critical value, reject the null hypothesis.
2	Compare the calculated test statistic with the bounds of the confidence interval.	If the hypothesized value of the population parameter under the null is outside the corresponding confidence interval, the null hypothesis is rejected.

5.3 Collect the Data and Calculate the Test Statistic

The fifth step in hypothesis testing is collecting the data and calculating the test statistic. The quality of our conclusions depends on not only the appropriateness of the statistical model but also the quality of the data we use in conducting the test. First, we need to ensure that the sampling procedure does not include biases, such as sample selection or time bias. Second, we need to cleanse the data, checking inaccuracies and other measurement errors in the data. Once assured that the sample is unbiased and accurate, the sample information is used to calculate the appropriate test statistic.

EXAMPLE 3

Using a Confidence Interval in Hypothesis Testing

Consider the hypotheses H_0: $\mu = 3$ versus H_a: $\mu \neq 3$. If the confidence interval based on sample information has a lower bound of 2.75 and an upper bound of 4.25, the *most* appropriate decision is:

A reject the null hypothesis.

B accept the null hypothesis.

C fail to reject the null hypothesis.

Solution

C is correct. Since the hypothesized population mean ($\mu = 3$) is within the bounds of the confidence interval (2.75, 4.25), the correct decision is to fail to reject the null hypothesis. It is only when the hypothesized value is outside these bounds that the null hypothesis is rejected. Note that the null hypothesis is never accepted; either the null is rejected on the basis of the evidence or there is a failure to reject the null hypothesis.

6 MAKE A DECISION

d explain a decision rule and the relation between confidence intervals and hypothesis tests, and determine whether a statistically significant result is also economically meaningful

6.1 Make a Statistical Decision

The sixth step in hypothesis testing is making the decision. Consider a test of the mean risk premium, comparing the population mean with zero. If the calculated z-statistic is 2.5 and with a two-sided alternative hypothesis and a 5% level of significance, we reject the null hypothesis because 2.5 is outside the bounds of ±1.96. This is a statistical decision: The evidence indicates that the mean risk premium is not equal to zero.

6.2 Make an Economic Decision

Another part of the decision making is making the economic or investment decision. The economic or investment decision takes into consideration not only the statistical decision but also all pertinent economic issues. If, for example, we reject the null that the risk premium is zero in favor of the alternative hypothesis that the risk premium is greater than zero, we have found evidence that the US risk premium is different from zero. The question then becomes whether this risk premium is economically meaningful. On the basis of these considerations, an investor might decide to commit funds to US equities. A range of non-statistical considerations, such as the investor's tolerance for risk and financial position, might also enter the decision-making process.

6.3 Statistically Significant but Not Economically Significant?

We frequently find that slight differences between a variable and its hypothesized value are statistically significant but not economically meaningful. For example, we may be testing an investment strategy and reject a null hypothesis that the mean return to the strategy is zero based on a large sample. In the case of a test of the mean, the smaller the standard error of the mean, the larger the value of the test statistic and the greater the chance the null will be rejected, all else equal. The standard error decreases as the sample size, n, increases, so that for very large samples, we can reject the null for small departures from it. We may find that although a strategy provides a statistically significant positive mean return, the results may not be economically significant when we account for transaction costs, taxes, and risk. Even if we conclude that a strategy's results are economically meaningful, we should explore the logic of why the strategy might work in the future before implementing it. Such considerations cannot be incorporated into a hypothesis test.

EXAMPLE 4

Decisions and Significance

An analyst is testing whether there are positive risk-adjusted returns to a trading strategy. He collects a sample and tests the hypotheses of H_0: $\mu \leq 0\%$ versus H_a: $\mu > 0\%$, where μ is the population mean risk-adjusted return. The mean risk-adjusted return for the sample is 0.7%. The calculated t-statistic is 2.428, and the critical t-value is 2.345. He estimates that the transaction costs are 0.3%. The results are *most likely*:

A statistically and economically significant.

B statistically significant but not economically significant.

C economically significant but not statistically significant.

Solution

A is correct. The results indicate that the mean risk-adjusted return is greater than 0% because the calculated test statistic of 2.428 is greater than the critical value of 2.245. The results are also economically significant because the risk-adjusted return exceeds the transaction cost associated with this strategy by 0.4% (= 0.7 − 0.3).

THE ROLE OF *P*-VALUES

7

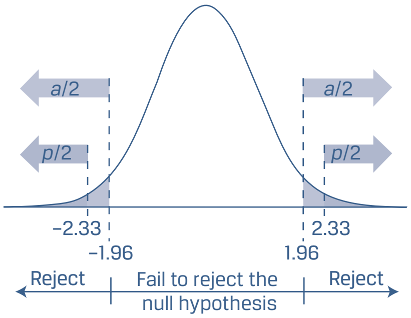
e explain and interpret the *p*-value as it relates to hypothesis testing

Analysts, researchers, and statistical software often report the *p*-value associated with hypothesis tests. The ***p*-value** is the area in the probability distribution outside the calculated test statistic; for a two-sided test, this is the area outside ± the calculated test statistic, but for a one-sided test, this is the area outside the calculated test statistic on the appropriate side of the probability distribution. We illustrated in Exhibit 7 the rejection region, which corresponds to the probability of a Type I error. However, the *p*-value is the area under the curve (so, the probability) associated with the calculated test statistic. Stated another way, the *p*-value is the smallest level of significance at which the null hypothesis can be rejected.

Consider the calculated z-statistic of 2.33 in a two-sided test: The *p*-value is the area in the z-distribution that lies outside ±2.33. Calculation of this area requires a bit of calculus, but fortunately statistical programs and other software calculate the *p*-value for us. For the value of the test statistic of 2.33, the *p*-value is approximately 0.02, or 2%. Using Excel, we can get the precise value of 0.019806 [(1-NORM.S.DIST(2.33,TRUE))*2]. We can reject the null hypothesis because we were willing to tolerate up to 5% outside the calculated value. The smaller the *p*-value, the stronger the evidence against the null hypothesis and in favor of the alternative hypothesis; if the *p*-value is less than the level of significance, we reject the null hypothesis.

We illustrate the comparison of the level of significance and the *p*-value in Exhibit 9. The fail-to-reject region is determined by the critical values of ±1.96, as we saw in Exhibit 7. There is 5% of the area under the distribution in the rejection regions—2.5% on the left side, 2.5% on the right. But now we introduce the area outside the calculated test statistic. For the calculated z-statistic of 2.33, there is 0.01, or 1%, of the area under the normal distribution above 2.33 and 1% of the area below −2.33 (or, in other words, 98% of the area between ±2.33). Since we are willing to tolerate a 5% Type I error, we reject the null hypothesis in the case of a calculated test statistic of 2.33 because there is a *p*-value of 2%; there is 2% of the distribution *outside* the calculated test statistic.

Exhibit 9 Comparison of the Level of Significance and the *p*-Value



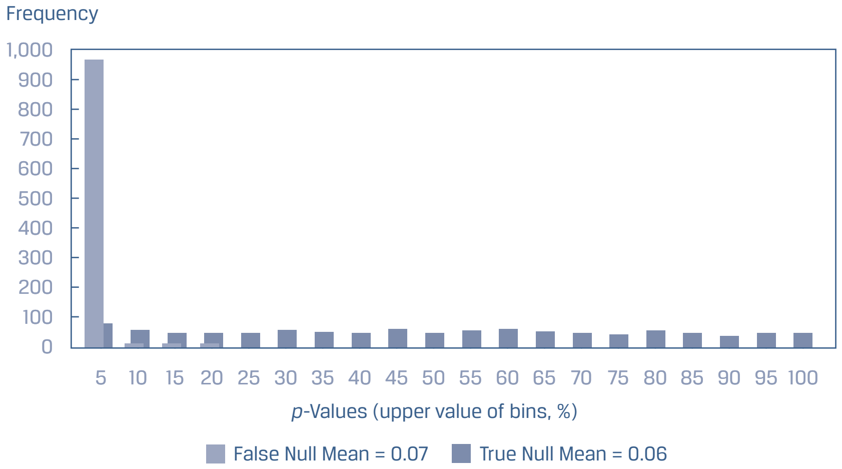
What if we are testing a one-sided alternative hypothesis? We focus solely on the area outside the calculated value on the side indicated by the alternative hypothesis. For example, if we are testing an alternative hypothesis that the population mean risk premium is greater than zero, calculate a *z*-statistic of 2.5, and have a level of significance of 5%, the *p*-value is the area in the probability distribution that is greater than 2.5. This area is 0.00621, or 0.621%. Since this is less than what we tolerate if the α is 5%, we reject the null hypothesis.

Consider a population of 1,000 assets that has a mean return of 6% and a standard deviation of 2%. Suppose we draw a sample of 50 returns and test whether the mean is equal to 6%, calculating the *p*-value for the calculated *z*-statistic. Then, suppose we repeat this process, draw 1,000 different samples, and, therefore, get 1,000 different calculated *z*-statistics and 1,000 different *p*-values. If we use a 5% level of significance, we should expect to reject the true null 5% of the time; if we use a 10% level of significance, we should expect to reject the true null 10% of the time.

Now suppose that with this same population, whose mean return is 6%, we test the hypothesis that the population mean is 7%, with the same standard deviation. As before, we draw 1,000 different samples and calculate 1,000 different *p*-values. If we use a 5% level of significance and a two-sided alternative hypothesis, we should expect to reject this false null hypothesis on the basis of the power of the test.

Putting this together, consider the histograms of *p*-values for the two different tests in Exhibit 10. The first bin is the *p*-values of 5% or less. What we see is that with the true null hypothesis of 6%, we reject the null approximately 5% of the time. For the false null hypothesis, that the mean is equal to 7%, we reject the null approximately 0.973, or 97.3%, of the time.

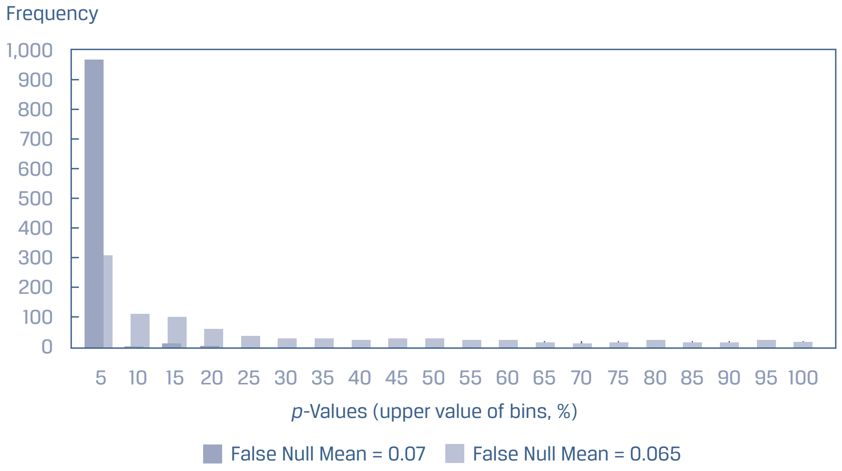
Exhibit 10 Distribution of *p*-values for 1,000 Different Samples of Size 50 Drawn from a Population with a Mean of 6%



The *p*-values for the true null hypothesis are generally uniformly distributed between 0% and 100% because under the null hypothesis, there is a 5% chance of the *p*-values being less than 5%, a 10% chance being less than 10%, and so on. Why is it not completely uniform? Because we took 1,000 samples of 50; taking more samples or larger samples would result in a more uniform distribution of *p*-values. When looking at the *p*-values for the false null hypothesis in Exhibit 10, we see that this is not a uniform distribution; rather, there is a peak around 0% and very little elsewhere. You can see the difference in the *p*-values for two false hypothesized means of 6.5% and 7% in Exhibit 11. It shows that the further the false hypothesis is away from the truth (i.e., mean of 6%), the greater the power of the test and the better the ability to detect the false hypothesis.

Software, such as Excel, Python, and R, is available for calculating *p*-values for most distributions.

Exhibit 11 Comparison of the Distribution of *p*-Values for the False Null Hypotheses H_0: μ = 7% and H_0: μ = 6.5%



EXAMPLE 5

Making a Decision Using *p*-Values

An analyst is testing the hypotheses H_0: $\sigma^2 = 0.01$ versus H_a: $\sigma^2 \neq 0.01$. Using software, she determines that the *p*-value for the test statistic is 0.03, or 3%. Which of the following statements are correct?

A Reject the null hypothesis at both the 1% and 5% levels of significance.

B Reject the null hypothesis at the 5% level but not at the 1% level of significance.

C Fail to reject the null hypothesis at both the 1% and 5% levels of significance.

Solution

B is correct. Rejection of the null hypothesis requires that the *p*-value be less than the level of significance. On the basis of this requirement, the null is rejected at the 5% level of significance but not at the 1% level of significance.

8 MULTIPLE TESTS AND INTERPRETING SIGNIFICANCE

f describe how to interpret the significance of a test in the context of multiple tests

A Type I error is the risk of rejection of a true null hypothesis. Another way of phrasing this is that it is a false positive result; that is, the null is rejected (the positive), yet the null is true (hence, a false positive). The expected portion of false positives is the **false discovery rate** (FDR). In the previous example of drawing 1,000 samples of 50 observations each, it is the case that there are samples in which we reject the true null hypothesis of a population mean of 6%. If we draw enough samples with a level of significance of 0.05, approximately 0.05 of the time you will reject the null hypothesis, even if the null is true. In other words, if you run 100 tests and use a 5% level of significance, you get five false positives, on average. This is referred to as the **multiple testing problem**.

The **false discovery approach** to testing requires adjusting the *p*-value when you have a series of tests. The idea of adjusting for the likelihood of significant results being false positives was first introduced by Benjamini and Hochberg (BH) in 1995. What they proposed is that the researcher rank the *p*-values from the various tests, from lowest to highest, and then make the following comparison, starting with the lowest *p*-value (with $k = 1$), $p(1)$:

$$p(1) \leq \alpha \frac{\text{Rank of } i}{\text{Number of tests}}.$$

This comparison is repeated, such that k is determined by the highest ranked $p(k)$ for which this is a true statement. If, say, k is 4, then the first four tests (ranked on the basis of the lowest *p*-values) are said to be significant.

Suppose we test the hypothesis that the population mean is equal to 6% and repeat the sampling process by drawing 20 samples and calculating 20 test statistics; the six test statistics with the lowest *p*-values are shown in . Using a significance level of 5%, if we simply relied on each test and its *p*-value, then there are five tests in which we would reject the null. However, using the BH criteria, only one test is considered significant, as shown in Exhibit 12.

Exhibit 12 Applying the Benjamini and Hochberg Criteria

(1) $\overline{X}$	(2) Calculated *z*-Statistic	(3) *p*-Value	(4) Rank of *p*-Value (lowest to highest)	(5) $\alpha \frac{\text{Rank of } i}{\text{Number of tests}}$	(6) Is value in (3) less than or equal to value in (5)?
0.0664	3.1966	0.0014	1	0.0025	Yes
0.0645	2.2463	0.0247	2	0.0050	No
0.0642	2.0993	0.0358	3	0.0075	No
0.0642	2.0756	0.0379	4	0.0100	No
0.0641	2.0723	0.0382	5	0.0125	No
0.0637	1.8627	0.0625	6	0.0150	No

Note: Level of significance = 5%.

So, what is the conclusion from looking at *p*-values and the multiple testing problem?

- First, if we sample, test, and find a result that is not statistically significant, this result is not wrong; in fact, the null hypothesis may well be true.
- Second, if the power of the test is low or the sample size is small, we should be cautious because there is a good chance of a false positive.
- Third, when we perform a hypothesis test and determine the critical values, these values are based on the assumption that the test is run once. Running multiple tests on data risks data snooping, which may result in spurious results. Determine the dataset and perform the test, but do not keep performing tests repeatedly to search out statistically significant results, because you may, by chance, find them (i.e., false positives).
- Fourth, in very large samples, we will find that nearly every test is significant. The approach to use to address this issue is to draw different samples; if the results are similar, the results are more robust.

EXAMPLE 6

False Discovery and Multiple Tests

A researcher is examining the mean return on assets of publicly traded companies that constitute an index of 2,000 mid-cap stocks and is testing hypotheses concerning whether the mean is equal to 15%: H_0: $\mu_{ROA} = 15$ versus Ha: $\mu_{ROA} \neq 15$. She uses a 10% level of significance and collects a sample of 50 firms. She wants to examine the robustness of her analysis, so she repeats the collection and test of the return on assets 30 times. The results for the samples with the five lowest *p*-values are given in Exhibit 13.

Exhibit 13 Five Lowest *p*-Values of the 30 Samples Tested

Sample	Calculated *z*-Statistic	*p*-Value	Ranked *p*-Value
1	3.203	0.00136	1
5	3.115	0.00184	2
14	2.987	0.00282	3
25	2.143	0.03211	4
29	1.903	0.05704	5

1 Of the 30 samples tested, how many should the researcher expect, on average, to have *p*-values less than the level of significance?

2 What are the corrected *p*-values based on her selected level of significance, and what is the effect on her decision?

Solution to 1

Of the 30 samples tested, she should expect $30 \times 0.10 = 3$ to have significant results just by chance. Consider why she ended up with more than three. Three is based on large sample sizes and large numbers of samples. Using a limited sample size (i.e., 50) and number of samples (i.e., 30), there is a risk of a false discovery with repeated samples and tests.

Solution to 2

Applying the BH criteria, the researcher determines the adjusted p-values shown in Exhibit 14.

Exhibit 14 Adjusted *p*-Values for Five Lowest *p*-Values from 30 Samples Tested

Calculated *z*-Statistic	*p*-Value	Rank of *p*-Value	$\alpha \dfrac{\text{Rank of } i}{\text{Number of tests}}$	Is *p*-value less than or equal to adjusted *p*-value?
3.203	0.00136	1	0.00333	Yes
3.115	0.00184	2	0.00667	Yes
2.987	0.00282	3	0.01000	Yes
2.143	0.03211	4	0.01333	No
1.903	0.05704	5	0.01667	No

On the basis of the results in Exhibit 14, there are three samples with *p*-values less than their adjusted *p*-values. So, the number of significant sample results is the same as would be expected from chance, given the 10% level of significance. The researcher concludes that the results for the samples with Ranks 4 and 5 are false discoveries, and she has not uncovered any evidence from her testing that supports rejecting the null hypothesis.

TESTS CONCERNING A SINGLE MEAN

g identify the appropriate test statistic and interpret the results for a hypothesis test concerning the population mean of both large and small samples when the population is normally or approximately normally distributed and the variance is (1) known or (2) unknown

Hypothesis tests concerning the mean are among the most common in practice. The sampling distribution of the mean when the population standard deviation is unknown is *t*-distributed, and when the population standard deviation is known, it is normally distributed, or *z*-distributed. Since the population standard deviation is unknown in almost all cases, we will focus on the use of a *t*-distributed test statistic.

The *t*-distribution is a probability distribution defined by a single parameter known as degrees of freedom (df). Like the standard normal distribution, a *t*-distribution is symmetrical with a mean of zero, but it has a standard deviation greater than 1 and generally fatter tails. As the number of degrees of freedom increases with the sample size, the *t*-distribution approaches the standard normal distribution.

For hypothesis tests concerning the population mean of a normally distributed population with unknown variance, the theoretically correct test statistic is the *t*-statistic. What if a normal distribution does not describe the population? The *t*-statistic is robust to moderate departures from normality, except for outliers and strong skewness. When we have large samples, departures of the underlying distribution from the normal case are of increasingly less concern. The sample mean is approximately normally distributed in large samples according to the central limit theorem, whatever the distribution describing the population. A traditional rule of thumb is that the normal distribution is used in cases when the sample size is larger than 30, but the more precise testing uses the *t*-distribution. Moreover, with software that aids us in such testing, we do not need to resort to rules of thumb.

If the population sampled has unknown variance, then the test statistic for hypothesis tests concerning a single population mean, μ, is

$$t_{n-1} = \frac{\overline{X} - \mu_0}{s/\sqrt{n}}, \tag{4}$$

where

$\overline{X}$ = sample mean

μ_0 = hypothesized value of the population mean

s = sample standard deviation

n = sample size

$s_{\overline{X}} = s/\sqrt{n}$ = estimate of the sample mean standard error

This test statistic is *t*-distributed with $n - 1$ degrees of freedom, which we can write as t_{n-1}. For simplicity, we often drop the subscript $n - 1$ because each particular test statistic has specified degrees of freedom, as we presented in Exhibit 4.

Consider testing whether Investment One's returns (from Exhibit 1) are different from 6%; that is, we are testing H_0: $\mu = 6$ versus H_a: $\mu \neq 6$. If the calculated *t*-distributed test statistic is outside the bounds of the critical values based on the level of significance, we will reject the null hypothesis in favor of the alternative. If we have a sample size of 33, there are $n - 1 = 32$ degrees of freedom. At a 5% significance level (two tailed) and 32 degrees of freedom, the critical *t*-values are ±2.037. We can determine the critical values from software:

- Excel [T.INV(0.025,32) and T.INV(0.975,32)]

- R [qt(c(.025,.975),32)]
- Python [from scipy.stats import t and t.ppf(.025,32) and t.ppf(.975,32)]

Suppose that the sample mean return is 5.2990% and the sample standard deviation is 1.4284%. The calculated test statistic is

$$t = \frac{5.2990 - 6}{1.4284/\sqrt{33}} = -2.8192$$

with 32 degrees of freedom. The calculated value is less than −2.037, so we reject the null that the population mean is 6%, concluding that it is different from 6%.

EXAMPLE 7

Risk and Return Characteristics of an Equity Mutual Fund

Suppose you are analyzing Sendar Equity Fund, a midcap growth fund that has been in existence for 24 months. During this period, it has achieved a mean monthly return of 1.50%, with a sample standard deviation of monthly returns of 3.60%. Given its level of market risk and according to a pricing model, this mutual fund was expected to have earned a 1.10% mean monthly return during that time period. Assuming returns are normally distributed, are the actual results consistent with an underlying or population mean monthly return of 1.10%?

1 Test the hypothesis using a 5% level of significance.

2 Test the hypothesis using the 95% confidence interval.

Solution to 1

Step 1	State the hypotheses.	H_0: $\mu = 1.1\%$ versus H_a: $\mu \neq 1.1\%$
Step 2	Identify the appropriate test statistic.	$t = \frac{\bar{X} - \mu_0}{s/\sqrt{n}}$ with 24 – 1 =23 degrees of freedom.
Step 3	Specify the level of significance.	$\alpha = 5\%$ (two tailed).
Step 4	State the decision rule.	Critical *t*-values = ±2.069. Reject the null if the calculated *t*-statistic is less than −2.069, and reject the null if the calculated *t*-statistic is greater than +2.069. **Excel** *Lower:* T.INV(0.025,23) *Upper:* T.INV(0.975,23) **R** qt(c(.025,.975),23) **Python** from scipy.stats import t *Lower:* t.ppf(.025,23) *Upper:* t.ppf(.975,23)
Step 5	Calculate the test statistic.	$t = \frac{1.5 - 1.1}{3.6/\sqrt{24}} = 0.54433$
Step 6	Make a decision.	Fail to reject the null hypothesis because the calculated *t*-statistic falls between the two critical values. There is not sufficient evidence to indicate that the population mean monthly return is different from 1.10%.

Solution to 2

The 95% confidence interval is $\overline{X}$ ± Critical value$\left(\frac{s}{\sqrt{n}}\right)$, so

$$\left\{1.5 - 2.069\left(3.6\big/\sqrt{24}\right),\ 1.5 + 2.069\left(3.6\big/\sqrt{24}\right)\right\}$$

$$\{1.5 - 1.5204,\ 1.5 + 1.5204\}$$

$$\{-0.0204,\ 3.0204\}$$

The hypothesized value of 1.1% is within the bounds of the 95% confidence interval, so we fail to reject the null hypothesis.

We stated previously that when population variance is not known, we use a *t*-test for tests concerning a single population mean. Given at least approximate normality, the *t*-distributed test statistic is always called for when we deal with small samples and do not know the population variance. For large samples, the central limit theorem states that the sample mean is approximately normally distributed, whatever the distribution of the population. The *t*-statistic is still appropriate, but an alternative test may be more useful when sample size is large.

For large samples, practitioners sometimes use a *z*-test in place of a *t*-test for tests concerning a mean. The justification for using the *z*-test in this context is twofold. First, in large samples, the sample mean should follow the normal distribution at least approximately, as we have already stated, fulfilling the normality assumption of the *z*-test. Second, the difference between the rejection points for the *t*-test and *z*-test becomes quite small when the sample size is large. Since the *t*-test is readily available as statistical program output and theoretically correct for unknown population variance, we present it as the test of choice.

In a very limited number of cases, we may know the population variance; in such cases, the *z*-statistic is theoretically correct. In this case, the appropriate test statistic is what we used earlier (Equation 2):

$$z = \frac{\overline{X} - \mu_0}{\sigma\big/\sqrt{n}}.$$

In cases of large samples, a researcher may use the *z*-statistic, substituting the sample standard deviation (s) for the population standard deviation (σ) in the formula. When we use a *z*-test, we usually refer to a rejection point in Exhibit 15.

Exhibit 15 Critical Values for Common Significance Levels for the Standard Normal Distribution

Level of Significance	Alternative	Reject the Null if . . . below the Critical Value	Reject the Null if . . . above the Critical Value
0.01	Two sided: H_0: $\mu = \mu_0$, H_a: $\mu \neq \mu_0$	−2.576	2.576
	One sided: H_0: $\mu \leq \mu_0$, H_a: $\mu > \mu_0$		2.326
	One sided: H_0: $\mu \geq \mu_0$, H_a: $\mu < \mu_0$	−2.326	

(continued)

Exhibit 15 (Continued)

Level of Significance	Alternative	Reject the Null if . . . below the Critical Value	Reject the Null if . . . above the Critical Value
0.05	Two sided: H_0: $\mu = \mu_0$, H_a: $\mu \neq \mu_0$	−1.960	1.960
	One sided: H_0: $\mu \leq \mu_0$, H_a: $\mu > \mu_0$		1.645
	One sided: H_0: $\mu \geq \mu_0$, H_a: $\mu < \mu_0$	−1.645	

EXAMPLE 8

Testing the Returns on the ACE High Yield Index

Suppose we want to test whether the daily return in the ACE High Yield Total Return Index is different from zero. Collecting a sample of 1,304 daily returns, we find a mean daily return of 0.0157%, with a standard deviation of 0.3157%.

1. Test whether the mean daily return is different from zero at the 5% level of significance.

2. Using the *z*-distributed test statistic as an approximation, test whether the mean daily return is different from zero at the 5% level of significance.

Solution to 1

Step 1 State the hypotheses. H_0: μ = 0% versus H_a: $\mu \neq$ 0%

Step 2 Identify the appropriate test statistic.

$$t = \frac{\bar{X} - \mu_0}{s/\sqrt{n}}$$

with 1,304 − 1 = 1,303 degrees of freedom.

Step 3 Specify the level of significance. α = 5%.

Step 4 State the decision rule. Critical *t*-values = ±1.962.

Reject the null if the calculated *t*-statistic is less than −1.962, and reject the null if the calculated *t*-statistic is greater than +1.962.

Excel

Lower: T.INV(0.025,1303)

Upper: T.INV(0.975,1303)

R qt(c(.025,.975),1303)

Python from scipy.stats import t

Lower: t.ppf(.025,1303)

Upper: t.ppf(.975,1303)

Step 5 Calculate the test statistic.

$$t = \frac{0.0157 - 0}{0.3157/\sqrt{1{,}304}} = 1.79582$$

Step 6 Make a decision. Fail to reject the null because the calculated *t*-statistic falls between the two critical values. There is not sufficient evidence to indicate that the mean daily return is different from 0%.

Solution to 2

Step 1 State the hypotheses. H_0: μ = 0% versus H_a: μ ≠ 0%

Step 2 Identify the appropriate test statistic.

$$z = \frac{\overline{X} - \mu_0}{s / \sqrt{n}}$$

with 1,304 − 1 = 1,303 degrees of freedom.

Step 3 Specify the level of significance. α = 5%.

Step 4 State the decision rule. Critical *t*-values = ±1.960.

Reject the null if the calculated *z*-statistic is less than −1.960, and reject the null if the calculated *z*-statistic is greater than +1.960.

Excel	*Lower:* NORM.S.INV(0.025)
	Upper: NORM.S.INV(0.975)
R	qnorm(.025,lower.tail=TRUE)
	qnorm(.975,lower.tail=FALSE)
Python	from scipy.stats import norm
	Lower: norm.ppf(.025,23)
	Upper: norm.ppf(.975,23)

$$z = \frac{0.0157 - 0}{0.3157 / \sqrt{1{,}304}} = 1.79582$$

Fail to reject the null because the calculated *z*-statistic falls between the two critical values. There is not sufficient evidence to indicate that the mean daily return is different from 0%.

Step 5 Calculate the test statistic.

Step 6 Make a decision.

TEST CONCERNING DIFFERENCES BETWEEN MEANS WITH INDEPENDENT SAMPLES

10

h identify the appropriate test statistic and interpret the results for a hypothesis test concerning the equality of the population means of two at least approximately normally distributed populations based on independent random samples with equal assumed variances

We often want to know whether a mean value—for example, a mean return—differs for two groups. Is an observed difference due to chance or to different underlying values for the mean? We test this by drawing a sample from each group. When it is reasonable to believe that the samples are from populations at least approximately normally distributed and that the samples are also independent of each other, we use the test of the differences in the means. We may assume that population variances are equal or unequal. However, our focus in discussing the test of the differences of means is using the assumption that the population variances are equal. In the calculation of the test statistic, we combine the observations from both samples to obtain a pooled estimate of the common population variance.

Let μ_1 and μ_2 represent, respectively, the population means of the first and second populations. Most often we want to test whether the population means are equal or whether one is larger than the other. Thus, we formulate the following sets of hypotheses:

Two sided:

$$H_0: \mu_1 - \mu_2 = 0 \text{ versus } H_a: \mu_1 - \mu_2 \neq 0,$$

or, equivalently,

$$H_0: \mu_1 = \mu_2 \text{ versus } H_a: \mu_1 \neq \mu_2$$

One sided (right side):

$$H_0: \mu_1 - \mu_2 \leq 0 \text{ versus } H_a: \mu_1 - \mu_2 > 0,$$

or, equivalently,

$$H_0: \mu_1 \leq \mu_2 \text{ versus } H_a: \mu_1 > \mu_2$$

One sided (left side):

$$H_0: \mu_1 - \mu_2 \geq 0 \text{ versus } H_a: \mu_1 - \mu_2 < 0,$$

or, equivalently,

$$H_0: \mu_1 \geq \mu_2 \text{ versus } H_a: \mu_1 < \mu_2$$

We can, however, formulate other hypotheses, where the difference is something other than zero, such as $H_0: \mu_1 - \mu_2 = 2$ versus $H_a: \mu_1 - \mu_2 \neq 2$. The procedure is the same.

When we can assume that the two populations are normally distributed and that the unknown population variances are equal, we use a t-distributed test statistic based on independent random samples:

$$t = \frac{\left(\bar{X}_1 - \bar{X}_2\right) - \left(\mu_1 - \mu_2\right)}{\sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}}, \tag{5}$$

Where $s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$ is a pooled estimator of the common variance. As you can see, the pooled estimate is a weighted average of the two samples' variances, with the degrees of freedom for each sample as the weight. The number of degrees of freedom for this t-distributed test statistic is $n_1 + n_2 - 2$.

EXAMPLE 9

Returns on the ACE High Yield Index Compared for Two Periods

Continuing the example of the returns in the ACE High Yield Total Return Index, suppose we want to test whether these returns, shown in Exhibit 16, are different for two different time periods, Period 1 and Period 2.

Exhibit 16 Descriptive Statistics for ACE High Yield Total Return Index for Periods 1 and 2

	Period 1	Period 2
Mean	0.01775%	0.01134%
Standard deviation	0.31580%	0.38760%
Sample size	445 days	859 days

Note that these periods are of different lengths and the samples are independent; that is, there is no pairing of the days for the two periods.

Test whether there is a difference between the mean daily returns in Period 1 and in Period 2 using a 5% level of significance.

Step 1 State the hypotheses.

H_0: $\mu_{Period1} = \mu_{Period2}$ versus H_a: $\mu_{Period1} \neq \mu_{Period2}$

Step 2 Identify the appropriate test statistic.

$$t = \frac{(\bar{X}_{Period1} - \bar{X}_{Period2}) - (\mu_{Period1} - \mu_{Period2})}{\sqrt{\frac{s_p^2}{n_{period1}} + \frac{s_p^2}{n_{period2}}}},$$

where $s_p^2 = \dfrac{(n_{period1} - 1)s_{Period1}^2 + (n_{period2} - 1)s_{Period2}^2}{n_{period1} + n_{period2} - 2}$

with 445 + 859 – 2 =1,302 degrees of freedom.

Step 3 Specify the level of significance.

$\alpha = 5\%$.

Step 4 State the decision rule.

Critical *t*-values = ±1.962.

Reject the null if the calculated *t*-statistic is less than −1.962, and reject the null if the calculated *t*-statistic is greater than +1.962.

Excel

Lower: T.INV(0.025,1302)

Upper: T.INV(0.975,1302)

R qt(c(.025,.975),1302)

Python from scipy.stats import t

Lower: t.ppf(.025,1302)

Upper: t.ppf(.975,1302)

Step 5 Calculate the test statistic.

$$s_p^2 = \frac{(445 - 1)0.09973 + (859 - 1)0.15023}{445 + 859 - 2} = 0.1330$$

$$t = \frac{(0.01775 - 0.01134) - 0}{\sqrt{\frac{0.1330}{445} + \frac{0.1330}{859}}} = \frac{0.0064}{0.0213} = 0.3009.$$

Step 6 Make a decision.

Fail to reject the null because the calculated *t*-statistic falls within the bounds of the two critical values. We conclude that there is insufficient evidence to indicate that the returns are different for the two time periods.

11 TEST CONCERNING DIFFERENCES BETWEEN MEANS WITH DEPENDENT SAMPLES

i. identify the appropriate test statistic and interpret the results for a hypothesis test concerning the mean difference of two normally distributed populations

When we compare two independent samples, we use a t-distributed test statistic that uses the difference in the means and a pooled variance. An assumption for the validity of those tests is that the samples are independent—that is, unrelated to each other. When we want to conduct tests on two means based on samples that we believe are dependent, we use the **test of the mean of the differences**.

The t-test in this section is based on data arranged in paired observations, and the test itself is sometimes referred to as the **paired comparisons test**. Paired observations are observations that are dependent because they have something in common. For example, we may be concerned with the dividend policy of companies before and after a change in the tax law affecting the taxation of dividends. We then have pairs of observations for the same companies; these are dependent samples because we have pairs of the sample companies before and after the tax law change. We may test a hypothesis about the mean of the differences that we observe across companies. For example, we may be testing whether the mean returns earned by two investment strategies were equal over a study period. The observations here are dependent in the sense that there is one observation for each strategy in each month, and both observations depend on underlying market risk factors. What is being tested are the differences, and the paired comparisons test assumes that the differences are normally distributed. By calculating a standard error based on differences, we can use a t-distributed test statistic to account for correlation between the observations.

How is this test of paired differences different from the test of the differences in means in independent samples? The test of paired comparisons is more powerful than the test of the differences in the means because by using the common element (such as the same periods or companies), we eliminate the variation between the samples that could be caused by something other than what we are testing.

Suppose we have observations for the random variables X_A and X_B and that the samples are dependent. We arrange the observations in pairs. Let d_i denote the difference between two paired observations. We can use the notation $d_i = x_{Ai} - x_{Bi}$, where x_{Ai} and x_{Bi} are the ith pair of observations, $i = 1, 2, \ldots, n$, on the two variables. Let μ_d stand for the population mean difference. We can formulate the following hypotheses, where μ_{d0} is a hypothesized value for the population mean difference:

Two sided: H_0: $\mu_d = \mu_{d0}$ versus H_a: $\mu_d \neq \mu_{d0}$

One sided (right side): H_0: $\mu_d \leq \mu_{d0}$ versus H_a: $\mu_d > \mu_{d0}$

One sided (left side) H_0: $\mu_d \geq \mu_{d0}$ versus H_a: $\mu_d < \mu_{d0}$

In practice, the most commonly used value for μ_{d0} is zero.

We are concerned with the case of normally distributed populations with unknown population variances, and we use a t-distributed test statistic. We begin by calculating $\bar{d}$, the sample mean difference, or the mean of the differences, d_i:

$$\bar{d} = \frac{1}{n}\sum_{i=1}^{n} d_i, \tag{6}$$

where n is the number of pairs of observations. The sample standard deviation, s_d, is the standard deviation of the differences, and the standard error of the mean differences is $s_{\bar{d}} = \dfrac{s_d}{\sqrt{n}}$.

When we have data consisting of paired observations from samples generated by normally distributed populations with unknown variances, the *t*-distributed test statistic is

$$t = \frac{\bar{d} - \mu_{d0}}{s_{\bar{d}}} \tag{7}$$

with *n* – 1 degrees of freedom, where *n* is the number of paired observations.

For example, suppose we want to see if there is a difference between the returns for Investments One and Two (from Exhibit 1), for which we have returns in each of 33 years. Using a 1% level of significance, the critical values for a two-sided hypothesis test are ±2.7385. Lining up these returns by the years and calculating the differences, we find a sample mean difference ($\bar{d}$) of 0.10353% and a standard deviation of these differences (s_d) of 2.35979%. Therefore, the calculated *t*-statistic for testing whether the mean of the differences is equal to zero is

$$t = \frac{0.10353 - 0}{2.35979/\sqrt{33}} = 0.25203$$

with 32 degrees of freedom. In this case, we fail to reject the null because the *t*-statistic falls within the bounds of the two critical values. We conclude that there is not sufficient evidence to indicate that the returns for Investment One and Investment Two are different.

Importantly, if we think of the differences between the two samples as a single sample, then the test of the mean of differences is identical to the test of a single sample mean.

EXAMPLE 10

Testing for the Mean of the Differences

In Exhibit 17, we report the quarterly returns for a three-year period for two actively managed portfolios specializing in precious metals. The two portfolios are similar in risk and had nearly identical expense ratios. A major investment services company rated Portfolio B more highly than Portfolio A. In investigating the portfolios' relative performance, suppose we want to test the hypothesis that the mean quarterly return on Portfolio A is equal to the mean quarterly return on Portfolio B during the three-year period. Since the two portfolios share essentially the same set of risk factors, their returns are not independent, so a paired comparisons test is appropriate. Use a 10% level of significance.

Exhibit 17 Quarterly Returns for Two Actively Managed Precious Metals Portfolios

Year	Quarter	Portfolio A (%)	Portfolio B (%)	Difference (Portfolio A – Portfolio B)
1	1	4.50	0.50	4.00
1	2	−4.10	−3.10	−1.00
1	3	−14.50	−16.80	2.30
1	4	−5.50	−6.78	1.28
2	1	12.00	−2.00	14.00
2	2	−7.97	−8.96	0.99
2	3	−14.01	−10.01	−4.00

(continued)

Exhibit 17 (Continued)

Year	Quarter	Portfolio A (%)	Portfolio B (%)	Difference (Portfolio A – Portfolio B)
2	4	4.11	−6.31	10.42
3	1	2.34	−5.00	7.34
3	2	26.36	12.77	13.59
3	3	10.72	9.23	1.49
3	4	3.60	1.20	2.40
Average		1.46	-2.94	4.40083
Standard deviation		11.18	7.82	5.47434

Using this sample information, we can summarize the test as follows:

Step 1 State the hypotheses.

H_0: $\mu_{d0} = 0$ versus H_a: $\mu_{d0} \neq 0$

Step 2 Identify the appropriate test statistic.

$$t = \frac{\bar{d} - \mu_{d0}}{s_{\bar{d}}}$$

Step 3 Specify the level of significance.

10%

Step 3 State the decision rule.

With 12 − 1 = 11 degrees of freedom, the critical values are ±1.796.

We reject the null hypothesis if the calculated test statistic is below −1.796 or above +1.796.

Excel

Lower: T.INV(0.05,11)

Upper: T.INV(0.95,11)

R qt(c(.05,.95),11)

Python from scipy.stats import t

Lower: t.ppf(.05,11)

Upper: t.ppf(.95,11)

Step 4 Calculate the test statistic.

$$\bar{d} = 4.40083$$

$$s_{\bar{d}} = \frac{5.47434}{\sqrt{12}} = 1.58031$$

$$t = \frac{4.40083 - 0}{1.58031} = 2.78480$$

Step 5 Make a decision.

Reject the null hypothesis because the calculated *t*-statistic falls outside the bounds of the two critical values. There is sufficient evidence to indicate that the mean of the differences of returns is not zero.

The following example illustrates the application of this test to evaluate two competing investment strategies.

EXAMPLE 11

A Comparison of the Returns of Two Indexes

Suppose we want to compare the returns of the ACE High Yield Index with those of the ACE BBB Index. We collect data over 1,304 days for both indexes and calculate the means and standard deviations as shown in Exhibit 18.

Exhibit 18 Mean and Standard Deviations for the ACE High Yield Index and the ACE BBB Index

	ACE High Yield Index (%)	ACE BBB Index (%)	Difference (%)
Mean return	0.0157	0.0135	−0.0021
Standard deviation	0.3157	0.3645	0.3622

Using a 5% level of significance, determine whether the mean of the differences is different from zero.

Solution

Step 1	State the hypotheses.	H_0: $\mu_{d0} = 0$ versus H_a: $\mu_{d0} \neq 0$
Step 2	Identify the appropriate test statistic.	$t = \frac{\bar{d} - \mu_{d0}}{s_{\bar{d}}}$
Step 3	Specify the level of significance.	5%
Step 4	State the decision rule.	With 1,304 − 1 = 1,303 degrees of freedom, the critical values are ±1.962. We reject the null hypothesis if the calculated *t*-statistic is less than −1.962 or greater than +1.962. **Excel** *Lower:* T.INV(0.025,1303) *Upper:* T.INV(0.975,1303) **R** qt(c(.025,.975),1303) **Python** from scipy.stats import t *Lower:* t.ppf(.025,1303) *Upper:* t.ppf(.975,1303)
Step 5	Calculate the test statistic.	$\bar{d} = -0.0021\%$ $s_{\bar{d}} = \frac{s_d}{\sqrt{n}} = \frac{0.3622}{\sqrt{1,304}} = 0.01003\%$ $t = \frac{-0.00210 - 0}{0.01003} = -0.20937$
Step 6	Make a decision.	Fail to reject the null hypothesis because the calculated *t*-statistic falls within the bounds of the two critical values. There is insufficient evidence to indicate that the mean of the differences of returns is different from zero.

12 TESTING CONCERNING TESTS OF VARIANCES (CHI-SQUARE TEST)

j identify the appropriate test statistic and interpret the results for a hypothesis test concerning (1) the variance of a normally distributed population and (2) the equality of the variances of two normally distributed populations based on two independent random samples

Often, we are interested in the volatility of returns or prices, and one approach to examining volatility is to evaluate variances. We examine two types of tests involving variance: tests concerning the value of a single population variance and tests concerning the difference between two population variances.

12.1 Tests of a Single Variance

Suppose there is a goal to keep the variance of a fund's returns below a specified target. In this case, we would want to compare the observed sample variance of the fund with the target. Performing a test of a population variance requires specifying the hypothesized value of the variance, σ_0^2 . We can formulate hypotheses concerning whether the variance is equal to a specific value or whether it is greater than or less than a hypothesized value:

Two-sided alternative: $H_0 : \sigma^2 = \sigma_0^2$ versus $H_a : \sigma^2 \neq \sigma_0^2$

One-sided alternative (right tail): $H_0 : \sigma^2 \leq \sigma_0^2$ versus $H_a : \sigma^2 > \sigma_0^2$

One-sided alternative (left tail): $H_0 : \sigma^2 \geq \sigma_0^2$ versus $H_a : \sigma^2 < \sigma_0^2$

In tests concerning the variance of a single normally distributed population, we make use of a chi-square test statistic, denoted χ^2. The chi-square distribution, unlike the normal distribution and *t*-distribution, is asymmetrical. Like the *t*-distribution, the chi-square distribution is a family of distributions, with a different distribution for each possible value of degrees of freedom, $n - 1$ (n is sample size). Unlike the *t*-distribution, the chi-square distribution is bounded below by zero; χ^2 does not take on negative values.

If we have n independent observations from a normally distributed population, the appropriate test statistic is

$$\chi^2 = \frac{(n-1)s^2}{\sigma_0^2} \tag{8}$$

with $n - 1$ degrees of freedom. The sample variance (s^2) is in the numerator, and the hypothesized variance (σ_0^2) is in the denominator.

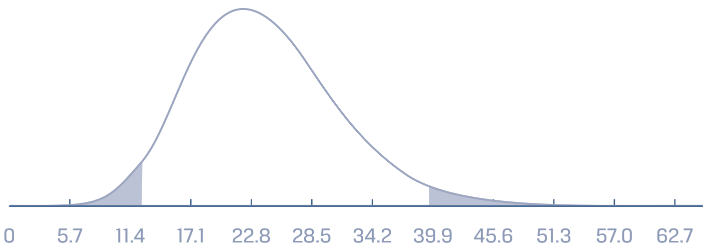
In contrast to the *t*-test, for example, the chi-square test is sensitive to violations of its assumptions. If the sample is not random or if it does not come from a normally distributed population, inferences based on a chi-square test are likely to be faulty.

Since the chi-square distribution is asymmetric and bounded below by zero, we no longer have the convenient ± for critical values as we have with the *z*- and the *t*-distributions, so we must either use a table of chi-square values or use software to generate the critical values. Consider a sample of 25 observations, so we have 24 degrees of freedom. We illustrate the rejection regions for the two- and one-sided tests at the 5% significance level in Exhibit 19.

Exhibit 19 Rejection Regions (Shaded) for the Chi-Square Distribution (df = 24) at 5% Significance

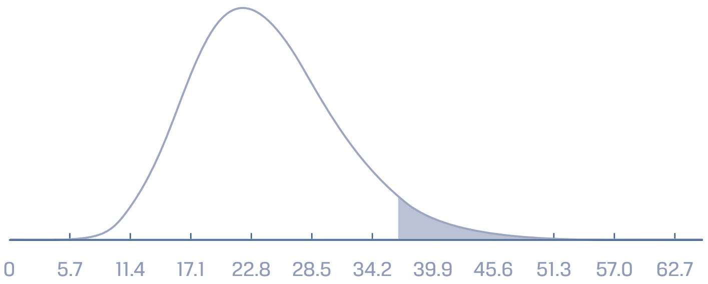
A. H_0: $\sigma^2 = \sigma_0^2$ versus H_a: $\sigma^2 \neq \sigma_0^2$

Critical values are 12.40115 and 39.36408



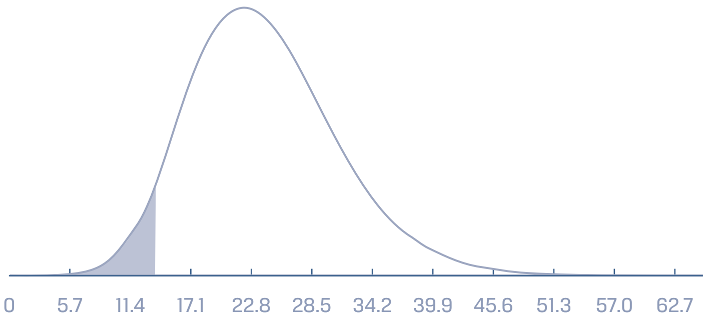
B. H_0: $\sigma^2 \leq \sigma_0^2$ versus H_a: $\sigma^2 > \sigma_0^2$

Critical value is 36.41503



C. H_0: $\sigma^2 \geq \sigma_0^2$ versus H_a: $\sigma^2 < \sigma_0^2$

Critical value is 13.84843



EXAMPLE 12

Risk and Return Characteristics of an Equity Mutual Fund

You continue with your analysis of Sendar Equity Fund, a midcap growth fund that has been in existence for only 24 months. During this period, Sendar Equity achieved a mean monthly return of 1.50% and a standard deviation of monthly returns of 3.60%.

1 Using a 5% level of significance, test whether the standard deviation of returns is different from 4%.

2 Using a 5% level of significance, test whether the standard deviation of returns is less than 4%.

Solution to 1

Step 1 State the hypotheses. H_0: $\sigma^2 = 16$ versus H_a: $\sigma^2 \neq 16$

Step 2 Identify the appropriate test statistic.

$$\chi^2 = \frac{(n-1)s^2}{\sigma_0^2}$$

Step 3 Specify the level of significance. 5%

Step 4 State the decision rule. With 24 – 1 = 23 degrees of freedom, the critical values are 11.68855 and 38.07563.

We reject the null hypothesis if the calculated χ^2 statistic is less than 11.68855 or greater than 38.07563.

Excel

Lower: CHISQ.INV(0.025,23)

Upper: CHISQ.INV(0.975,23)

R qchisq(c(.025,.975),23)

Python from scipy.stats import chi2

Lower: chi2.ppf(.025,23)

Upper: chi2.ppf(.975,23)

Step 5 Calculate the test statistic.

$$\chi^2 = \frac{(24-1)12.96}{16} = 18.63000$$

Step 6 Make a decision Fail to reject the null hypothesis because the calculated χ^2 statistic falls within the bounds of the two critical values. There is insufficient evidence to indicate that the variance is different from 16% (or, equivalently, that the standard deviation is different from 4%).

Solution to 2:

Step 1 State the hypotheses. H_0: $\sigma^2 \geq 16$ versus H_a: $\sigma^2 < 16$

Step 2 Identify the appropriate test statistic.

$$\chi^2 = \frac{(n-1)s^2}{\sigma_0^2}$$

Step 3 Specify the level of significance. 5%

Step 4 State the decision rule. With 24 – 1 = 23 degrees of freedom, the critical value is 13.09051.

We reject the null hypothesis if the calculated χ^2 statistic is less than 13.09051.

Excel CHISQ.INV(0.05,23)

R qchisq(.05,23)

Python from scipy.stats import chi2

chi2.ppf(.05,23)

Step 5 Calculate the test statistic.

$$\chi^2 = \frac{(24-1)12.96}{16} = 18.63000$$

Step 6 Make a decision.

Fail to reject the null hypothesis because the calculated χ^2 statistic is greater than the critical value. There is insufficient evidence to indicate that the variance is less than 16% (or, equivalently, that the standard deviation is less than 4%).

12.2 Test Concerning the Equality of Two Variances (*F*-Test)

j identify the appropriate test statistic and interpret the results for a hypothesis test concerning (1) the variance of a normally distributed population and (2) the equality of the variances of two normally distributed populations based on two independent random samples

There are many instances in which we want to compare the volatility of two samples, in which case we can test for the equality of two variances. Examples include comparisons of baskets of securities against indexes or benchmarks, as well as comparisons of volatility in different periods. Suppose we have a hypothesis about the relative values of the variances of two normally distributed populations with variances of σ_1^2 and σ_2^2, distinguishing the two populations as 1 or 2. We can formulate the hypotheses as two sided or one sided:

Two-sided alternative:

$$H_0 : \sigma_1^2 = \sigma_2^2 \text{ versus } H_a : \sigma_1^2 \neq \sigma_2^2$$

or, equivalently,

$$H_0 : \frac{\sigma_1^2}{\sigma_2^2} = 1 \text{ versus } H_a : \frac{\sigma_1^2}{\sigma_2^2} \neq 1$$

One-sided alternative (right side):

$$H_0 : \sigma_1^2 \leq \sigma_2^2 \text{ versus } H_a : \sigma_1^2 > \sigma_2^2$$

or, equivalently,

$$H_0 : \frac{\sigma_1^2}{\sigma_2^2} \leq 1 \text{ versus } H_a : \frac{\sigma_1^2}{\sigma_2^2} > 1$$

One-sided alternative (left side):

$$H_0 : \sigma_1^2 \geq \sigma_2^2 \text{ versus } H_a : \sigma_1^2 < \sigma_2^2$$

or, equivalently,

$$H_0 : \frac{\sigma_1^2}{\sigma_2^2} \geq 1 \text{ versus } H_a : \frac{\sigma_1^2}{\sigma_2^2} < 1$$

Given independent random samples from these populations, tests related to these hypotheses are based on an *F*-test, which is the ratio of sample variances. Tests concerning the difference between the variances of two populations make use of the *F*-distribution. Like the chi-square distribution, the *F*-distribution is a family of asymmetrical distributions bounded from below by zero. Each *F*-distribution is defined by two values of degrees of freedom, which we refer to as the numerator and denominator degrees of freedom. The *F*-test, like the chi-square test, is not robust to violations of its assumptions.

Suppose we have two samples, the first with n_1 observations and a sample variance s_1^2 and the second with n_2 observations and a sample variance s_2^2. The samples are random, independent of each other, and generated by normally distributed populations. A test concerning differences between the variances of the two populations is based on the ratio of sample variances, as follows:

$$F = \frac{s_1^2}{s_2^2} \tag{9}$$

with $\text{df}_1 = (n_1 - 1)$ numerator degrees of freedom and $\text{df}_2 = (n_2 - 1)$ denominator degrees of freedom. Note that df_1 and df_2 are the divisors used in calculating s_1^2 and s_2^2, respectively.

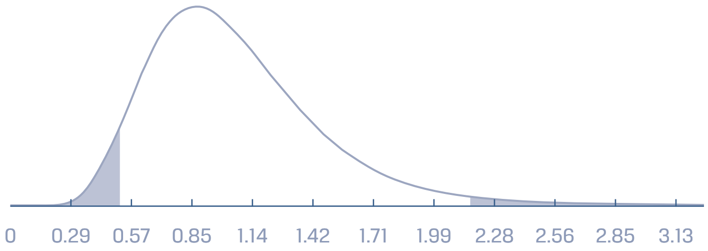
When we rely on tables to arrive at critical values, a convention is to use the larger of the two sample variances in the numerator in Equation 9; doing so reduces the number of *F*-tables needed. The key is to be consistent with how the alternative hypothesis is specified and the order of the sample sizes for the degrees of freedom.

Consider two samples, the first with 25 observations and the second with 40 observations. We show the rejection region and critical values in Exhibit 20 for two- and one-sided alternative hypotheses at the 5% significance level.

Exhibit 20 **Rejection Regions (Shaded) for the *F*-Distribution Based on Sample Sizes of 25 and 40 at 5% Significance**

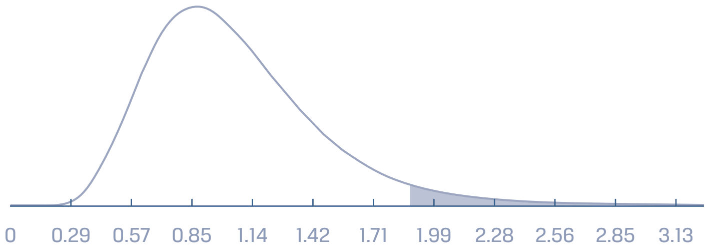
A. H_0: $\sigma_1^2 = \sigma_2^2$ versus H_a: $\sigma_1^2 \neq \sigma_2^2$

Critical values are 0.49587 and 2.15095



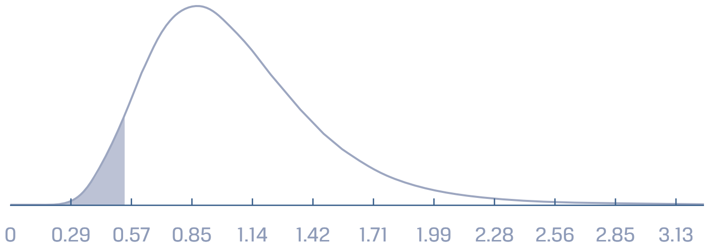
B. H_0: $\sigma_1^2 \leq \sigma_2^2$ versus H_a: $\sigma_1^2 > \sigma_2^2$

Critical value is 1.89566



C. H_0: $\sigma_1^2 \geq \sigma_2^2$ versus H_a: $\sigma_1^2 < \sigma_2^2$

Critical value is 0.55551



Consider Investments One and Two (from Exhibit 1), with standard deviations of returns of 1.4284 and 2.5914, respectively, calculated over the 33-year period. If we want to know whether the variance of Investment One is different from that of Investment Two, we use the *F*-distributed test statistic. With 32 and 32 degrees of freedom, the critical values are 0.49389 and 2.02475 at the 5% significance level. The calculated *F*-statistic is

$$F = \frac{2.5914^2}{1.4284^2} = 3.29131.$$

Therefore, we reject the null hypothesis that the variances of these two investments are the same because the calculated *F*-statistic is outside of the critical values. We can conclude that one investment is riskier than the other.

EXAMPLE 13

Volatility and Regulation

You are investigating whether the population variance of returns on a stock market index changed after a change in market regulation. The first 418 weeks occurred before the regulation change, and the second 418 weeks occurred after the regulation change. You gather the data in Exhibit 21 for 418 weeks of returns both before and after the change in regulation. You have specified a 5% level of significance.

Exhibit 21 Index Returns and Variances before and after the Market Regulation Change

	n	Mean Weekly Return (%)	Variance of Returns
Before regulation change	418	0.250	4.644
After regulation change	418	0.110	3.919

1. Test whether the variance of returns is different before the regulation change versus after the regulation change, using a 5% level of significance.
2. Test whether the variance of returns is greater before the regulation change versus after the regulation change, using a 5% level of significance.

Solution to 1

Step 1	State the hypotheses.	$H_0: \sigma^2_{Before} = \sigma^2_{After}$ versus $H_a: \sigma^2_{Before} \neq \sigma^2_{After}$
Step 2	Identify the appropriate test statistic.	$F = \dfrac{s^2_{Before}}{s^2_{After}}$
Step 3	Specify the level of significance.	5%
Step 4	State the decision rule.	With 418 − 1 = 417 and 418 − 1 = 417 degrees of freedom, the critical values are 0.82512 and 1.21194. Reject the null if the calculated *F*-statistic is less than 0.82512 or greater than 1.21194.

Excel

Left side: F.INV(0.025,417,417)

Right side: F.INV(0.975,417,417)

R qf(c(.025,.975),417,417)

Python from scipy.stats import f

Left side: f.ppf(.025,417,417)

Right side: f.ppf(.975,417,417)

Step 5 Calculate the test statistic.

$$F = \frac{4.644}{3.919} = 1.18500$$

Step 6 Make a decision.

Fail to reject the null hypothesis since the calculated *F*-statistic falls within the bounds of the two critical values. There is not sufficient evidence to indicate that the weekly variances of returns are different in the periods before and after the regulation change.

Solution to 2

Step 1 State the hypotheses.

$$H_0 : \sigma^2_{Before} \leq \sigma^2_{After} \text{ versus } H_a : \sigma^2_{Before} > \sigma^2_{After}$$

Step 2 Identify the appropriate test statistic.

$$F = \frac{s^2_{Before}}{s^2_{After}}$$

Step 3 Specify the level of significance.

5%

Step 4 State the decision rule.

With 418 − 1 = 417 and 418 − 1 = 417 degrees of freedom, the critical value is 1.17502.

We reject the null hypothesis if the calculated *F*-statistic is greater than 1.17502.

Excel F.INV(0.95,417,417)

R qf(.95,417,417)

Python from scipy.stats import f

f.ppf(.95,417,417)

Step 5 Calculate the test statistic.

$$F = \frac{4.644}{3.919} = 1.18500$$

Step 6 Make a decision.

Reject the null hypothesis since the calculated *F*-statistic is greater than 1.17502. There is sufficient evidence to indicate that the weekly variances of returns before the regulation change are greater than the variances after the regulation change.

EXAMPLE 14

The Volatility of Derivatives Expiration Days

You are interested in investigating whether quadruple witching days—that is, the occurrence of stock option, index option, index futures, and single stock futures expirations on the same day—exhibit greater volatility than normal trading days. Exhibit 22 presents the daily standard deviation of returns for normal trading days and quadruple witching days during a four-year period.

Exhibit 22 Standard Deviation of Returns: Normal Trading Days and Derivatives Expiration Days

Period	Type of Day	*n*	Standard Deviation (%)
1	Normal trading days	138	0.821
2	Quadruple witching days	16	1.217

Test to determine whether the variance of returns for quadruple witching days is greater than the variance for non-expiration, normal trading days. Use a 5% level of significance.

Solution

Step 1	State the hypotheses.	$H_0: \sigma^2_{Period2} \leq \sigma^2_{Period1}$ versus $H_a: \sigma^2_{Period2} > \sigma^2_{Period1}$
Step 2	Identify the appropriate test statistic.	$F = \frac{s^2_{Period2}}{s^2_{Period1}}$
Step 3	Specify the level of significance.	5%
Step 4	State the decision rule.	With 16 − 1 = 15 and 138 − 1 = 137 degrees of freedom, the critical value is 1.73997. We reject the null hypothesis if the calculated *F*-statistic is greater than 1.73997. **Excel** F.INV(0.95,15,137) **R** qf(.95,15,137) **Python** from scipy.stats import f f.ppf(.95,15,137)
Step 5	Calculate the test statistic.	$F = \frac{1.48109}{0.67404} = 2.19733$
Step 6	Make a decision.	Reject the null hypothesis since the calculated *F*-statistic is greater than 1.73997. There is sufficient evidence to indicate that the variance of returns for quadruple witching days is greater than the variance for normal trading days.

13 PARAMETRIC VS. NONPARAMETRIC TESTS

k compare and contrast parametric and nonparametric tests, and describe situations where each is the more appropriate type of test

The hypothesis-testing procedures we have discussed up to this point have two characteristics in common. First, they are concerned with parameters, and second, their validity depends on a definite set of assumptions. Mean and variance, for example, are two parameters, or defining quantities, of a normal distribution. The tests also make specific assumptions—in particular, assumptions about the distribution of the population producing the sample. Any test or procedure with either of these two characteristics is a **parametric test** or procedure. In some cases, however, we are concerned about quantities other than parameters of distributions. In other cases, we may believe that the assumptions of parametric tests do not hold. In cases where we are examining quantities other than population parameters or where assumptions of the parameters are not satisfied, a nonparametric test or procedure can be useful.

A **nonparametric test** is a test that is not concerned with a parameter or a test that makes minimal assumptions about the population from which the sample comes. In Exhibit 23, we give examples of nonparametric alternatives to the parametric, *t*-distributed tests concerning means.

Exhibit 23 Nonparametric Alternatives to Parametric Tests Concerning Means

	Parametric	Nonparametric
Tests concerning a single mean	*t*-distributed test *z*-distributed test	Wilcoxon signed-rank test
Tests concerning differences between means	*t*-distributed test	Mann–Whitney *U* test (Wilcoxon rank sum test)
Tests concerning mean differences (paired comparisons tests)	*t*-distributed test	Wilcoxon signed-rank test Sign test

13.1 Uses of Nonparametric Tests

We primarily use nonparametric procedures in four situations: (1) when the data we use do not meet distributional assumptions, (2) when there are outliers, (3) when the data are given in ranks or use an ordinal scale, or (4) when the hypotheses we are addressing do not concern a parameter.

The first situation occurs when the data available for analysis suggest that the distributional assumptions of the parametric test are not satisfied. For example, we may want to test a hypothesis concerning the mean of a population but believe that neither *t*- nor *z*-distributed tests are appropriate because the sample is small and may come from a markedly non-normally distributed population. In that case, we may use a nonparametric test. The nonparametric test will frequently involve the conversion of observations (or a function of observations) into ranks according to magnitude, and sometimes it will involve working with only "greater than" or "less than" relationships (using the + and − signs to denote those relationships). Characteristically, one must refer to specialized statistical tables to determine the rejection points of the test statistic, at least for small samples. Such tests, then, typically interpret the null hypothesis as a hypothesis about ranks or signs.

Second, whereas the underlying distribution of the population may be normal, there may be extreme values or outliers that influence the parametric statistics but not the nonparametric statistics. For example, we may want to use a nonparametric test of the median, in the case of outliers, instead of a test of the mean.

Third, we may have a sample in which observations are ranked. In those cases, we also use nonparametric tests because parametric tests generally require a stronger measurement scale than ranks. For example, if our data were the rankings of investment managers, we would use nonparametric procedures to test the hypotheses concerning those rankings.

A fourth situation in which we use nonparametric procedures occurs when our question does not concern a parameter. For example, if the question concerns whether a sample is random or not, we use the appropriate nonparametric test (a "runs test"). The nonparametric runs test is used to test whether stock price changes can be used to forecast future stock price changes—in other words, a test of the random-walk theory. Another type of question that nonparametric methods can address is whether a sample came from a population following a particular probability distribution.

13.2 Nonparametric Inference: Summary

Nonparametric statistical procedures extend the reach of inference because they make few assumptions, can be used on ranked data, and may address questions unrelated to parameters. Quite frequently, nonparametric tests are reported alongside parametric tests; the user can then assess how sensitive the statistical conclusion is to the assumptions underlying the parametric test. However, if the assumptions of the parametric test are met, the parametric test (where available) is generally preferred over the nonparametric test because the parametric test may have more power—that is, a greater ability to reject a false null hypothesis.

EXAMPLE 15

The Use of Nonparametric Tests

A nonparametric test is most appropriate when the:

A data consist of ranked values.

B validity of the test depends on many assumptions.

C sample sizes are large but are drawn from a population that may be non-normal.

Solution

A is correct. When the samples consist of ranked values, parametric tests are not appropriate. In such cases, nonparametric tests are most appropriate.

14 TESTS CONCERNING CORRELATION

l. explain parametric and nonparametric tests of the hypothesis that the population correlation coefficient equals zero, and determine whether the hypothesis is rejected at a given level of significance

In many contexts in investments, we want to assess the strength of the linear relationship between two variables; that is, we want to evaluate the **correlation** between them. A significance test of a correlation coefficient allows us to assess whether the relationship between two random variables is the result of chance. If we decide that the relationship does not result from chance, then we are inclined to use this information in modeling or forecasting.

If the correlation between two variables is zero, we conclude that there is no linear relation between the two variables. We use a test of significance to assess whether the correlation is different from zero. After we estimate a correlation coefficient, we need to ask whether the estimated correlation is significantly different from zero.

A correlation may be positive (that is, the two variables tend to move in the same direction at the same time) or negative (that is, the two variables tend to move in different directions at the same time). The correlation coefficient is a number between −1 and +1, where −1 denotes a perfect negative or inverse, straight-line relationship between the two variables; +1 denotes a perfect positive, straight-line relationship; and 0 represents the absence of any straight-line relationship (that is, no correlation).

The most common hypotheses concerning correlation occur when comparing the population correlation coefficient with zero because we are often asking whether there is a relationship, which implies a null of the correlation coefficient equal to zero (that is, no relationship). Hypotheses concerning the population correlation coefficient may be two or one sided, as we have seen in other tests. Let ρ represent the population correlation coefficient. The possible hypotheses are as follows:

Two sided: H_0: $\rho = 0$ versus H_a: $\rho \neq 0$

One sided (right side): H_0: $\rho \leq 0$ versus H_a: $\rho > 0$

One sided (left side): H_0: $\rho \geq 0$ versus H_a: $\rho < 0$

We use the sample correlation to test these hypotheses on the population correlation.

14.1 Parametric Test of a Correlation

The parametric pairwise correlation coefficient is often referred to as the **Pearson correlation**, the **bivariate correlation**, or simply the correlation. Our focus is on the testing of the correlation and not the actual calculation of this statistic, but it helps distinguish this correlation from the nonparametric correlation if we look at the formula for the sample correlation. Consider two variables, X and Y. The sample correlation, r_{XY}, is

$$r_{XY} = \frac{s_{XY}}{s_X s_Y},$$

where s_{XY} is the sample covariance between the X and Y variables, s_X is the standard deviation of the X variable, and s_Y is the standard deviation of the Y variable. We often drop the subscript to represent the correlation as simply r.

Therefore, you can see from this formula that each observation is compared with its respective variable mean and that, because of the covariance, it matters how much each observation differs from its respective variable mean. Note that the covariance drives the sign of the correlation.

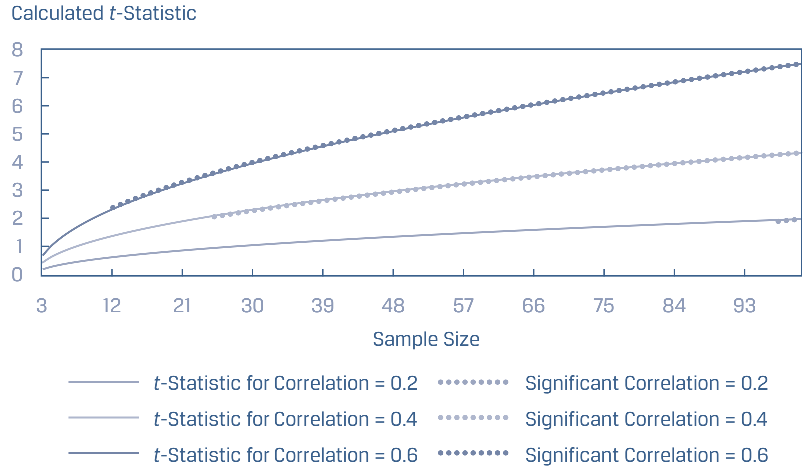
If the two variables are normally distributed, we can test to determine whether the null hypothesis (H_0: $\rho = 0$) should be rejected using the sample correlation, r. The formula for the t-test is

$$t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}. \tag{10}$$

This test statistic is t-distributed with $n - 2$ degrees of freedom. One practical observation concerning Equation 10 is that the magnitude of r needed to reject the null hypothesis decreases as sample size n increases, for two reasons. First, as n increases, the number of degrees of freedom increases and the absolute value of the critical value of the t-statistic decreases. Second, the absolute value of the numerator increases with larger n, resulting in a larger magnitude of the calculated t-statistic. For example, with sample size $n = 12$, $r = 0.35$ results in a t-statistic of 1.182, which is not different from zero at the 0.05 level ($t_{\alpha/2} = \pm 2.228$). With a sample size of $n = 32$, the same sample correlation, $r = 0.35$, yields a t-statistic of 2.046, which is just significant at the 0.05 level ($t_{\alpha/2} = \pm 2.042$).

Another way to make this point is that when sampling from the same population, a false null hypothesis is more likely to be rejected (that is, the power of the test increases) as we increase the sample size, all else equal, because a higher number of observations increases the numerator of the test statistic. We show this in Exhibit 24 for three different sample correlation coefficients, with the corresponding calculated t-statistics and significance at the 5% level for a two-sided alternative hypothesis. As the sample size increases, significance is more likely to be indicated, but the rate of achieving this significance depends on the sample correlation coefficient; the higher the sample correlation, the faster significance is achieved when increasing the sample size. As the sample sizes increase as ever-larger datasets are examined, the null hypothesis is almost always rejected and other tools of data analysis must be applied.

Exhibit 24 **Calculated Test Statistics for Different Sample Sizes and Sample Correlations with a 5% Level of Significance**



EXAMPLE 16

Examining the Relationship between Returns on Investment One and Investment Two

An analyst is examining the annual returns for Investment One and Investment Two, as displayed in Exhibit 1. Although this time series plot provides some useful information, the analyst is most interested in quantifying how the returns of these two series are related, so she calculates the correlation coefficient, equal to 0.43051, between these series.

Is there a significant positive correlation between these two return series if she uses a 1% level of significance?

Solution

Step 1	State the hypotheses.	$H_0 : \rho \leq 0$ versus $H_a : \rho > 0$
Step 2	Identify the appropriate test statistic.	$t = \dfrac{r\sqrt{n-2}}{\sqrt{1-r^2}}$
Step 3	Specify the level of significance.	1%
Step 4	State the decision rule	With 33 – 2 = 31 degrees of freedom and a one-sided test with a 1% level of significance, the critical value is 2.45282. We reject the null hypothesis if the calculated *t*-statistic is greater than 2.45282.
Step 5	Calculate the test statistic.	$t = \dfrac{0.43051\sqrt{33-2}}{\sqrt{1-0.18534}} = 2.65568$
Step 6	Make a decision	Reject the null hypothesis since the calculated *t*-statistic is greater than 2.45282. There is sufficient evidence to reject the H_0 in favor of H_a, that the correlation between the annual returns of these two investments is positive.

14.2 Tests Concerning Correlation: The Spearman Rank Correlation Coefficient

l. explain parametric and nonparametric tests of the hypothesis that the population correlation coefficient equals zero, and determine whether the hypothesis is rejected at a given level of significance

When we believe that the population under consideration meaningfully departs from normality, we can use a test based on the **Spearman rank correlation coefficient**, r_S. The Spearman rank correlation coefficient is essentially equivalent to the usual correlation coefficient but is calculated on the *ranks* of the two variables (say, X and Y) within their respective samples. The calculation of r_S requires the following steps:

1. Rank the observations on X from largest to smallest. Assign the number 1 to the observation with the largest value, the number 2 to the observation with second largest value, and so on. In case of ties, assign to each tied observation the average of the ranks that they jointly occupy. For example, if the third and fourth largest values are tied, we assign both observations the rank of 3.5 (the average of 3 and 4). Perform the same procedure for the observations on Y.
2. Calculate the difference, d_i, between the ranks for each pair of observations on X and Y, and then calculate d_i^2 (the squared difference in ranks).
3. With n as the sample size, the Spearman rank correlation is given by

$$r_s = 1 - \frac{6\sum_{i=1}^{n} d_i^2}{n(n^2 - 1)}. \tag{11}$$

Suppose an analyst is examining the relationship between returns for two investment funds, A and B, of similar risk over 35 years. She is concerned that the assumptions for the parametric correlation may not be met, so she decides to test Spearman rank correlations. Her hypotheses are H_0: $r_S = 0$ and H_a: $r_S \neq 0$. She gathers the returns, ranks the returns for each fund, and calculates the difference in ranks and the squared differences. A partial table is provided in Exhibit 25.

Exhibit 25 Differences and Squared Differences in Ranks for Fund A and Fund B over 35 Years

Year	Fund A	Fund B	Rank of A	Rank of B	*d*	*d*²
1	2.453	1.382	27	31	−4	16
2	3.017	3.110	24	24	0	0
3	4.495	6.587	19	7	12	144
4	3.627	3.300	23	23	0	0
.						
.						
.						
30	2.269	0.025	28	35	−7	49
31	6.354	4.428	10	19	−9	81
32	6.793	4.165	8	20	−12	144
33	7.300	7.623	5	5	0	0
34	6.266	4.527	11	18	−7	49

(continued)

Exhibit 25 (Continued)

Year	Fund A	Fund B	Rank of A	Rank of B	d	d^2
35	1.257	4.704	34	16	18	324
					Sum =	2,202

The Spearman rank correlation is:

$$r_s = 1 - \frac{6\sum_{i=1}^{n} d_i^2}{n(n^2 - 1)} = 1 - \frac{6(2,202)}{35(1,225 - 1)} = 0.6916.$$

The test of hypothesis for the Spearman rank correlation depends on whether the sample is small or large ($n > 30$). For small samples, the researcher requires a specialized table of critical values, but for large samples, we can conduct a t-test using the test statistic in Equation 10, which is t-distributed with $n - 2$ degrees of freedom.

In this example, for a two-tailed test with a 5% significance level, the critical values for $n - 2 = 35 - 2 = 33$ degrees of freedom are ±2.0345. For the sample information in Exhibit 24, the calculated test statistic is

$$t = \frac{0.6916\sqrt{33}}{\sqrt{1 - (0.6916^2)}} = 5.5005.$$

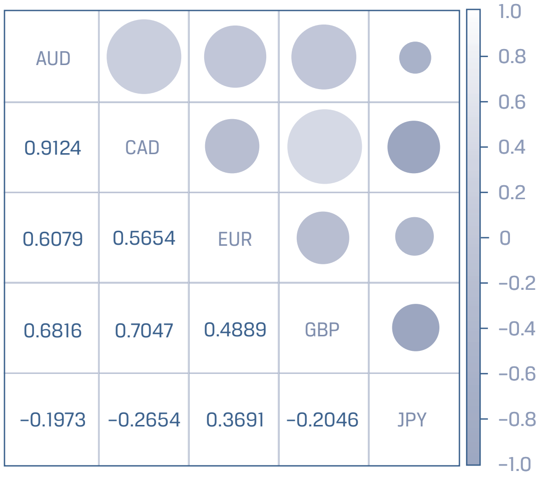
Accordingly, we reject the null hypothesis (H_0: $r_S = 0$), concluding that there is sufficient evidence to indicate that the correlation between the returns of Fund A and Fund B is different from zero.

EXAMPLE 17

Testing the Exchange Rate Correlation

An analyst gathers exchange rate data for five currencies relative to the US dollar. Upon inspection of the distribution of these exchange rates, she observes a departure from normality, especially with negative skewness for four of the series and positive skewness for the fifth. Therefore, she decides to examine the relationships among these currencies using Spearman rank correlations. She calculates these correlations between the currencies over 180 days, which are shown in the correlogram in Exhibit 26. In this correlogram, the lower triangle reports the pairwise correlations and the upper triangle provides a visualization of the magnitude of the correlations, with larger circles indicating larger absolute value of the correlations and darker circles indicating correlations that are negative.

Exhibit 26 **Spearman Rank Correlations between Exchanges Rates Relative to the US Dollar**



AUD				
0.9124	CAD			
0.6079	0.5654	EUR		
0.6816	0.7047	0.4889	GBP	
−0.1973	−0.2654	0.3691	−0.2046	JPY

For any of these pairwise Spearman rank correlations, can we reject the null hypothesis of no correlation (H_0: $r_S = 0$ and H_a: $r_S \neq 0$) at the 5% level of significance?

Solution

The critical t-values for 2.5% in each tail of the distribution are ±1.97338.

There are five exchange rates, so there are ${}_5C_2$, or 10, unique correlation pairs. Therefore, we need to calculate 10 t-statistics. For example, the correlation between EUR/USD and AUD/USD is 0.6079. The calculated t-statistic is $\frac{0.6079\sqrt{180-2}}{\sqrt{1-0.6079^2}} = \frac{8.11040}{0.79401} = 10.2144$. Repeating this t-statistic calculation for each pair of exchange rates yields the test statistics shown in Exhibit 27.

Exhibit 27 **Calculated Test Statistics for Test of Spearman Rank Correlations**

	AUD/USD	CAD/USD	EUR/USD	GBP/USD
CAD/USD	29.7409			
EUR/USD	10.2144	9.1455		
GBP/USD	12.4277	13.2513	7.4773	
JPY/USD	−2.6851	−3.6726	5.2985	−2.7887

The analyst should reject all 10 null hypotheses, because the calculated t-statistics for all exchange rate pairs fall outside the bounds of the two critical values. She should conclude that all the exchange rate pair correlations are different from zero at the 5% level.

15 TEST OF INDEPENDENCE USING CONTINGENCY TABLE DATA

m explain tests of independence based on contingency table data

When faced with categorical or discrete data, we cannot use the methods that we have discussed up to this point to test whether the classifications of such data are independent. Suppose we observe the following **frequency table** of 1,594 exchange-traded funds (ETFs) based on two classifications: size (that is, market capitalization) and investment type (value, growth, or blend), as shown in Exhibit 28. The classification of the investment type is discrete, so we cannot use correlation to assess the relationship between size and investment type.

Exhibit 28 Size and Investment Type Classifications of 1,594 ETFs

	Size Based on Market Capitalization			
Investment Type	**Small**	**Medium**	**Large**	**Total**
Value	50	110	343	503
Growth	42	122	202	366
Blend	56	149	520	725
Total	148	381	1,065	1,594

This table is referred to as a **contingency table** or a **two-way table** (because there are two classifications, or classes—size and investment type).

If we want to test whether there is a relationship between the size and investment type, we can perform a test of independence using a nonparametric test statistic that is chi-square distributed:

$$\chi^2 = \sum_{i=1}^{m} \frac{\left(O_{ij} - E_{ij}\right)^2}{E_{ij}}, \quad (12)$$

where

m = the number of cells in the table, which is the number of groups in the first class multiplied by the number of groups in the second class

O_{ij} = the number of observations in each cell of row i and column j (i.e., observed frequency)

E_{ij} = the expected number of observations in each cell of row i and column j, assuming independence (i.e., expected frequency)

This test statistic has $(r - 1)(c - 1)$ degrees of freedom, where r is the number of rows and c is the number of columns.

In Exhibit 28, size class has three groups (small, medium, and large) and investment type class has three groups (value, growth, and blend), so m is 9 (= 3 × 3). The number of ETFs in each cell (O_{ij}), the observed frequency, is given, so to calculate the chi-square test statistic, we need to estimate E_{ij}, the expected frequency, which is the number of ETFs we would expect to be in each cell if size and investment type are completely independent. The expected number of ETFs (E_{ij}) is calculated using

$$E_{ij} = \frac{(\text{Total row } i) \times (\text{Total column } j)}{\text{Overall total}}. \quad (13)$$

Consider one combination of size and investment type, small-cap value:

$$E_{ij} = \frac{503 \times 148}{1{,}594} = 46.703.$$

We repeat this calculation for each combination of size and investment type (i.e., m = 9 pairs) to arrive at the expected frequencies, shown in Panel A of Exhibit 29.

Next, we calculate $\frac{\left(O_{ij} - E_{ij}\right)^2}{E_{ij}}$, the squared difference between observed and expected frequencies scaled by expected frequency, for each cell as shown in Panel B of Exhibit 29. Finally, by summing the values of $\frac{\left(O_{ij} - E_{ij}\right)^2}{E_{ij}}$ for each of the m cells, we calculate the chi-square statistic as 32.08025.

Exhibit 29 Inputs to Chi-Square Test Statistic Calculation for 1,594 ETFs Assuming Independence of Size and Investment Type

A. Expected Frequency of ETFs by Size and Investment Type

	Size Based on Market Capitalization		
Investment Type	**Small**	**Medium**	**Large**
Value	46.703	120.228	336.070
Growth	33.982	87.482	244.536
Blend	67.315	173.290	484.395
Total	148.000	381.000	1,065.000

B. Scaled Squared Deviation for Each Combination of Size and Investment Type

	Size Based on Market Capitalization		
Investment Type	**Small**	**Medium**	**Large**
Value	0.233	0.870	0.143
Growth	1.892	13.620	7.399
Blend	1.902	3.405	2.617

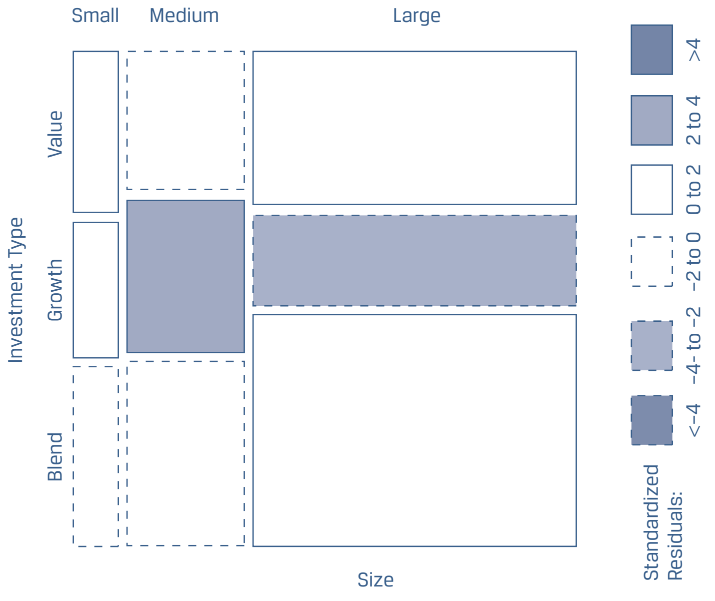
In our ETF example, we test the null hypothesis of independence between the two classes (i.e., no relationship between size and investment type) versus the alternative hypothesis of dependence (i.e., a relationship between size and investment type) using a 5% level of significance, as shown in Exhibit 30. If, on the one hand, the observed values are equal to the expected values, the calculated test statistic would be zero. If, on the other hand, there are differences between the observed and expected values, these differences are squared, so the calculated chi-square statistic will be positive. Therefore, for the test of independence using a contingency table, there is only one rejection region, on the right side.

Exhibit 30 Test of Independence of Size and Investment Type for 1,594 ETFs

Step 1	State the hypotheses.	H_0: ETF size and investment type are not related, so these classifications are independent; H_a : ETF size and investment type are related, so these classifications are not independent.
Step 2	Identify the appropriate test statistic.	$\chi^2 = \sum_{i=1}^{m} \frac{\left(O_{ij} - E_{ij}\right)^2}{E_{ij}}$
Step 3	Specify the level of significance.	5%
Step 4	State the decision rule.	With (3 – 1) × (3 – 1) = 4 degrees of freedom and a one-sided test with a 5% level of significance, the critical value is 9.4877. We reject the null hypothesis if the calculated χ^2 statistic is greater than 9.4877. **Excel** CHISQ.INV(0.95,4) **R** qchisq(.95,4) **Python** from scipy.stats import chi2 chi2.ppf(.95,4)
Step 5	Calculate the test statistic.	$\chi^2 = 32.08025$
Step 6	Make a decision.	Reject the null hypothesis of independence because the calculated χ^2 test statistic is greater than 9.4877. There is sufficient evidence to conclude that ETF size and investment type are related (i.e., not independent).

We can visualize the contingency table in a graphic referred to as a mosaic. In a mosaic, a grid reflects the comparison between the observed and expected frequencies. Consider Exhibit 31, which represents the ETF contingency table.

Exhibit 31 Mosaic of the ETF Contingency Table



The width of the rectangles in Exhibit 31 reflect the proportion of ETFs that are small, medium, and large, whereas the height reflects the proportion that are value, growth, and blend. The darker shading indicates whether there are more observations than expected under the null hypothesis of independence, whereas the lighter shading indicates that there are fewer observations than expected, with "more" and "fewer" determined by reference to the standardized residual boxes. The standardized residual, also referred to as a Pearson residual, is

$$\text{Standardized residual} = \frac{O_{ij} - E_{ij}}{\sqrt{E_{ij}}}. \quad (14)$$

The interpretation for this ETF example is that there are more medium-size growth ETFs (standardized residual of 3.69) and fewer large-size growth ETFs (standardized residual of –2.72) than would be expected if size and investment type were independent.

EXAMPLE 18

Using Contingency Tables to Test for Independence

Consider the contingency table in Exhibit 32, which classifies 500 randomly selected companies on the basis of two environmental, social, and governance (ESG) rating dimensions: environmental rating and governance rating.

Exhibit 32 Classification of 500 Randomly Selected Companies Based on Environmental and Governance Ratings

	Governance Rating			
Environmental Rating	**Progressive**	**Average**	**Poor**	**Total**
Progressive	35	40	5	80
Average	80	130	50	260
Poor	40	60	60	160
Total	155	230	115	500

1 What are the expected frequencies for these two ESG rating dimensions if these categories are independent?

2 Using a 5% level of significance, determine whether these two ESG rating dimensions are independent of one another.

Solution to 1

The expected frequencies based on independence of the governance rating and the environmental rating are shown in Panel A of Exhibit 33. For example, using Equation 12, the expected frequency for the combination of progressive governance and progressive environmental ratings is

$$E_{ij} = \frac{155 \times 80}{500} = 24.80.$$

Exhibit 33 Inputs to Chi-Square Test Statistic Calculation Assuming Independence of Environmental and Governance Ratings

A. Expected Frequencies of Environmental and Governance Ratings Assuming Independence

	Governance Rating		
Environmental Rating	**Progressive**	**Average**	**Poor**
Progressive	24.8	36.8	18.4
Average	80.6	119.6	59.8
Poor	49.6	73.6	36.8

B. Scaled Squared Deviation for Each Combination of Environmental and Governance Ratings

	Governance Rating		
Environmental Rating	**Progressive**	**Average**	**Poor**
Progressive	4.195	0.278	9.759
Average	0.004	0.904	1.606
Poor	1.858	2.513	14.626

Solution to 2

Step 1 State the hypotheses.

H_0: Governance and environmental ratings are not related, so these ratings are independent;
H_a: Governance and environmental ratings are related, so these ratings are not independent.

Step 2 Identify the appropriate test statistic.

$$\chi^2 = \sum_{i=1}^{m} \frac{\left(O_{ij} - E_{ij}\right)^2}{E_{ij}}$$

Step 3 Specify the level of significance.

5%

Step 4 State the decision rule.

With (3 − 1) × (3 − 1) = 4 degrees of freedom and a one-sided test with a 5% level of significance, the critical value is 9.487729.

We reject the null hypothesis if the calculated χ^2 statistic is greater than 9.487729.

Excel CHISQ.INV(0.95,4)

R qchisq(.95,4)

Python from scipy.stats import chi2
chi2.ppf(.95,4)

Step 5 Calculate the test statistic.

$\chi^2 = 35.74415$

To calculate the test statistic, we first calculate the squared difference between observed and expected frequencies scaled by expected frequency for each cell, as shown in Panel B of Exhibit 33. Then, summing the values in each of the *m* cells (see Equation 11), we calculate the chi-square statistic as 35.74415.

Step 6 Make a decision.

Reject the null hypothesis because the calculated χ^2 test statistic is greater than 9.487729. There is sufficient evidence to indicate that the environmental and governance ratings are related, so they are not independent.

SUMMARY

In this reading, we have presented the concepts and methods of statistical inference and hypothesis testing.

- A hypothesis is a statement about one or more populations.
- The steps in testing a hypothesis are as follows:
  1. State the hypotheses.
  2. Identify the appropriate test statistic and its probability distribution.
  3. Specify the significance level.
  4. State the decision rule.
  5. Collect the data and calculate the test statistic.
  6. Make a decision.
- We state two hypotheses: The null hypothesis is the hypothesis to be tested; the alternative hypothesis is the hypothesis accepted if the null hypothesis is rejected.
- There are three ways to formulate hypotheses. Let θ indicate the population parameters:
  1. Two-sided alternative: H_0: $\theta = \theta_0$ versus H_a: $\theta \neq \theta_0$
  2. One-sided alternative (right side): H_0: $\theta \leq \theta_0$ versus H_a: $\theta > \theta_0$
  3. One-sided alternative (left side): H_0: $\theta \geq \theta_0$ versus H_a: $\theta < \theta_0$

  where θ_0 is a hypothesized value of the population parameter and θ is the true value of the population parameter.
- When we have a "suspected" or "hoped for" condition for which we want to find supportive evidence, we frequently set up that condition as the alternative hypothesis and use a one-sided test. However, the researcher may select a "not equal to" alternative hypothesis and conduct a two-sided test to emphasize a neutral attitude.
- A test statistic is a quantity, calculated using a sample, whose value is the basis for deciding whether to reject or not reject the null hypothesis. We compare the computed value of the test statistic to a critical value for the same test statistic to decide whether to reject or not reject the null hypothesis.
- In reaching a statistical decision, we can make two possible errors: We may reject a true null hypothesis (a Type I error, or false positive), or we may fail to reject a false null hypothesis (a Type II error, or false negative).
- The level of significance of a test is the probability of a Type I error that we accept in conducting a hypothesis test. The standard approach to hypothesis testing involves specifying only a level of significance (that is, the probability of a Type I error). The complement of the level of significance is the confidence level.
- The power of a test is the probability of correctly rejecting the null (rejecting the null when it is false). The complement of the power of the test is the probability of a Type II error.
- A decision rule consists of determining the critical values with which to compare the test statistic to decide whether to reject or not reject the null hypothesis. When we reject the null hypothesis, the result is said to be statistically significant.
- The $(1 - \alpha)$ confidence interval represents the range of values of the test statistic for which the null hypothesis is not be rejected.

- The statistical decision consists of rejecting or not rejecting the null hypothesis. The economic decision takes into consideration all economic issues pertinent to the decision.
- The *p*-value is the smallest level of significance at which the null hypothesis can be rejected. The smaller the *p*-value, the stronger the evidence against the null hypothesis and in favor of the alternative hypothesis. The *p*-value approach to hypothesis testing involves computing a *p*-value for the test statistic and allowing the user of the research to interpret the implications for the null hypothesis.
- For hypothesis tests concerning the population mean of a normally distributed population with unknown variance, the theoretically correct test statistic is the *t*-statistic.
- When we want to test whether the observed difference between two means is statistically significant, we must first decide whether the samples are independent or dependent (related). If the samples are independent, we conduct a test concerning differences between means. If the samples are dependent, we conduct a test of mean differences (paired comparisons test).
- When we conduct a test of the difference between two population means from normally distributed populations with unknown but equal variances, we use a *t*-test based on pooling the observations of the two samples to estimate the common but unknown variance. This test is based on an assumption of independent samples.
- In tests concerning two means based on two samples that are not independent, we often can arrange the data in paired observations and conduct a test of mean differences (a paired comparisons test). When the samples are from normally distributed populations with unknown variances, the appropriate test statistic is *t*-distributed.
- In tests concerning the variance of a single normally distributed population, the test statistic is chi-square with $n - 1$ degrees of freedom, where n is sample size.
- For tests concerning differences between the variances of two normally distributed populations based on two random, independent samples, the appropriate test statistic is based on an *F*-test (the ratio of the sample variances). The degrees of freedom for this *F*-test are $n_1 - 1$ and $n_2 - 1$, where n_1 corresponds to the number of observations in the calculation of the numerator and n_2 is the number of observations in the calculation of the denominator of the *F*-statistic.
- A parametric test is a hypothesis test concerning a population parameter or a hypothesis test based on specific distributional assumptions. In contrast, a nonparametric test either is not concerned with a parameter or makes minimal assumptions about the population from which the sample comes.
- A nonparametric test is primarily used when data do not meet distributional assumptions, when there are outliers, when data are given in ranks, or when the hypothesis we are addressing does not concern a parameter.
- In tests concerning correlation, we use a *t*-statistic to test whether a population correlation coefficient is different from zero. If we have n observations for two variables, this test statistic has a *t*-distribution with $n - 2$ degrees of freedom.
- The Spearman rank correlation coefficient is calculated on the ranks of two variables within their respective samples.
- A chi-square distributed test statistic is used to test for independence of two categorical variables. This nonparametric test compares actual frequencies with those expected on the basis of independence. This test statistic has degrees of freedom of $(r - 1)(c - 2)$, where r is the number of categories for the first variable and c is the number of categories of the second variable.

Benjamini, Y., and Y. Hochberg. 1995. “Controlling the False Discovery Rate: A Practical and Powerful Approach to Multiple Testing.” *Journal of the Royal Statistical Society. Series B. Methodological* 57:289–300.

PRACTICE PROBLEMS

1 Which of the following statements about hypothesis testing is correct?

A The null hypothesis is the condition a researcher hopes to support.

B The alternative hypothesis is the proposition considered true without conclusive evidence to the contrary.

C The alternative hypothesis exhausts all potential parameter values not accounted for by the null hypothesis.

2 Identify the appropriate test statistic or statistics for conducting the following hypothesis tests. (Clearly identify the test statistic and, if applicable, the number of degrees of freedom. For example, "We conduct the test using an *x*-statistic with *y* degrees of freedom.")

A H_0: $\mu = 0$ versus H_a: $\mu \neq 0$, where μ is the mean of a normally distributed population with unknown variance. The test is based on a sample of 15 observations.

B H_0: $\mu = 5$ versus H_a: $\mu \neq 5$, where μ is the mean of a normally distributed population with unknown variance. The test is based on a sample of 40 observations.

C H_0: $\mu \leq 0$ versus H_a: $\mu > 0$, where μ is the mean of a normally distributed population with known variance σ^2. The sample size is 45.

D H_0: $\sigma^2 = 200$ versus H_a: $\sigma^2 \neq 200$, where σ^2 is the variance of a normally distributed population. The sample size is 50.

E $H_0 : \sigma_1^2 = \sigma_2^2$ versus $H_a : \sigma_1^2 \neq \sigma_2^2$, where σ_1^2 is the variance of one normally distributed population and σ_2^2 is the variance of a second normally distributed population. The test is based on two independent samples, with the first sample of size 30 and the second sample of size 40.

F H_0: $\mu_1 - \mu_2 = 0$ versus H_a: $\mu_1 - \mu_2 \neq 0$, where the samples are drawn from normally distributed populations with unknown but assumed equal variances. The observations in the two samples (of size 25 and 30, respectively) are independent.

3 For each of the following hypothesis tests concerning the population mean, μ, state the conclusion regarding the test of the hypotheses.

A H_0: $\mu = 10$ versus H_a: $\mu \neq 10$, with a calculated *t*-statistic of 2.05 and critical *t*-values of ±1.984.

B H_0: $\mu \leq 10$ versus H_a: $\mu > 10$, with a calculated *t*-statistic of 2.35 and a critical *t*-value of +1.679

C H_0: $\mu = 10$ versus H_a: $\mu \neq 10$, with a calculated *t*-statistic of 2.05, a *p*-value of 4.6352%, and a level of significance of 5%.

D H_0: $\mu \leq 10$ versus H_a: $\mu > 10$, with a 2% level of significance and a calculated test statistic with a *p*-value of 3%.

4 For each of the following hypothesis tests concerning the population mean, state the conclusion.

A H_0: $\sigma^2 = 0.10$ versus H_a: $\sigma^2 \neq 0.10$, with a calculated chi-square test statistic of 45.8 and critical chi-square values of 42.950 and 86.830.

B H_0: $\sigma^2 = 0.10$ versus H_a: $\sigma^2 \neq 0.10$, with a 5% level of significance and a *p*-value for this calculated chi-square test statistic of 4.463%.

© 2021 CFA Institute. All rights reserved.

C H_0: $\sigma_1{}^2 = \sigma_2{}^2$ versus H_a: $\sigma_1{}^2 \neq \sigma_2{}^2$, with a calculated F-statistic of 2.3. With 40 and 30 degrees of freedom, the critical F-values are 0.498 and 1.943.

D H_0: $\sigma^2 \leq 10$ versus H_a: $\mu\sigma^2 > 10$, with a calculated test statistic of 32 and a critical chi-square value of 26.296.

5 Willco is a manufacturer in a mature cyclical industry. During the most recent industry cycle, its net income averaged \$30 million per year with a standard deviation of \$10 million ($n = 6$ observations). Management claims that Willco's performance during the most recent cycle results from new approaches and that Willco's profitability will exceed the \$24 million per year observed in prior cycles.

A With μ as the population value of mean annual net income, formulate null and alternative hypotheses consistent with testing Willco management's claim.

B Assuming that Willco's net income is at least approximately normally distributed, identify the appropriate test statistic and calculate the degrees of freedom.

C Based on critical value of 2.015, determine whether to reject the null hypothesis.

The following information relates to Questions 6–7

Performance in Forecasting Quarterly Earnings per Share

	Number of Forecasts	Mean Forecast Error (Predicted – Actual)	Standard Deviation of Forecast Errors
Analyst A	10	0.05	0.10
Analyst B	15	0.02	0.09

Critical t-values:

	Area in the Right-Side Rejection Area	
Degrees of Freedom	$p = 0.05$	$p = 0.025$
8	1.860	2.306
9	1.833	2.262
10	1.812	2.228
11	1.796	2.201
12	1.782	2.179
13	1.771	2.160
14	1.761	2.145
15	1.753	2.131
16	1.746	2.120
17	1.740	2.110
18	1.734	2.101
19	1.729	2.093
20	1.725	2.086
21	1.721	2.080

(continued)

26	1.706	2.056
27	1.703	2.052

6 Investment analysts often use earnings per share (EPS) forecasts. One test of forecasting quality is the zero-mean test, which states that optimal forecasts should have a mean forecasting error of zero. The forecasting error is the difference between the predicted value of a variable and the actual value of the variable.

You have collected data (shown in the previous table) for two analysts who cover two different industries: Analyst A covers the telecom industry; Analyst B covers automotive parts and suppliers.

A With μ as the population mean forecasting error, formulate null and alternative hypotheses for a zero-mean test of forecasting quality.

B For Analyst A, determine whether to reject the null at the 0.05 level of significance.

C For Analyst B, determine whether to reject the null at the 0.05 level of significance.

7 Reviewing the EPS forecasting performance data for Analysts A and B, you want to investigate whether the larger average forecast errors of Analyst A relative to Analyst B are due to chance or to a higher underlying mean value for Analyst A. Assume that the forecast errors of both analysts are normally distributed and that the samples are independent.

A Formulate null and alternative hypotheses consistent with determining whether the population mean value of Analyst A's forecast errors (μ_1) are larger than Analyst B's (μ_2).

B Identify the test statistic for conducting a test of the null hypothesis formulated in Part A.

C Identify the rejection point or points for the hypotheses tested in Part A at the 0.05 level of significance.

D Determine whether to reject the null hypothesis at the 0.05 level of significance.

---

8 The following table gives data on the monthly returns on the S&P 500 Index and small-cap stocks for a 40-year period and provides statistics relating to their mean differences. Further, the entire sample period is split into two subperiods of 20 years each, and the return data for these subperiods is also given in the table.

Measure	S&P 500 Return (%)	Small-Cap Stock Return (%)	Differences (S&P 500 – Small-Cap Stock)
Entire sample period, 480 months			
Mean	1.0542	1.3117	–0.258
Standard deviation	4.2185	5.9570	3.752
First subperiod, 240 months			
Mean	0.6345	1.2741	–0.640
Standard deviation	4.0807	6.5829	4.096
Second subperiod, 240 months			
Mean	1.4739	1.3492	0.125
Standard deviation	4.3197	5.2709	3.339

Use a significance level of 0.05 and assume that mean differences are approximately normally distributed.

A Formulate null and alternative hypotheses consistent with testing whether any difference exists between the mean returns on the S&P 500 and small-cap stocks.

B Determine whether to reject the null hypothesis for the entire sample period if the critical values are ±1.96.

C Determine whether to reject the null hypothesis for the first subperiod if the critical values are ±1.96.

D Determine whether to reject the null hypothesis for the second subperiod if the critical values are ±1.96.

9 During a 10-year period, the standard deviation of annual returns on a portfolio you are analyzing was 15% a year. You want to see whether this record is sufficient evidence to support the conclusion that the portfolio's underlying variance of return was less than 400, the return variance of the portfolio's benchmark.

A Formulate null and alternative hypotheses consistent with your objective.

B Identify the test statistic for conducting a test of the hypotheses in Part A, and calculate the degrees of freedom.

C Determine whether the null hypothesis is rejected or not rejected at the 0.05 level of significance using a critical value of 3.325.

10 You are investigating whether the population variance of returns on an index changed subsequent to a market disruption. You gather the following data for 120 months of returns before the disruption and for 120 months of returns after the disruption. You have specified a 0.05 level of significance.

Time Period	*n*	Mean Monthly Return (%)	Variance of Returns
Before disruption	120	1.416	22.367
After disruption	120	1.436	15.795

A Formulate null and alternative hypotheses consistent with the research goal.

B Identify the test statistic for conducting a test of the hypotheses in Part A, and calculate the degrees of freedom.

C Determine whether to reject the null hypothesis at the 0.05 level of significance if the critical values are 0.6969 and 1.4349.

11 The following table shows the sample correlations between the monthly returns for four different mutual funds and the S&P 500. The correlations are based on 36 monthly observations. The funds are as follows:

Fund 1	Large-cap fund
Fund 2	Mid-cap fund
Fund 3	Large-cap value fund
Fund 4	Emerging market fund
S&P 500	US domestic stock index

	Fund 1	**Fund 2**	**Fund 3**	**Fund 4**	**S&P 500**
Fund 1	1				
Fund 2	0.9231	1			
Fund 3	0.4771	0.4156	1		
Fund 4	0.7111	0.7238	0.3102	1	
S&P 500	0.8277	0.8223	0.5791	0.7515	1

Test the null hypothesis that each of these correlations, individually, is equal to zero against the alternative hypothesis that it is not equal to zero. Use a 5% significance level and critical t-values of ±2.032.

12 In the step "stating a decision rule" in testing a hypothesis, which of the following elements must be specified?

A Critical value

B Power of a test

C Value of a test statistic

13 Which of the following statements is correct with respect to the null hypothesis?

A It can be stated as "not equal to" provided the alternative hypothesis is stated as "equal to."

B Along with the alternative hypothesis, it considers all possible values of the population parameter.

C In a two-tailed test, it is rejected when evidence supports equality between the hypothesized value and the population parameter.

14 An analyst is examining a large sample with an unknown population variance. Which of the following is the *most* appropriate test to test the hypothesis that the historical average return on an index is less than or equal to 6%?

A One-sided t-test

B Two-sided t-test

C One-sided chi-square test

15 A hypothesis test for a normally distributed population at a 0.05 significance level implies a:

A 95% probability of rejecting a true null hypothesis.

B 95% probability of a Type I error for a two-tailed test.

C 5% critical value rejection region in a tail of the distribution for a one-tailed test.

16 Which of the following statements regarding a one-tailed hypothesis test is correct?

- **A** The rejection region increases in size as the level of significance becomes smaller.
- **B** A one-tailed test more strongly reflects the beliefs of the researcher than a two-tailed test.
- **C** The absolute value of the rejection point is larger than that of a two-tailed test at the same level of significance.

17 The value of a test statistic is *best* described as the basis for deciding whether to:

- **A** reject the null hypothesis.
- **B** accept the null hypothesis.
- **C** reject the alternative hypothesis.

18 Which of the following is a Type I error?

- **A** Rejecting a true null hypothesis
- **B** Rejecting a false null hypothesis
- **C** Failing to reject a false null hypothesis

19 A Type II error is *best* described as:

- **A** rejecting a true null hypothesis.
- **B** failing to reject a false null hypothesis.
- **C** failing to reject a false alternative hypothesis.

20 The level of significance of a hypothesis test is *best* used to:

- **A** calculate the test statistic.
- **B** define the test's rejection points.
- **C** specify the probability of a Type II error.

21 You are interested in whether excess risk-adjusted return (alpha) is correlated with mutual fund expense ratios for US large-cap growth funds. The following table presents the sample.

Mutual Fund	Alpha	Expense Ratio
1	−0.52	1.34
2	−0.13	0.40
3	−0.50	1.90
4	−1.01	1.50
5	−0.26	1.35
6	−0.89	0.50
7	−0.42	1.00
8	−0.23	1.50
9	−0.60	1.45

- **A** Formulate null and alternative hypotheses consistent with the verbal description of the research goal.
- **B** Identify and justify the test statistic for conducting a test of the hypotheses in Part A.
- **C** Determine whether to reject the null hypothesis at the 0.05 level of significance if the critical values are ±2.306.

22 All else equal, is specifying a smaller significance level in a hypothesis test likely to increase the probability of a:

	Type I error?	Type II error?
A.	No	No
B.	No	Yes
C.	Yes	No

23 The probability of correctly rejecting the null hypothesis is the:

A *p*-value.

B power of a test.

C level of significance.

24 The power of a hypothesis test is:

A equivalent to the level of significance.

B the probability of not making a Type II error.

C unchanged by increasing a small sample size.

25 When making a decision about investments involving a statistically significant result, the:

A economic result should be presumed to be meaningful.

B statistical result should take priority over economic considerations.

C economic logic for the future relevance of the result should be further explored.

26 An analyst tests the profitability of a trading strategy with the null hypothesis that the average abnormal return before trading costs equals zero. The calculated *t*-statistic is 2.802, with critical values of ±2.756 at significance level $\alpha = 0.01$. After considering trading costs, the strategy's return is near zero. The results are *most likely*:

A statistically but not economically significant.

B economically but not statistically significant.

C neither statistically nor economically significant.

27 Which of the following statements is correct with respect to the *p*-value?

A It is a less precise measure of test evidence than rejection points.

B It is the largest level of significance at which the null hypothesis is rejected.

C It can be compared directly with the level of significance in reaching test conclusions.

28 Which of the following represents a correct statement about the *p*-value?

A The *p*-value offers less precise information than does the rejection points approach.

B A larger *p*-value provides stronger evidence in support of the alternative hypothesis.

C A *p*-value less than the specified level of significance leads to rejection of the null hypothesis.

29 Which of the following statements on *p*-value is correct?

A The *p*-value indicates the probability of making a Type II error.

B The lower the *p*-value, the weaker the evidence for rejecting the H_0.

C The *p*-value is the smallest level of significance at which H_0 can be rejected.

30 The following table shows the significance level (α) and the *p*-value for two hypothesis tests.

	α	*p*-Value
Test 1	0.02	0.05
Test 2	0.05	0.02

In which test should we reject the null hypothesis?

A Test 1 only

B Test 2 only

C Both Test 1 and Test 2

31 Which of the following tests of a hypothesis concerning the population mean is *most* appropriate?

A A z-test if the population variance is unknown and the sample is small

B A z-test if the population is normally distributed with a known variance

C A t-test if the population is non-normally distributed with unknown variance and a small sample

32 For a small sample from a normally distributed population with unknown variance, the *most* appropriate test statistic for the mean is the:

A z-statistic.

B t-statistic.

C χ^2 statistic.

33 An investment consultant conducts two independent random samples of five-year performance data for US and European absolute return hedge funds. Noting a return advantage of 50 bps for US managers, the consultant decides to test whether the two means are different from one another at a 0.05 level of significance. The two populations are assumed to be normally distributed with unknown but equal variances. Results of the hypothesis test are contained in the following tables.

	Sample Size	Mean Return (%)	Standard Deviation
US managers	50	4.7	5.4
European managers	50	4.2	4.8

Null and alternative hypotheses	H_0: $\mu_{US} - \mu_E = 0$; H_a: $\mu_{US} - \mu_E \neq 0$
Calculated test statistic	0.4893
Critical value rejection points	±1.984

The mean return for US funds is μ_{US}, and μ_E is the mean return for European funds.

The results of the hypothesis test indicate that the:

A null hypothesis is not rejected.

B alternative hypothesis is statistically confirmed.

C difference in mean returns is statistically different from zero.

34 A pooled estimator is used when testing a hypothesis concerning the:

A equality of the variances of two normally distributed populations.

B difference between the means of two at least approximately normally distributed populations with unknown but assumed equal variances.

C difference between the means of two at least approximately normally distributed populations with unknown and assumed unequal variances.

35 When evaluating mean differences between two dependent samples, the *most* appropriate test is a:

A z-test.

B chi-square test.

C paired comparisons test.

36 A chi-square test is *most* appropriate for tests concerning:

A a single variance.

B differences between two population means with variances assumed to be equal.

C differences between two population means with variances assumed to not be equal.

37 Which of the following should be used to test the difference between the variances of two normally distributed populations?

A t-test

B F-test

C Paired comparisons test

38 Jill Batten is analyzing how the returns on the stock of Stellar Energy Corp. are related with the previous month's percentage change in the US Consumer Price Index for Energy (CPIENG). Based on 248 observations, she has computed the sample correlation between the Stellar and CPIENG variables to be –0.1452. She also wants to determine whether the sample correlation is significantly different from zero. The critical value for the test statistic at the 0.05 level of significance is approximately 1.96. Batten should conclude that the statistical relationship between Stellar and CPIENG is:

A significant, because the calculated test statistic is outside the bounds of the critical values for the test statistic.

B significant, because the calculated test statistic has a lower absolute value than the critical value for the test statistic.

C insignificant, because the calculated test statistic is outside the bounds of the critical values for the test statistic.

39 In which of the following situations would a nonparametric test of a hypothesis *most likely* be used?

A The sample data are ranked according to magnitude.

B The sample data come from a normally distributed population.

C The test validity depends on many assumptions about the nature of the population.

40 An analyst is examining the monthly returns for two funds over one year. Both funds' returns are non-normally distributed. To test whether the mean return of one fund is greater than the mean return of the other fund, the analyst can use:

A a parametric test only.

B a nonparametric test only.

C both parametric and nonparametric tests.

41 An analyst group follows 250 firms and classifies them in two dimensions. First, they use dividend payment history and earnings forecasts to classify firms into one of three groups, with 1 indicating the dividend stars and 3 the dividend laggards. Second, they classify firms on the basis of financial leverage, using debt ratios, debt features, and corporate governance to classify the firms into three groups, with 1 indicating the least risky firms based on financial leverage and 3 indicating the riskiest. The classification of the 250 firms is as follows:

Financial Leverage Group	Dividend Group		
	1	2	3
1	40	40	40
2	30	10	20
3	10	50	10

A What are the null and alternative hypotheses to test whether the dividend and financial leverage groups are independent of one another?

B What is the appropriate test statistic to use in this type of test?

C If the critical value for the 0.05 level of significance is 9.4877, what is your conclusion?

42 Which of the following statements is correct regarding the chi-square test of independence?

A The test has a one-sided rejection region.

B The null hypothesis is that the two groups are dependent.

C If there are two categories, each with three levels or groups, there are six degrees of freedom.

SOLUTIONS

1 C is correct. Together, the null and alternative hypotheses account for all possible values of the parameter. Any possible values of the parameter not covered by the null must be covered by the alternative hypothesis (e.g., H_0: $\mu \le 5$ versus H_a: $\mu > 5$).

2 **A** The appropriate test statistic is a t-statistic, $t = \dfrac{\bar{X} - \mu_0}{\frac{s}{\sqrt{n}}}$, with $n - 1 = 15 - 1 = 14$ degrees of freedom. A t-statistic is correct when the sample comes from an approximately normally distributed population with unknown variance.

B The appropriate test statistic is a t-statistic, $t = \dfrac{\bar{X} - \mu_0}{\frac{s}{\sqrt{n}}}$, with $40 - 1 = 39$ degrees of freedom. A t-statistic is theoretically correct when the sample comes from a normally distributed population with unknown variance.

C The appropriate test statistic is a z-statistic, $z = \dfrac{\bar{X} - \mu_0}{\frac{\sigma}{\sqrt{n}}}$, because the sample comes from a normally distributed population with a known variance.

D The appropriate test statistic is chi-square, $x^2 = \dfrac{s^2(n-1)}{\sigma_0^2}$, with $50 - 1 = 49$ degrees of freedom.

E The appropriate test statistic is the F-statistic, $F = \sigma_1^2 \big/ \sigma_2^2$, with 29 and 39 degrees of freedom.

F The appropriate test statistic is a t-statistic using a pooled estimate of the population variance: $t = \dfrac{\left(\bar{X}_1 - \bar{X}_2\right) - \left(\mu_1 - \mu_2\right)}{\sqrt{\dfrac{s_p^2}{n_1} + \dfrac{s_p^2}{n_2}}}$, where $s_p^2 = \dfrac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$. The t-statistic has $25 + 30 - 2 = 53$ degrees of freedom. This statistic is appropriate because the populations are normally distributed with unknown variances; because the variances are assumed to be equal, the observations can be pooled to estimate the common variance. The requirement of independent samples for using this statistic has been met.

3 We make the decision either by comparing the calculated test statistic with the critical values or by comparing the p-value for the calculated test statistic with the level of significance.

A Reject the null hypothesis because the calculated test statistic is outside the bounds of the critical values.

B The calculated t-statistic is in the rejection region that is defined by +1.679, so we reject the null hypothesis.

C The p-value corresponding to the calculated test statistic is less than the level of significance, so we reject the null hypothesis.

D We fail to reject because the *p*-value for the calculated test statistic is greater than what is tolerated with a 2% level of significance.

4 We make the decision either by comparing the calculated test statistic with the critical values or by comparing the *p*-value for the calculated test statistic with the level of significance.

A The calculated chi-square falls between the two critical values, so we fail to reject the null hypothesis.

B The *p*-value for the calculated test statistic is less than the level of significance (the 5%), so we reject the null hypothesis.

C The calculated *F*-statistic falls outside the bounds of the critical *F*-values, so we reject the null hypothesis.

D The calculated chi-square exceeds the critical value for this right-side test, so we reject the null hypothesis.

5 **A** As stated in the text, we often set up the "hoped for" or "suspected" condition as the alternative hypothesis. Here, that condition is that the population value of Willco's mean annual net income exceeds $24 million. Thus, we have H_0: $\mu \leq 24$ versus H_a: $\mu > 24$.

B Given that net income is normally distributed with unknown variance, the appropriate test statistic is $t = \dfrac{\bar{X} - \mu_0}{s/\sqrt{n}} = 1.469694$ with $n - 1 = 6 - 1 = 5$ degrees of freedom.

C We reject the null if the calculated *t*-statistic is greater than 2.015. The calculated *t*-statistic is $t = \dfrac{30 - 24}{10/\sqrt{6}} = 1.469694$. Because the calculated test statistic does not exceed 2.015, we fail to reject the null hypothesis. There is not sufficient evidence to indicate that the mean net income is greater than $24 million.

6 **A** H_0: $\mu = 0$ versus H_a: $\mu \neq 0$.

B The *t*-test is based on $t = \dfrac{\bar{X} - \mu_0}{s/\sqrt{n}}$ with $n - 1 = 10 - 1 = 9$ degrees of freedom. At the 0.05 significance level, we reject the null if the calculated *t*-statistic is outside the bounds of ±2.262 (from the table for 9 degrees of freedom and 0.025 in the right side of the distribution). For Analyst A, we have a calculated test statistic of $t = \dfrac{0.05 - 0}{0.10/\sqrt{10}} = 1.58114$. We, therefore, fail to reject the null hypothesis at the 0.05 level.

C For Analyst B, the *t*-test is based on *t* with 15 − 1 = 14 degrees of freedom. At the 0.05 significance level, we reject the null if the calculated *t*-statistic is outside the bounds of ±2.145 (from the table for 14 degrees of freedom). The calculated test statistic is $t = \dfrac{0.02 - 0}{0.09/\sqrt{10}} = 0.86066$. Because 0.86066 is within the range of ±2.145, we fail to reject the null at the 0.05 level.

7 **A** Stating the suspected condition as the alternative hypothesis, we have

$$H_0: \mu_A - \mu_B \leq 0 \text{ versus } H_a: \mu_A - \mu_B > 0,$$

where

μ_A = the population mean value of Analyst A's forecast errors
μ_B = the population mean value of Analyst B's forecast errors

B We have two normally distributed populations with unknown variances. Based on the samples, it is reasonable to assume that the population variances are equal. The samples are assumed to be independent; this assumption is reasonable because the analysts cover different industries. The appropriate test statistic is t using a pooled estimate of the common variance: $t = \frac{(\bar{X}_1 - \bar{X}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}}$, where $s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$. The number of degrees of freedom is $n_A + n_B - 2 = 10 + 15 - 2 = 23$.

C For df = 23, according to the table, the rejection point for a one-sided (right side) test at the 0.05 significance level is 1.714.

D We first calculate the pooled estimate of variance:

$$s_p^2 = \frac{(10-1)0.01 + (15-1)0.0081}{10 + 15 - 2} = 0.0088435.$$

We then calculate the t-distributed test statistic:

$$t = \frac{(0.05 - 0.02) - 0}{\sqrt{\frac{0.0088435}{10} + \frac{0.0088435}{15}}} = \frac{0.03}{0.0383916} = 0.78142.$$

Because 0.78142 < 1.714, we fail to reject the null hypothesis. There is not sufficient evidence to indicate that the mean for Analyst A exceeds that for Analyst B.

8 **A** We test H_0: $\mu_d = 0$ versus H_a: $\mu_d \neq 0$, where μ_d is the population mean difference.

B This is a paired comparisons t-test with $n - 1 = 480 - 1 = 479$ degrees of freedom. At the 0.05 significance level, we reject the null hypothesis if the calculated t is less than −1.96 or greater than 1.96.

$$t = \frac{\bar{d} - \mu_{d0}}{s_{\bar{d}}} = \frac{-0.258 - 0}{3.752/\sqrt{480}} = \frac{-0.258}{0.171255} = -1.506529, \text{ or } -1.51.$$

Because the calculate t-statistic is between ±1.96, we do not reject the null hypothesis that the mean difference between the returns on the S&P 500 and small-cap stocks during the entire sample period was zero.

C This t-test now has $n - 1 = 240 - 1 = 239$ degrees of freedom. At the 0.05 significance level, we reject the null hypothesis if the calculated t is less than −1.96 or greater than 1.96.

$$t = \frac{\bar{d} - \mu_{d0}}{s_{\bar{d}}} = \frac{-0.640 - 0}{4.096/\sqrt{240}} = \frac{-0.640}{0.264396} = -2.420615, \text{ or } -2.42.$$

Because −2.42 < −1.96, we reject the null hypothesis at the 0.05 significance level. We conclude that during this subperiod, small-cap stocks significantly outperformed the S&P 500.

D This t-test has $n - 1 = 240 - 1 = 239$ degrees of freedom. At the 0.05 significance level, we reject the null hypothesis if the calculated t-statistic is less than −1.96 or greater than 1.96. The calculated test statistic is

$$t = \frac{\bar{d} - \mu_{d0}}{s_{\bar{d}}} = \frac{0.125 - 0}{3.339/\sqrt{240}} = \frac{0.125}{0.215532} = 0.579962, \text{ or } 0.58.$$

At the 0.05 significance level, because the calculated test statistic of 0.58 is between ±1.96, we fail to reject the null hypothesis for the second subperiod.

9 **A** We have a "less than" alternative hypothesis, where σ^2 is the variance of return on the portfolio. The hypotheses are H_0: $\sigma^2 \geq 400$ versus H_a: $\sigma^2 < 400$, where 400 is the hypothesized value of variance, σ_0^2. This means that the rejection region is on the left side of the distribution.

B The test statistic is chi-square distributed with $10 - 1 = 9$ degrees of freedom: $Ç^2 = \frac{(n-1)s^2}{Ã_0^2}$.

C The test statistic is calculated as

$$\chi^2 = \frac{(n-1)s^2}{\sigma_0^2} = \frac{9 \times 15^2}{400} = \frac{2{,}025}{400} = 5.0625, \text{ or } 5.06.$$

Because 5.06 is not less than 3.325, we do not reject the null hypothesis; the calculated test statistic falls to the right of the critical value, where the critical value separates the left-side rejection region from the region where we fail to reject.

We can determine the critical value for this test using software:

Excel [CHISQ.INV(0.05,9)]
R [qchisq(.05,9)]
Python [from scipy.stats import chi2 and chi2.ppf(.05,9)]

We can determine the p-value for the calculated test statistic of 17.0953 using software:

Excel [CHISQ.DIST(5.06,9,TRUE)]
R [pchisq(5.06,9,lower.tail=TRUE)]
Python [from scipy.stats import chi2 and chi2.cdf(5.06,9)]

10 **A** We have a "not equal to" alternative hypothesis:

$$H_0\text{: } \sigma^2_{Before} = \sigma^2_{After} \text{ versus } H_a\text{: } \sigma^2_{Before} \neq \sigma^2_{After}$$

B To test a null hypothesis of the equality of two variances, we use an F-test:

$$F = \frac{s_1^2}{s_2^2}.$$

$F = 22.367/15.795 = 1.416$, with $120 - 1 = 119$ numerator and $120 - 1 = 119$ denominator degrees of freedom. Because this is a two-tailed test, we use critical values for the $0.05/2 = 0.025$ level. The calculated test statistic falls within the bounds of the critical values (that is, between 0.6969 and 1.4349), so we fail to reject the null hypothesis; there is not enough evidence to indicate that the variances are different before and after the disruption. Note that we could also have formed the F-statistic as 15.796/22.367 = 0.706 and draw the same conclusion.

We could also use software to calculate the critical values:

Excel [F.INV(0.025,119,119) and F.INV(0.975,119,119)]

R [qf(c(.025,.975),119,119)]

Python from scipy.stats import f and f.ppf
[(.025,119,119) and
f.ppf(.975,119,119)]

Additionally, we could use software to calculate the p-value of the calculated test statistic, which is 5.896% and then compare it with the level of significance:

Excel [(1-F.DIST(22.367/15.796,119,119,TRUE))*2 or
F.DIST(15.796/22.367,119,119,TRUE)*2]

R [(1-pf(22.367/15.796,119,119))*2 or
pf(15.796/22.367,119,119)*2]

Python from scipy.stats import f and f.cdf
[(15.796/22.367,119,119)*2 or
(1-f.cdf(22.367/15.796,119,119))*2]

11 The hypotheses are H_0: ρ = 0 and H_a: ρ ≠ 0. The calculated test statistics are based on the formula $t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}$. For example, the calculated t-statistic for the correlation of Fund 3 and Fund 4 is

$$t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}} = \frac{0.3102\sqrt{36-2}}{\sqrt{1-0.3102^2}} = 1.903.$$

Repeating this calculation for the entire matrix of correlations gives the following:

	Calculated *t*-Statistics for Correlations				
	Fund 1	**Fund 2**	**Fund 3**	**Fund 4**	**S&P 500**
Fund 1					
Fund 2	13.997				
Fund 3	3.165	2.664			
Fund 4	5.897	6.116	1.903		
S&P 500	8.600	8.426	4.142	6.642	

With critical values of ±2.032, with the exception of the correlation between Fund 3 and Fund 4 returns, we reject the null hypothesis for these correlations. In other words, there is sufficient evidence to indicate that the correlations are different from zero, with the exception of the correlation of returns between Fund 3 and Fund 4.

We could use software to determine the critical values:

Excel [T.INV(0.025,34) and T.INV(0.975,34)]

R [qt(c(.025,.975),34)]

Python [from scipy.stats import t and t.ppf(.025,34) and t.ppf(.975,34)]

We could also use software to determine the *p*-value for the calculated test statistic to enable a comparison with the level of significance. For example, for $t = 2.664$, the *p*-value is 0.01172:

Excel [(1-T.DIST(2.664,34,TRUE))*2]

R [(1-pt(2.664,34))*2]

Python [from scipy.stats import t and (1-t.cdf(2.664,34))*2]

12 B is correct. The critical value in a decision rule is the rejection point for the test. It is the point with which the test statistic is compared to determine whether to reject the null hypothesis, which is part of the fourth step in hypothesis testing.

13 A is correct. The null hypothesis and the alternative hypothesis are complements of one another and together are exhaustive; that is, the null and alternative hypotheses combined consider all the possible values of the population parameter.

14 A is correct. If the population sampled has unknown variance and the sample is large, a *z*-test may be used. Hypotheses involving "greater than" or "less than" postulations are one sided (one tailed). In this situation, the null and alternative hypotheses are stated as H_0: $\mu \leq 6\%$ and H_a: $\mu > 6\%$, respectively. A one-tailed *t*-test is also acceptable in this case, and the rejection region is on the right side of the distribution.

15 C is correct. For a one-tailed hypothesis test, there is a 5% rejection region in one tail of the distribution.

16 B is correct. One-tailed tests in which the alternative is "greater than" or "less than" represent the beliefs of the researcher more firmly than a "not equal to" alternative hypothesis.

17 A is correct. Calculated using a sample, a test statistic is a quantity whose value is the basis for deciding whether to reject the null hypothesis.

18 A is correct. The definition of a Type I error is when a true null hypothesis is rejected.

19 B is correct. A Type II error occurs when a false null hypothesis is not rejected.

20 B is correct. The level of significance is used to establish the rejection points of the hypothesis test.

21 **A** We have a "not equal to" alternative hypothesis:

$$H_0: \rho = 0 \text{ versus } H_a: \rho \neq 0$$

B Mutual fund expense ratios are bounded from above and below; in practice, there is at least a lower bound on alpha (as any return cannot be less than −100%), and expense ratios cannot be negative. These variables may not be normally distributed, and the assumptions of a parametric test are not likely to be fulfilled. Thus, a nonparametric test appears to be appropriate.

We would use the nonparametric Spearman rank correlation coefficient to conduct the test: $r_s = 1 - \frac{6\sum_{i=1}^{n} d_i^2}{n(n^2 - 1)}$ with the t-distributed test statistic of $t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}$.

C The calculation of the Spearman rank correlation coefficient is given in the following table.

Mutual Fund	Alpha	Expense Ratio	Rank by Alpha	Rank by Expense Ratio	Difference in Rank	Difference Squared
1	−0.52	1.34	6	6	0	0
2	−0.13	0.40	1	9	−8	64
3	−0.50	1.90	5	1	4	16
4	−1.01	1.50	9	2	7	49
5	−0.26	1.35	3	5	−2	4
6	−0.89	0.50	8	8	0	0
7	−0.42	1.00	4	7	−3	9
8	−0.23	1.50	2	2	0	0
9	−0.60	1.45	7	4	3	9
						151

$$r_s = 1 - \frac{6(151)}{9(80)} = -0.25833.$$

The calculated test statistic, using the t-distributed test statistic $t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}$ is $t = \frac{-0.25833\sqrt{7}}{\sqrt{1 - 0.066736}} = \frac{-0.683486}{0.9332638} = -0.7075$. On the basis of this value falling within the range of ±2.306, we fail to reject the null hypothesis that the Spearman rank correlation coefficient is zero.

22 B is correct. Specifying a smaller significance level decreases the probability of a Type I error (rejecting a true null hypothesis) but increases the probability of a Type II error (not rejecting a false null hypothesis). As the level of significance decreases, the null hypothesis is less frequently rejected.

23 B is correct. The power of a test is the probability of rejecting the null hypothesis when it is false.

24 B is correct. The power of a hypothesis test is the probability of correctly rejecting the null when it is false. Failing to reject the null when it is false is a Type II error. Thus, the power of a hypothesis test is the probability of not committing a Type II error.

25 C is correct. When a statistically significant result is also economically meaningful, one should further explore the logic of why the result might work in the future.

26 A is correct. The hypothesis is a two-tailed formulation. The t-statistic of 2.802 falls outside the critical rejection points of less than −2.756 and greater than 2.756. Therefore, the null hypothesis is rejected; the result is statistically significant. However, despite the statistical results, trying to profit on the strategy is not likely to be economically meaningful because the return is near zero after transaction costs.

27 C is correct. When directly comparing the *p*-value with the level of significance, it can be used as an alternative to using rejection points to reach conclusions on hypothesis tests. If the *p*-value is smaller than the specified level of significance, the null hypothesis is rejected. Otherwise, the null hypothesis is not rejected.

28 C is correct. The *p*-value is the smallest level of significance at which the null hypothesis can be rejected for a given value of the test statistic. The null hypothesis is rejected when the *p*-value is less than the specified significance level.

29 C is correct. The *p*-value is the smallest level of significance (α) at which the null hypothesis can be rejected.

30 B is correct. The *p*-value is the smallest level of significance (α) at which the null hypothesis can be rejected. If the *p*-value is less than α, the null is rejected. In Test 1, the *p*-value exceeds the level of significance, whereas in Test 2, the *p*-value is less than the level of significance.

31 B is correct. The *z*-test is theoretically the correct test to use in those limited cases when testing the population mean of a normally distributed population with known variance.

32 B is correct. A *t*-statistic is the most appropriate for hypothesis tests of the population mean when the variance is unknown and the sample is small but the population is normally distributed.

33 A is correct. The calculated *t*-statistic value of 0.4893 falls within the bounds of the critical *t*-values of ±1.984. Thus, H_0 cannot be rejected; the result is not statistically significant at the 0.05 level.

34 B is correct. The assumption that the variances are equal allows for the combining of both samples to obtain a pooled estimate of the common variance.

35 C is correct. A paired comparisons test is appropriate to test the mean differences of two samples believed to be dependent.

36 A is correct. A chi-square test is used for tests concerning the variance of a single normally distributed population.

37 B is correct. An *F*-test is used to conduct tests concerning the difference between the variances of two normally distributed populations with random independent samples.

38 A is correct. The calculated test statistic is

$$\begin{aligned} t &= \frac{r\sqrt{n-2}}{\sqrt{1-r^2}} \\ &= \frac{-0.1452\sqrt{248-2}}{\sqrt{1-\left(-0.1452\right)^2}} = -2.30177. \end{aligned}$$

Because the value of $t = -2.30177$ is outside the bounds of ±1.96, we reject the null hypothesis of no correlation and conclude that there is enough evidence to indicate that the correlation is different from zero.

39 A is correct. A nonparametric test is used when the data are given in ranks.

40 B is correct. There are only 12 (monthly) observations over the one year of the sample and thus the samples are small. Additionally, the funds' returns are non-normally distributed. Therefore, the samples do not meet the distributional assumptions for a parametric test. The Mann–Whitney U test (a nonparametric test) could be used to test the differences between population means.

41 **A** The hypotheses are as follows:

H_0: Dividend and financial leverage ratings are not related, so these groupings are independent.

H_a: Dividend and financial leverage ratings are related, so these groupings are not independent.

B The appropriate test statistic is $\chi^2 = \sum_{i=1}^{m} \frac{\left(O_{ij} - E_{ij}\right)^2}{E_{ij}}$, where O_{ij} represents the observed frequency for the i and j group and E_{ij} represents the expected frequency for the i and j group if the groupings are independent.

C The expected frequencies based on independence are as follows:

Financial Leverage Group	Dividend Group 1	2	3	Sum
1	38.4	48	33.6	120
2	19.2	24	16.8	60
3	22.4	28	19.6	70
Sum	80	100	70	250

The scaled squared deviations for each combination of financial leverage and dividend grouping are:

Financial Leverage Group	Dividend Group 1	2	3
1	0.06667	1.33333	1.21905
2	6.07500	8.16667	0.60952
3	6.86429	17.28571	4.70204

The sum of these scaled squared deviations is the calculated chi-square statistic of 46.3223. Because this calculated value exceeds the critical value of 9.4877, we reject the null hypothesis that these groupings are independent.

42 A is correct. The test statistic comprises squared differences between the observed and expected values, so the test involves only one side, the right side. B is incorrect because the null hypothesis is that the groups are independent, and C is incorrect because with three levels of groups for the two categorical variables, there are four degrees of freedom.

Introduction to Linear Regression

by Pamela Peterson Drake, PhD, CFA

Pamela Peterson Drake, PhD, CFA, is at James Madison University (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** describe a simple linear regression model and the roles of the dependent and independent variables in the model;
☐	**b.** describe the least squares criterion, how it is used to estimate regression coefficients, and their interpretation;
☐	**c.** explain the assumptions underlying the simple linear regression model, and describe how residuals and residual plots indicate if these assumptions may have been violated;
☐	**d.** calculate and interpret the coefficient of determination and the *F*-statistic in a simple linear regression;
☐	**e.** describe the use of analysis of variance (ANOVA) in regression analysis, interpret ANOVA results, and calculate and interpret the standard error of estimate in a simple linear regression;
☐	**f.** formulate a null and an alternative hypothesis about a population value of a regression coefficient, and determine whether the null hypothesis is rejected at a given level of significance;
☐	**g.** calculate and interpret the predicted value for the dependent variable, and a prediction interval for it, given an estimated linear regression model and a value for the independent variable;
☐	**h.** describe different functional forms of simple linear regressions.

SIMPLE LINEAR REGRESSION

1

a describe a simple linear regression model and the roles of the dependent and independent variables in the model

Financial analysts often need to examine whether a variable is useful for explaining another variable. For example, the analyst may want to know whether earnings growth, or perhaps cash flow growth, helps explain the company's value in the marketplace. **Regression analysis** is a tool for examining this type of issue.

Suppose an analyst is examining the return on assets (ROA) for an industry and observes the ROA for the six companies shown in Exhibit 1. The average of these ROAs is 12.5%, but the range is from 4% to 20%.

Exhibit 1 Return on Assets of Selected Companies

Company	ROA (%)
A	6
B	4
C	15
D	20
E	10
F	20

In trying to understand why the ROAs differ among these companies, we could look at why the ROA of Company A differs from that of Company B, why the ROA of Company A differs from that of Company D, why the ROA of Company F differs from that of Company C, and so on, comparing each pair of ROAs. A way to make this a simpler exploration is to try to understand why each company's ROA differs from the mean ROA of 12.5%. We look at the sum of squared deviations of the observations from the mean to capture variations in ROA from their mean. Let Y represent the variable that we would like to explain, which in this case is the return on assets. Let Y_i represent an observation of a company's ROA, and let $\overline{Y}$ represent the mean ROA for the sample of size n. We can describe the variation of the ROAs as

$$\text{Variation of } Y = \sum\nolimits_{i=1}^{n}(Y_i - \overline{Y})^2. \tag{1}$$

Our goal is to understand what drives these returns on assets or, in other words, what explains the variation of Y. The variation of Y is often referred to as the **sum of squares total (SST)**, or the total sum of squares.

We now ask whether it is possible to explain the variation of the ROA using another variable that also varies among the companies; note that if this other variable is constant or random, it would not serve to explain why the ROAs differ from one another. Suppose the analyst believes that the capital expenditures in the previous period, scaled by the prior period's beginning property, plant, and equipment, are a driver for the ROA variable. Let us represent this scaled capital expenditures variable as CAPEX, as we show in Exhibit 2.

Exhibit 2 Return on Assets and Scaled Capital Expenditures

Company	ROA (%)	CAPEX (%)
A	6.0	0.7
B	4.0	0.4
C	15.0	5.0

Exhibit 2 (Continued)

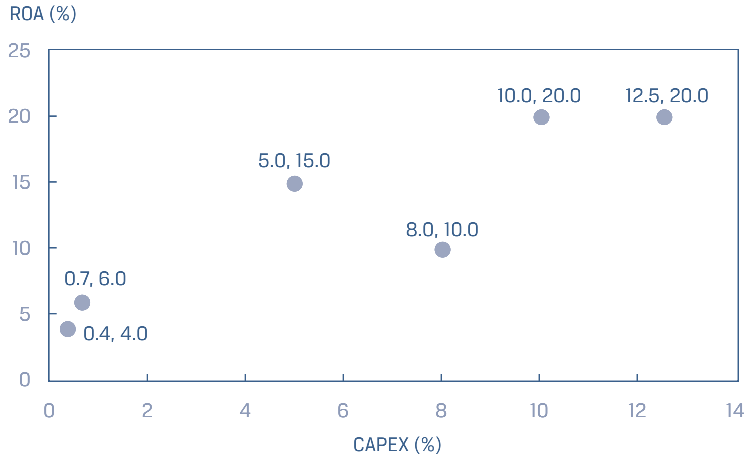
Company	ROA (%)	CAPEX (%)
D	20.0	10.0
E	10.0	8.0
F	20.0	12.5
Arithmetic mean	12.50	6.10

The variation of X, in this case CAPEX, is calculated as

$$\text{Variation of } X = \sum_{i=1}^{n}(X_i - \bar{X})^2. \tag{2}$$

We can see the relation between ROA and CAPEX in the **scatter plot** (or scattergram) in Exhibit 3, which represents the two variables in two dimensions. Typically, we present the variable whose variation we want to explain along the vertical axis and the variable whose variation we want to use to explain that variation along the horizontal axis. Each point in this scatter plot represents a paired observation that consists of CAPEX and ROA. From a casual visual inspection, there appears to be a positive relation between ROA and CAPEX: Companies with higher CAPEX tend to have a higher ROA.

Exhibit 3 Scatter Plot of ROA and CAPEX



In the ROA example, we use the capital expenditures to explain the returns on assets. We refer to the variable whose variation is being explained as the **dependent variable**, or the explained variable; it is typically denoted by Y. We refer to the variable whose variation is being used to explain the variation of the dependent variable as the **independent variable**, or the explanatory variable; it is typically denoted by X. Therefore, in our example, the ROA is the dependent variable (Y) and CAPEX is the independent variable (X).

A common method for relating the dependent and independent variables is through the estimation of a linear relationship, which implies describing the relation between the two variables as represented by a straight line. If we have only one independent variable, we refer to the method as **simple linear regression (SLR)**; if we have more than one independent variable, we refer to the method as multiple regression.

Linear regression allows us to test hypotheses about the relationship between two variables, by quantifying the strength of the relationship between the two variables, and to use one variable to make predictions about the other variable. Our focus is on linear regression with a single independent variable—that is, simple linear regression.

EXAMPLE 1

Identifying the Dependent and Independent Variables in a Regression

An analyst is researching the relationship between corporate earnings growth and stock returns. Specifically, she is interested in whether earnings revisions affect stock price returns in the same period. She collects five years of monthly data on "Wall Street" EPS revisions for a sample of 100 companies and on their monthly stock price returns over the five-year period.

What are the dependent and independent variables in her model?

Solution

The dependent variable is monthly stock price returns, and the independent variable is Wall Street EPS revisions, since in the analyst's model, the variation in monthly stock price returns is being explained by the variation in EPS revisions.

2 ESTIMATING THE PARAMETERS OF A SIMPLE LINEAR REGRESSION

b describe the least squares criterion, how it is used to estimate regression coefficients, and their interpretation

2.1 The Basics of Simple Linear Regression

Regression analysis begins with the dependent variable, the variable whose variation you are seeking to explain. The independent variable is the variable whose variation you are using to explain changes in the dependent variable. For example, you might try to explain small-stock returns (the dependent variable) using returns to the S&P 500 Index (the independent variable). Or you might try to explain a country's inflation rate (the dependent variable) as a function of growth in its money supply (the independent variable).

As the name implies, **linear regression** assumes a linear relationship between the dependent and the independent variables. The goal is to fit a line to the observations on Y and X to minimize the squared deviations from the line; this is the least squares criterion—hence, the name least squares regression. Because of its common use, linear regression is often referred to as ordinary least squares (OLS) regression.

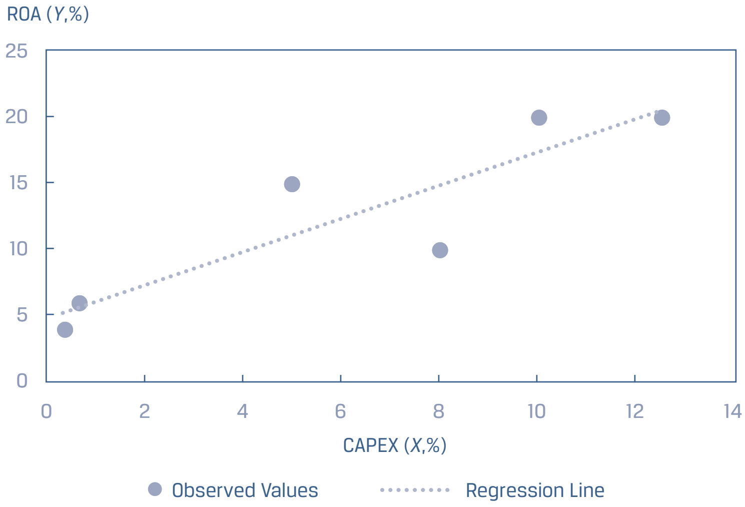
Using notation, the linear relation between the dependent and independent variables is described as

$$Y_i = b_0 + b_1 X_i + \varepsilon_i,\ i = 1, \ldots, n. \quad (3)$$

Equation 3 is a model that does not require that every (Y, X) pair for an observation fall on the regression line. This equation states that the dependent variable, Y, is equal to the **intercept**, b_0, plus a **slope coefficient**, b_1, multiplied by the independent variable, X, plus an **error term**, ε. The error term, or simply the error, represents the difference between the observed value of Y and that expected from the true underlying population relation between Y and X. We refer to the intercept, b_0, and the slope coefficient, b_1, as the **regression coefficients**. A way that we often describe this simple linear regression relation is that Y is regressed on X.

Consider the ROA and CAPEX scatter diagram from Exhibit 3, which we elaborate on in Exhibit 4 by including the fitted regression line. This line represents the average relationship between ROA and CAPEX; not every observation falls on the line, but the line describes the mean relation between ROA and CAPEX.

Exhibit 4 Fitted Regression Line of ROA and CAPEX



2.2 Estimating the Regression Line

We cannot observe the population parameter values b_0 and b_1 in a regression model. Instead, we observe only $\hat{b}_0$ and $\hat{b}_1$, which are estimates (as indicated by the "hats" above the coefficients) of the population parameters based on the sample. Thus, predictions must be based on the parameters' estimated values, and testing is based on estimated values in relation to the hypothesized population values.

We estimate the regression line as the line that best fits the observations. *In simple linear regression, the estimated intercept, $\hat{b}_0$, and slope, $\hat{b}_1$, are such that the sum of the squared vertical distances from the observations to the fitted line is minimized.* The focus is on the sum of the squared differences between the observations on Y_i and the corresponding estimated value, $\hat{Y}_i$, on the regression line.

We represent the value of the dependent variable for the ith observation that falls on the line as $\hat{Y}_i$, which is equal to $\hat{b}_0 + \hat{b}_1 X_i$. The $\hat{Y}_i$ is what the estimated value of the Y variable would be for the ith observation based on the mean relationship between

Y and X. The **residual** for the ith observation, e_i, is how much the observed value of Y_i differs from the $\hat{Y}_i$ estimated using the regression line: $e_i = Y_i - \hat{Y}_i$. Note the subtle difference between the error term and the residual: The error term refers to the true underlying population relationship, whereas the residual refers to the fitted linear relation based on the sample.

Fitting the line requires minimizing the sum of the squared residuals, the **sum of squares error (SSE)**, also known as the residual sum of squares:

$$\text{Sum of squares error} = \sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2$$

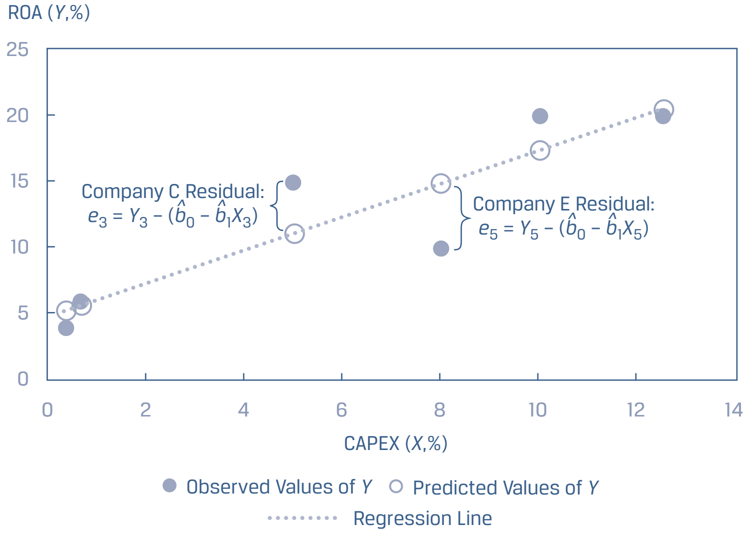
$$= \sum_{i=1}^{n}\left[Y_i - \left(\hat{b}_0 + \hat{b}_1 X_i\right)\right]^2 \qquad (4)$$

$$= \sum_{i=1}^{n} e_i^2.$$

Using least squares regression to estimate the values of the population parameters of b_0 and b_1, we can fit a line through the observations of X and Y that explains the value that Y takes for any particular value of X.

As seen in Exhibit 5, the residuals are represented by the vertical distances from the fitted line (see the third and fifth observations, Companies C and E, respectively) and are, therefore, in the units of measurement represented by the dependent variable. The residual is in the same unit of measurement as the dependent variable: If the dependent variable is in euros, the error term is in euros, and if the dependent variable is in growth rates, the error term is in growth rates.

Exhibit 5 Residuals of the Linear Regression



How do we calculate the intercept ($\hat{b}_0$) and the slope ($\hat{b}_1$) for a given sample of (Y, X) pairs of observations? The slope is the ratio of the covariance between Y and X to the variance of X, where $\overline{Y}$ is the mean of the Y variable and $\overline{X}$ is the mean of X variable:

$$\hat{b}_1 = \frac{\text{Covariance of } Y \text{ and } X}{\text{Variance of } X} = \frac{\dfrac{\sum_{i=1}^{n}(Y_i - \overline{Y})(X_i - \overline{X})}{n-1}}{\dfrac{\sum_{i=1}^{n}(X_i - \overline{X})^2}{n-1}}.$$

Simplifying,

$$\hat{b}_1 = \frac{\sum_{i=1}^{n}(Y_i - \overline{Y})(X_i - \overline{X})}{\sum_{i=1}^{n}(X_i - \overline{X})^2}. \tag{5}$$

Once we estimate the slope, we can then estimate the intercept using the mean of Y and the mean of X:

$$\hat{b}_0 = \overline{Y} - \hat{b}_1\overline{X}. \tag{6}$$

We show the calculation of the slope and the intercept in Exhibit 6.

Exhibit 6 Estimating Slope and Intercept for the ROA Model

Company	ROA (Y_i)	CAPEX (X_i)	$(Y_i - \overline{Y})^2$	$(X_i - \overline{X})^2$	$(Y_i - \overline{Y})(X_i - \overline{X})$
A	6.0	0.7	42.25	29.16	35.10
B	4.0	0.4	72.25	32.49	48.45
C	15.0	5.0	6.25	1.21	−2.75
D	20.0	10.0	56.25	15.21	29.25
E	10.0	8.0	6.25	3.61	−4.75
F	20.0	12.5	56.25	40.96	48.00
Sum	75.0	36.6	239.50	122.64	153.30
Arithmetic mean	12.5	6.100			

Slope coefficient: $\hat{b}_1 = \dfrac{153.30}{122.64} = 1.25.$

Intercept: $\hat{b}_0 = 12.5 - (1.25 \times 6.10) = 4.875$

ROA regression model: $\hat{Y}_i = 4.875 + 1.25X_i + \varepsilon_i.$

Notice the similarity of the formula for the slope coefficient and that of the pairwise correlation. The sample correlation, r, is the ratio of the covariance to the product of the standard deviations:

$$r = \frac{\text{Covariance of } Y \text{ and } X}{\left(\begin{array}{c}\text{Standard deviation}\\ \text{of } Y\end{array}\right)\left(\begin{array}{c}\text{Standard deviation}\\ \text{of } X\end{array}\right)}.$$

The subtle difference between the slope and the correlation formulas is in the denominator: For the slope, this is the variance of the independent variable, but for the correlation, the denominator is the product of the standard deviations. For our ROA and CAPEX analysis,

$$\text{Covariance of } Y \text{ and } X\text{: } \operatorname{cov}_{XY} = \frac{\sum_{i=1}^{n}(Y_i - \bar{Y})(X_i - \bar{X})}{n-1} = \frac{153.30}{5} = 30.66. \tag{7a}$$

Standard deviation of Y and X:

$$\begin{aligned} S_Y &= \sqrt{\frac{\sum_{i=1}^{n}(Y_i - \bar{Y})^2}{n-1}} = \sqrt{\frac{239.50}{5}} = 6.9210; \\ S_X &= \sqrt{\frac{\sum_{i=1}^{n}(X_i - \bar{X})^2}{n-1}} = \sqrt{\frac{122.64}{5}} = 4.9526. \end{aligned} \tag{7b}$$

$$r = \frac{30.66}{(6.9210)(4.9526)} = 0.89458945.$$

Because the denominators of both the slope and the correlation are positive, the sign of the slope and the correlation are driven by the numerator: If the covariance is positive, both the slope and the correlation are positive, and if the covariance is negative, both the slope and the correlation are negative.

HOW DO ANALYSTS PERFORM SIMPLE LINEAR REGRESSION?

Typically, an analyst will use the data analysis functions on a spreadsheet, such as Microsoft Excel, or a statistical package in the R or Python programming languages to perform linear regression analysis. The following are some of the more common choices in practice.

Simple Linear Regression: Intercept and Slope

- *Excel*: Use the INTERCEPT, SLOPE functions.
- *R*: Use the lm function.
- *Python*: Use the sm.OLS function in the statsmodels package.

Correlations

- *Excel*: Use the CORREL function.
- *R*: Use the cor function in the stats library.
- *Python*: Use the corrcoef function in the numpy library.

Note that in R and Python, there are many choices for regression and correlation analysis.

2.3 Interpreting the Regression Coefficients

What is the meaning of the regression coefficients? The intercept is the value of the dependent variable if the value of the independent variable is zero. Importantly, this does not make sense in some contexts, especially if it is unrealistic that the independent variable would be zero. For example, if we have a model where money supply explains GDP growth, the intercept has no meaning because, practically speaking, zero money supply is not possible. If the independent variable were money supply growth, however, the intercept is meaningful. The slope is the change in the dependent variable for a one-unit change in the independent variable. If the slope is positive, then the change in the independent variable and that of the dependent variable will be in the same direction; if the slope is negative, the change in the independent variable and that of the dependent variable will be in opposite directions.

INTERPRETING POSITIVE AND NEGATIVE SLOPES

Suppose the dependent variable (Y) is in millions of euros and the independent variable (*X*) is in millions of US dollars.

If the slope is positive 1.2, then
↑ USD1 million → ↑ EUR1.2 million
↓ USD1 million → ↓ EUR1.2 million
If the slope is negative 1.2, then
↑ USD1 million → ↓ EUR1.2 million
↓ USD1 million → ↑ EUR1.2 million

Using the ROA regression model from Exhibit 6, we would interpret the estimated coefficients as follows:

- The return on assets for a company is 4.875% if the company makes no capital expenditures.
- If CAPEX increases by one unit—say, from 4% to 5%—ROA increases by 1.25%.

Using the estimated regression coefficients, we can determine the values of the dependent variable if they follow the average relationship between the dependent and independent variables. A result of the mathematics of the least squares fitting of the regression line is that the expected value of the residual term is zero: E(ε) = 0.

We show the calculation of the predicted dependent variable and residual term for each observation in the ROA example in Exhibit 7. Note that the sum and average of Y_i and $\hat{Y}_1$ are the same, and the sum of the residuals is zero.

Exhibit 7 Calculation of the Dependent Variable and Residuals for the ROA and CAPEX Model

	(1)	(2)	(3)	(4)
Company	**ROA (Y_i)**	**CAPEX (X_i)**	**Predicted ROA ($\hat{Y}_i$)**	**(1) – (3) Residual (e_i)**
A	6.0	0.7	5.750	0.250
B	4.0	0.4	5.375	–1.375
C	15.0	5.0	11.125	3.875
D	20.0	10.0	17.375	2.625
E	10.0	8.0	14.875	–4.875
F	20.0	12.5	20.500	–0.500

(continued)

Exhibit 7 (Continued)

Company	(1) ROA (Y_i)	(2) CAPEX (X_i)	(3) Predicted ROA ($\hat{Y}_i$)	(4) (1) – (3) Residual (e_i)
Sum	75.0	36.6	75.000	0.000
Average	12.5	6.1	12.5	0.000

For Company C (i = 3),

$$\hat{Y}_i = \hat{b}_0 + \hat{b}_1 X_i + \varepsilon_i = 4.875 + 1.25X_i + \varepsilon_i$$

$$\hat{Y}_i = 4.875 + (1.25 \times 5.0) = 4.875 + 6.25 = 11.125$$

$Y_i - \hat{Y}_i = e_i = 15.0 - 11.125 = 3.875$, the vertical distance in Exhibit 5.

Whereas the sum of the residuals must equal zero by design, the focus of fitting the regression line in a simple linear regression is minimizing the sum of the squared residual terms.

2.4 Cross-Sectional vs. Time-Series Regressions

Regression analysis uses two principal types of data: cross sectional and time series. A cross-sectional regression involves many observations of X and Y for the same time period. These observations could come from different companies, asset classes, investment funds, countries, or other entities, depending on the regression model. For example, a cross-sectional model might use data from many companies to test whether predicted EPS growth explains differences in price-to-earnings ratios during a specific time period. Note that if we use cross-sectional observations in a regression, we usually denote the observations as $i = 1, 2, \ldots, n$.

Time-series data use many observations from different time periods for the same company, asset class, investment fund, country, or other entity, depending on the regression model. For example, a time-series model might use monthly data from many years to test whether a country's inflation rate determines its short-term interest rates. If we use time-series data in a regression, we usually denote the observations as $t = 1, 2, \ldots, T$. Note that in the sections that follow, we primarily use the notation $i = 1, 2, \ldots, n$, even for time series.

EXAMPLE 2

Estimating a Simple Linear Regression Model

An analyst is exploring the relationship between a company's net profit margin and research and development expenditures. He collects data for an industry and calculates the ratio of research and development expenditures to revenues (RDR) and the net profit margin (NPM) for eight companies. Specifically, he wants to explain the variation that he observes in the net profit margin by using the variation he observes in the companies' research and development spending. He reports the data in Exhibit 8.

Exhibit 8 Observations on NPM and RDR for Eight Companies

Company	NPM (%)	RDR (%)
1	4	8
2	5	10
3	10	6
4	9	5
5	5	7
6	6	9
7	12	5
8	3	10

1. What is the slope coefficient for this simple linear regression model?
2. What is the intercept for this regression model?
3. How is this estimated linear regression model represented?
4. What is the pairwise correlation between NPM and RDR?

Solutions

1. The slope coefficient for the regression model is −1.3, and the details for the inputs to this calculation are in Exhibit 9.

Exhibit 9 Details of Calculation of Slope of NPM Regressed on RDR

Company	NPM (%) (Y_i)	RDR (%) (X_i)	$Y_i - \bar{Y}$	$X_i - \bar{X}$	$(Y_i - \bar{Y})^2$	$(X_i - \bar{X})^2$	$(Y_i - \bar{Y})(X_i - \bar{X})$
1	4	8	−2.8	0.5	7.5625	0.25	−1.375
2	5	10	−1.8	2.5	3.0625	6.25	−4.375
3	10	6	3.3	−1.5	10.5625	2.25	−4.875
4	9	5	2.3	−2.5	5.0625	6.25	−5.625
5	5	7	−1.8	−0.5	3.0625	0.25	0.875
6	6	9	−0.8	1.5	0.5625	2.25	−1.125
7	12	5	5.3	−2.5	27.5625	6.25	−13.125
8	3	10	−3.8	2.5	14.0625	6.25	−9.375
Sum	54.0	60.0	0.0	0.0	71.5000	30.00	−39.0
Average	6.75	7.5					

Slope coefficient: $\hat{b}_1 = \frac{-39}{30} = -1.3.$

2. The intercept of the regression model is 16.5:

$$\text{Intercept: } \hat{b}_0 = 6.75 - (-1.3 \times 7.5) = 6.75 + 9.75 = 16.5$$

3 The regression model is represented by $\hat{Y}_i = 16.5 - 1.3X_i + \varepsilon_i$.

4 The pairwise correlation is –0.8421:

$$r = \frac{-39/7}{\sqrt{71.5/7}\sqrt{30/7}} = \frac{-5.5714}{(3.1960)(2.0702)} = -0.8421.$$

EXAMPLE 3

Interpreting Regression Coefficients

An analyst has estimated a model that regresses a company's return on equity (ROE) against its growth opportunities (GO), defined as the company's three-year compounded annual growth rate in sales, over 20 years and produces the following estimated simple linear regression:

$$\text{ROE}_i = 4 + 1.8\ \text{GO}_i + \varepsilon_i.$$

Both variables are stated in percentages, so a GO observation of 5% is included as 5.

1 The predicted value of the company's ROE if its GO is 10% is closest to:
- A 1.8%.
- B 15.8%.
- C 22.0%.

2 The change in ROE for a change in GO from 5% to 6% is closest to:
- A 1.8%.
- B 4.0%.
- C 5.8%.

3 The residual in the case of a GO of 8% and an observed ROE of 21% is closest to:
- A –1.8%.
- B 2.6%.
- C 12.0%.

Solutions

1 C is correct. The predicted value of ROE = 4 + (1.8 × 10) = 22.

2 A is correct. The slope coefficient of 1.8 is the expected change in the dependent variable (ROE) for a one-unit change in the independent variable (GO).

3 B is correct. The predicted value is ROE = 4 + (1.8 × 8) = 18.4. The observed value of ROE is 21, so the residual is 2.6 = 21.0 – 18.4.

ASSUMPTIONS OF THE SIMPLE LINEAR REGRESSION MODEL

3

c explain the assumptions underlying the simple linear regression model, and describe how residuals and residual plots indicate if these assumptions may have been violated

We have discussed how to interpret the coefficients in a simple linear regression model. Now we turn to the statistical assumptions underlying this model. Suppose that we have *n* observations of both the dependent variable, *Y*, and the independent variable, *X*, and we want to estimate the simple linear regression of *Y* regressed on *X*. We need to make the following four key assumptions to be able to draw valid conclusions from a simple linear regression model:

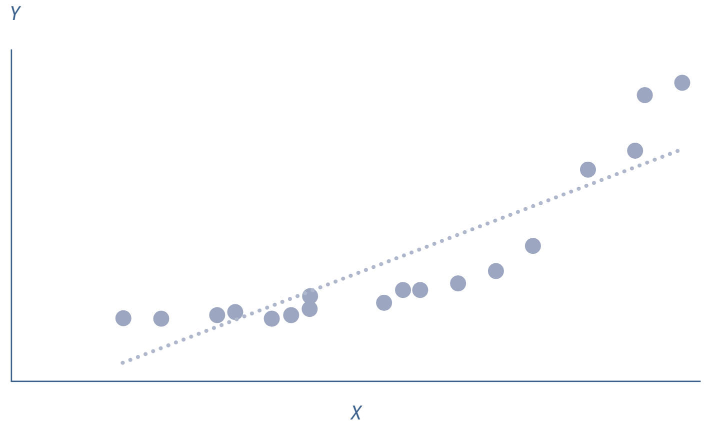
1. Linearity: The relationship between the dependent variable, *Y*, and the independent variable, *X*, is linear.
2. Homoskedasticity: The variance of the regression residuals is the same for all observations.
3. Independence: The observations, pairs of *Y*s and *X*s, are independent of one another. This implies the regression residuals are uncorrelated across observations.
4. Normality: The regression residuals are normally distributed.

Now we take a closer look at each of these assumptions and introduce the "best practice" of examining residual plots of regression results to identify potential violations of these key assumptions.

3.1 Assumption 1: Linearity

We are fitting a linear model, so we must assume that the true underlying relationship between the dependent and independent variables is linear. If the relationship between the independent and dependent variables is nonlinear in the parameters, estimating that relation with a simple linear regression model will produce invalid results: The model will be biased, because it will under- and overestimate the dependent variable at certain points. For example, $Y_i = b_0 e^{b_1 X_i} + \varepsilon_i$ is nonlinear in b_1, so we should not apply the linear regression model to it. Exhibit 10 shows an example of this exponential model, with a regression line indicated. You can see that this line does not fit this relationship well: For lower and higher values of *X*, the linear model underestimates the *Y*, whereas for the middle values, the linear model overestimates *Y*.

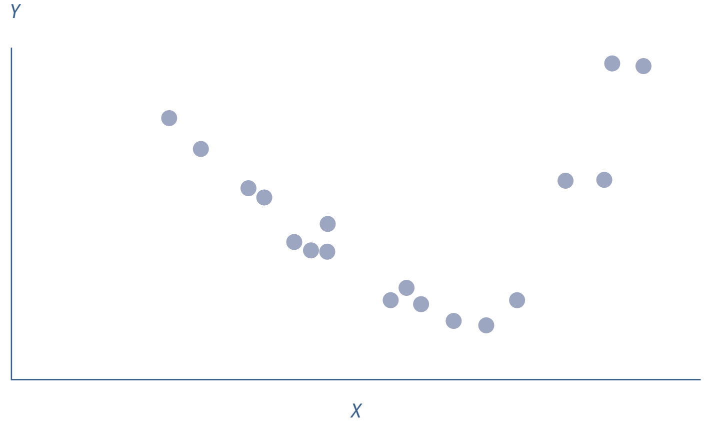
Exhibit 10 **Illustration of Nonlinear Relationship Estimated as a Linear Relationship**



Another implication of this assumption is that the independent variable, X, must not be random; that is, it is non-stochastic. If the independent variable is random, there would be no linear relation between the dependent and independent variables. Although we may initially assume that the independent variable in the regression model is not random, that assumption may not always be true.

When we look at the residuals of a model, what we would like to see is that the residuals are random. The residuals should not exhibit a pattern when plotted against the independent variable. As we show in Exhibit 11, the residuals from the Exhibit 10 linear regression do not appear to be random but, rather, exhibit a relationship with the independent variable, X, falling for some range of X and rising in another.

Exhibit 11 **Illustration of Residuals in a Nonlinear Relationship Estimated as a Linear Relationship**



3.2 Assumption 2: Homoskedasticity

Assumption 2, that the variance of the residuals is the same for all observations, is known as the **homoskedasticity** assumption. In terms of notation, this assumption relates to the squared residuals:

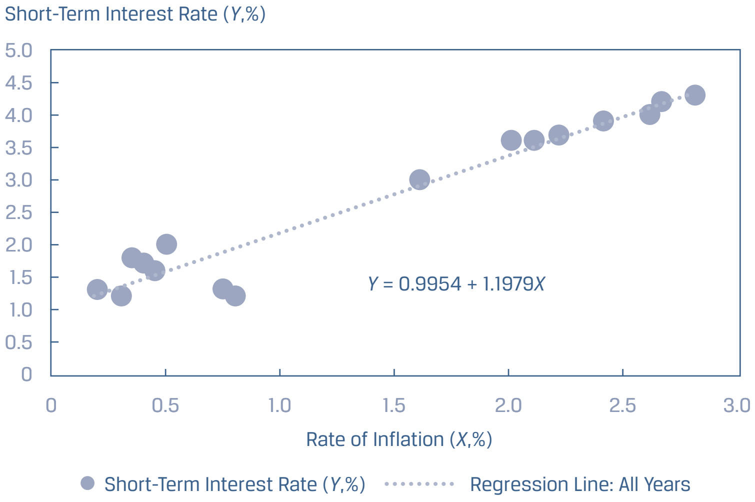
$$\mathrm{E}\left(\varepsilon_i^2\right) = \sigma_\varepsilon^2,\ i = 1, \ldots, n. \tag{8}$$

If the residuals are not homoscedastic, that is, if the variance of residuals differs across observations, then we refer to this as **heteroskedasticity**.

Suppose you are examining a time series of short-term interest rates as the dependent variable and inflation rates as the independent variable over 16 years. We may believe that short-term interest rates (Y) and inflation rates (X) should be related (that is, interest rates are higher with higher rates of inflation. If this time series spans many years, with different central bank actions that force short-term interest rates to be (artificially) low for the last eight years of the series, then it is likely that the residuals in this estimated model will appear to come from two different models. We will refer to the first eight years as Regime 1 (normal rates) and the second eight years as Regime 2 (low rates). If the model fits differently in the two regimes, the residuals and their variances will be different.

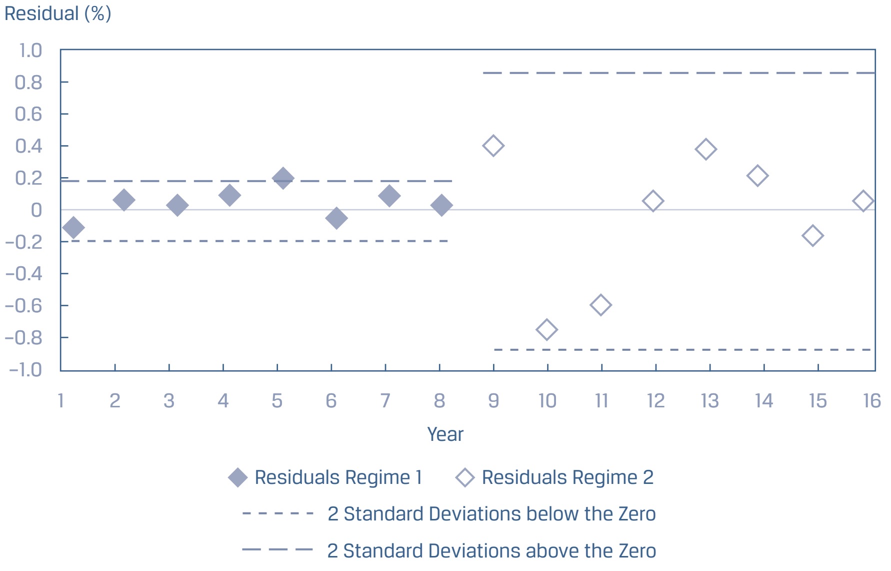
You can see this situation in Exhibit 12, which shows a scatter plot with an estimated regression line. The slope of the regression line over all 16 years is 1.1979.

Exhibit 12 Scatter Plot of Interest Rates (*Y*) and Inflation Rates (*X*)



We plot the residuals of this model in Exhibit 13 against the years. In this plot, we indicate the distance that is two standard deviations from zero (the mean of the residuals) for the first eight years' residuals and then do the same for the second eight years. As you can see, the residuals appear different for the two regimes: the variation in the residuals for the first eight years is much smaller than the variation for the second eight years.

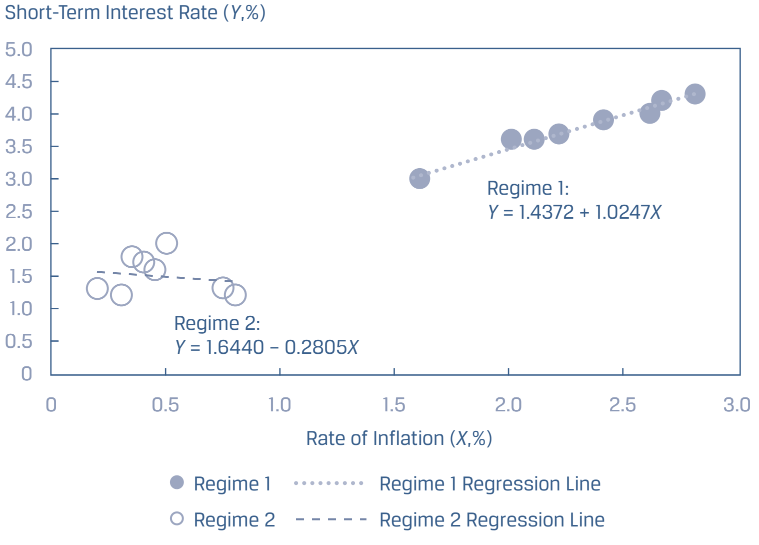
Exhibit 13 Residual Plot for Interest Rates (*Y*) vs. Inflation Rates (*X*) Model



Why does this happen? The model seems appropriate, but when we examine the residuals (Exhibit 13), an important step in assessing the model fit, we see that the model fits better in some years compared with others. The difference in variance of residuals between the two regimes is apparent from the much wider band around residuals for Regime 2 (the low-rate period). This indicates a clear violation of the homoskedasticity assumption.

If we estimate a regression line for each regime, we can see that the model for the two regimes is quite different, as we show in Exhibit 14. In the case of Regime 1 (normal rates), the slope is 1.0247, whereas in Regime 2 (low rates) the slope is −0.2805. In sum, the clustering of residuals in two groups with much different variances clearly indicates the existence of distinct regimes for the relationship between short-term interest rates and the inflation rate.

Exhibit 14 Fitted Regression Lines for the Two Regimes

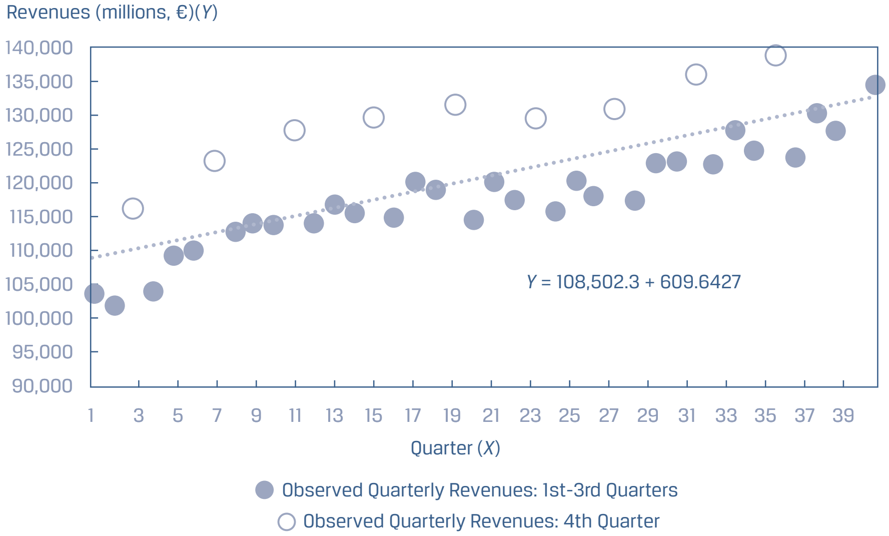


3.3 Assumption 3: Independence

We assume that the observations (Y and X pairs) are uncorrelated with one another, meaning they are independent. If there is correlation between observations (that is, autocorrelation), they are not independent and the residuals will be correlated. The assumption that the residuals are uncorrelated across observations is also necessary for correctly estimating the variances of the **estimated parameters** of b_0 and b_1 (i.e., $\hat{b}_0$ and $\hat{b}_1$) that we use in hypothesis tests of the intercept and slope, respectively. It is important to examine whether the residuals exhibit a pattern, suggesting a violation of this assumption. Therefore, we need to visually and statistically examine the residuals for a regression model.

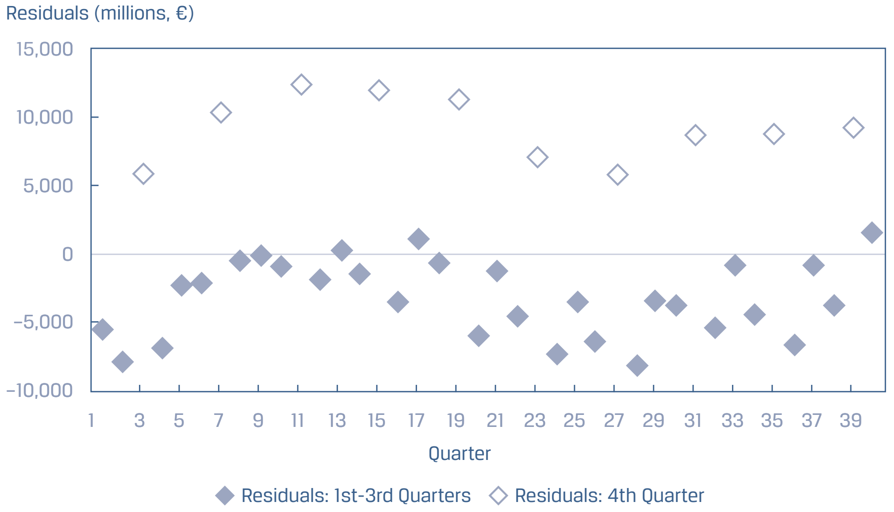
Consider the quarterly revenues of a company regressed over 40 quarters, as shown in Exhibit 15, with the regression line included. It is clear that these revenues display a seasonal pattern, an indicator of autocorrelation.

Exhibit 15 Regression of Quarterly Revenues vs. Time (40 Quarters)



In Exhibit 16, we plot the residuals from this model and see that there is a pattern. These residuals are correlated, specifically jumping up in Quarter 4 and then falling back the subsequent quarter. In sum, the patterns in both Exhibits 15 and 16 indicate a violation of the assumption of independence.

Exhibit 16 Residual Plot for Quarterly Revenues vs. Time Model



3.4 Assumption 4: Normality

The assumption of normality requires that the residuals be normally distributed. This does not mean that the dependent and independent variables must be normally distributed; it only means that the residuals from the model are normally distributed. However, in estimating any model, it is good practice to understand the distribution of the dependent and independent variables to explore for outliers. An outlier in either or both variables can substantially influence the fitted line such that the estimated model will not fit well for most of the other observations.

With normally distributed residuals, we can test a particular hypothesis about a linear regression model. For large sample sizes, we may be able to drop the assumption of normality by appealing to the central limit theorem; asymptotic theory (which deals with large samples) shows that in many cases, the test statistics produced by standard regression programs are valid even if the model's residuals are not normally distributed.

EXAMPLE 4

Assumptions of Simple Linear Regression

An analyst is investigating a company's revenues and estimates a simple linear time-series model by regressing revenues against time, where time—1, 2, . . . , 15—is measured in years. She plots the company's observed revenues and the estimated regression line, as shown in Exhibit 17. She also plots the residuals from this regression model, as shown in Exhibit 18.

Exhibit 17 Revenues vs. Time Using Simple Linear Regression

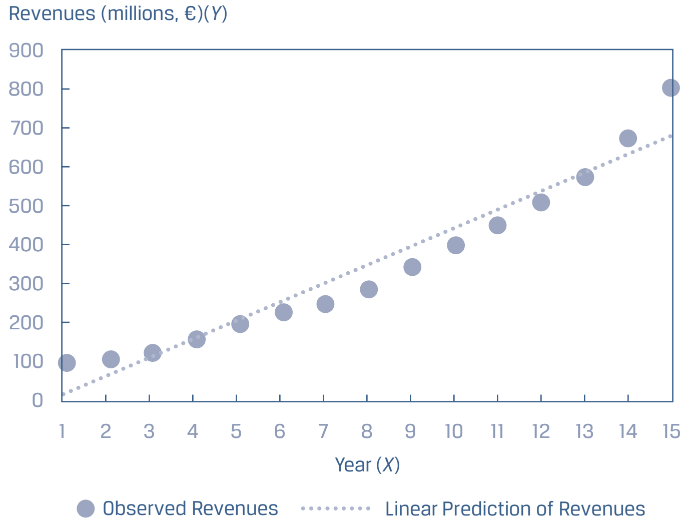


Exhibit 18 Residual Plot for Revenues vs. Time

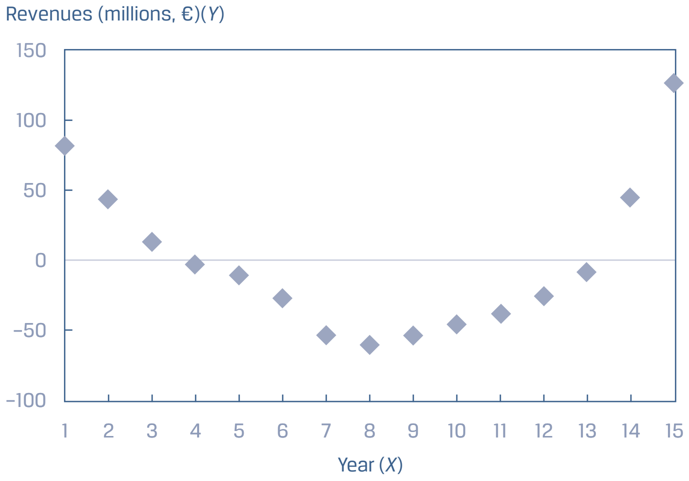


Based on Exhibits 17 and 18, describe which assumption(s) of simple linear regression the analyst's model may be violating.

Solution

The correct model is not linear, as evident from the pattern of the revenues in Exhibit 17. In the earlier years (i.e., 1 and 2) and later years (i.e., 14 and 15), the linear model underestimates revenues, whereas for the middle years (i.e., 7–11), the linear model overestimates revenues. Moreover, the curved pattern of residuals in Exhibit 18 indicates potential heteroskedasticity (residuals have unequal variances), lack of independence of observations, and non-normality (a concern given the small sample size of $n = 15$). In sum, the analyst should be concerned that her model violates all the assumptions governing simple linear regression (linearity, homoskedasticity, independence, and normality).

4

ANALYSIS OF VARIANCE

d calculate and interpret the coefficient of determination and the *F*-statistic in a simple linear regression

The simple linear regression model sometimes describes the relationship between two variables quite well, but sometimes it does not. We must be able to distinguish between these two cases to use regression analysis effectively. Remember our goal is to explain the variation of the dependent variable. So, how well has this goal been achieved, given our choice of independent variable?

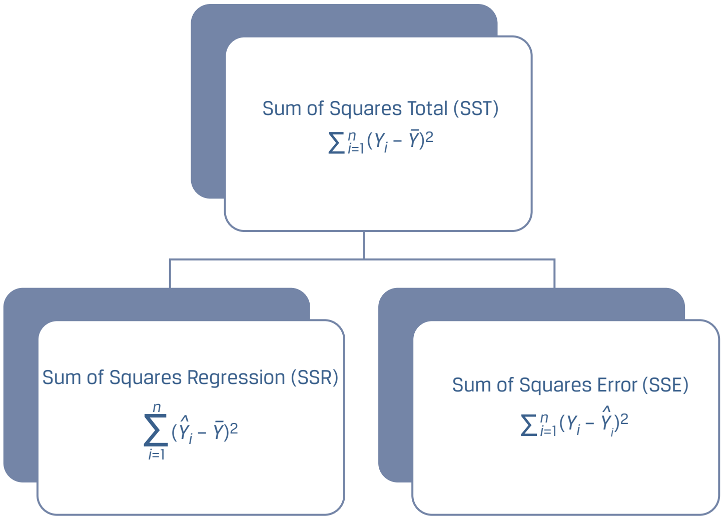
4.1 Breaking down the Sum of Squares Total into Its Components

We begin with the sum of squares total and then break it down into two parts: the sum of squares error and the **sum of squares regression (SSR)**. The sum of squares regression is the sum of the squared differences between the predicted value of the dependent variable, $\hat{Y}_i$, based on the estimated regression line, and the mean of the dependent variable, $\overline{Y}$:

$$\sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2. \tag{9}$$

We have already defined the sum of squares total, which is the total variation in *Y*, and the sum of squares error, the unexplained variation in *Y*. Note that the sum of squares regression is the explained variation in *Y*. So, as illustrated in Exhibit 19, SST = SSR + SSE, meaning total variation in *Y* equals explained variation in *Y* plus unexplained variation in *Y*.

Exhibit 19 Breakdown of Variation of Dependent Variable



Sum of Squares Total (SST)
$\sum_{i=1}^{n}(Y_i - \bar{Y})^2$
Sum of Squares Regression (SSR)
$\sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2$
Sum of Squares Error (SSE)
$\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2$

We show the breakdown of the sum of squares total formula for our ROA regression example in Exhibit 20. The total variation of ROA that we want to explain (SST) is 239.50. This number comprises the variation unexplained (SSE), 47.88, and the variation explained (SSR), 191.63. These sum of squares values are important inputs into measures of the fit of the regression line.

Exhibit 20 Breakdown of Sum of Squares Total for ROA Model

Company	ROA (Y_i)	CAPEX (X_i)	Predicted ROA ($\hat{Y}$)	Variation to Be Explained $\left(Y_i - \bar{Y}\right)^2$	Variation Unexplained $\left(Y_i - \hat{Y}_i\right)^2$	Variation Explained $\left(\hat{Y}_i - \bar{Y}\right)^2$
A	6.0	0.7	5.750	42.25	0.063	45.563
B	4.0	0.4	5.375	72.25	1.891	50.766
C	15.0	5.0	11.125	6.25	15.016	1.891
D	20.0	10.0	17.375	56.25	6.891	23.766
E	10.0	8.0	14.875	6.25	23.766	5.641
F	20.0	12.5	20.500	56.25	0.250	64.000
				239.50	47.88	191.625
Mean	12.50					

Sum of squares total = 239.50.
Sum of squares error = 47.88.
Sum of squares regression = 191.63.

4.2 Measures of Goodness of Fit

There are several measures that we can use to evaluate goodness of fit—that is, how well the regression model fits the data. These include the coefficient of determination, the *F*-statistic for the test of fit, and the standard error of the regression.

The **coefficient of determination**, also referred to as the *R*-squared or R^2, is the percentage of the variation of the dependent variable that is explained by the independent variable:

$$\begin{gathered}\text{Coefficient of determination} = \frac{\text{Sum of squares regression}}{\text{Sum of squares total}} \\ \text{Coefficient of determination} = \frac{\sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2}{\sum_{i=1}^{n}(Y_i - \bar{Y})^2}.\end{gathered} \tag{10}$$

By construction, the coefficient of determination ranges from 0% to 100%. In our ROA example, the coefficient of determination is 191.625 ÷ 239.50, or 0.8001, so 80.01% of the variation in ROA is explained by CAPEX. In a simple linear regression, the square of the pairwise correlation is equal to the coefficient of determination:

$$r^2 = \frac{\sum_{i=1}^{n}\left(\hat{Y}_i - \bar{Y}\right)^2}{\sum_{i=1}^{n}\left(Y_i - \bar{Y}\right)^2} = R^2.$$

In our earlier ROA regression analysis, $r = 0.8945$, so we now see that r^2 is indeed equal to the coefficient of determination (R^2), since $(0.8945)^2 = 0.8001$.

Whereas the coefficient of determination—the portion of the variation of the dependent variable explained by the independent variable—is descriptive, it is not a statistical test. To see if our regression model is likely to be statistically meaningful, we will need to construct an *F*-distributed test statistic.

In general, we use an F-distributed test statistic to compare two variances. In regression analysis, we can use an F-distributed test statistic to test whether the slopes in a regression are equal to zero, with the slopes designated as b_i, against the alternative hypothesis that at least one slope is not equal to zero:

H_0: $b_1 = b_2 = b_3 = \ldots = b_k = 0$.

H_a: At least one b_k is not equal to zero.

For simple linear regression, these hypotheses simplify to

H_0: $b_1 = 0$.

H_a: $b_1 \neq 0$.

The F-distributed test statistic is constructed by using the sum of squares regression and the sum of squares error, each adjusted for degrees of freedom; in other words, it is the ratio of two variances. We divide the sum of squares regression by the number of independent variables, represented by k. In the case of a simple linear regression, k = 1, so we arrive at the **mean square regression (MSR)**, which is the same as the sum of squares regression:

$$\text{MSR} = \frac{\text{Sum of squares regression}}{k} = \frac{\sum_{i=1}^{n}(\widehat{Y}_i - \bar{Y})^2}{1}.$$

So, for simple linear regression,

$$\text{MSR} = \sum_{i=1}^{n}(\widehat{Y}_i - \bar{Y})^2. \tag{11}$$

Next, we calculate the **mean square error (MSE)**, which is the sum of squares error divided by the degrees of freedom, which are $n - k - 1$. In simple linear regression, $n - k - 1$ becomes $n - 2$:

$$\text{MSE} = \frac{\text{Sum of squares error}}{n - k - 1}.$$

$$\text{MSE} = \frac{\sum_{i=1}^{n}(Y_i - \widehat{Y}_i)^2}{n - 2}. \tag{12}$$

Therefore, the F-distributed test statistic (MSR/MSE) is

$$F = \frac{\dfrac{\text{Sum of squares regression}}{k}}{\dfrac{\text{Sum of squares error}}{n - k - 1}} = \frac{\text{MSR}}{\text{MSE}}$$

$$F = \frac{\dfrac{\sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2}{1}}{\dfrac{\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2}{n - 2}}, \tag{13}$$

which is distributed with 1 and $n - 2$ degrees of freedom in simple linear regression. The F-statistic in regression analysis is one sided, with the rejection region on the right side, because we are interested in whether the variation in Y explained (the numerator) is larger than the variation in Y unexplained (the denominator).

4.3 ANOVA and Standard Error of Estimate in Simple Linear Regression

e describe the use of analysis of variance (ANOVA) in regression analysis, interpret ANOVA results, and calculate and interpret the standard error of estimate in a simple linear regression

We often represent the sums of squares from a regression model in an **analysis of variance (ANOVA)** table, as shown in Exhibit 21, which presents the sums of squares, the degrees of freedom, the mean squares, and the *F*-statistic. Notice that the variance of the dependent variable is the ratio of the sum of squares total to $n - 1$.

Exhibit 21 Analysis of Variance Table for Simple Linear Regression

Source	Sum of Squares	Degrees of Freedom	Mean Square	*F*-Statistic
Regression	$\text{SSR} = \sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2$	1	$\text{MSR} = \frac{\sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2}{1}$	$F = \frac{\text{MSR}}{\text{MSE}} = \frac{\frac{\sum_{i=1}^{n}(\hat{Y}_i - \bar{Y})^2}{1}}{\frac{\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2}{n-2}}$
Error	$\text{SSE} = \sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2$	$n - 2$	$\text{MSE} = \frac{\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2}{n-2}$	
Total	$\text{SST} = \sum_{i=1}^{n}(Y_i - \bar{Y})^2$	$n - 1$		

From the ANOVA table, we can also calculate the **standard error of the estimate** (s_e), which is also known as the standard error of the regression or the root mean square error. The s_e is a measure of the distance between the observed values of the dependent variable and those predicted from the estimated regression; the smaller the s_e, the better the fit of the model. The s_e, along with the coefficient of determination and the *F*-statistic, is a measure of the goodness of the fit of the estimated regression line. Unlike the coefficient of determination and the *F*-statistic, which are relative measures of fit, the standard error of the estimate is an absolute measure of the distance of the observed dependent variable from the regression line. Thus, the s_e is an important statistic used to evaluate a regression model and is used in calculating prediction intervals and performing tests on the coefficients. The calculation of s_e is straightforward once we have the ANOVA table because it is the square root of the MSE:

$$\text{Standard error of the estimate } (s_e) = \sqrt{\text{MSE}} = \sqrt{\frac{\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2}{n-2}}. \tag{14}$$

We show the ANOVA table for our ROA regression example in Exhibit 22, using the information from Exhibit 20. For a 5% level of significance, the critical *F*-value for the test of whether the model is a good fit (that is, whether the slope coefficient is different from zero) is 7.71. We can get this critical value in the following ways:

- *Excel* [F.INV(0.95,1,4)]
- *R* [qf(.95,1,4)]
- *Python* [from scipy.stats import f *and* f.ppf(.95,1,4)]

With a calculated *F*-statistic of 16.0104 and a critical *F*-value of 7.71, we reject the null hypothesis and conclude that the slope of our simple linear regression model for ROA is different from zero.

Exhibit 22 ANOVA Table for ROA Regression Model

Source	Sum of Squares	Degrees of Freedom	Mean Square	*F*-Statistic
Regression	191.625	1	191.625	16.0104
Error	47.875	4	11.96875	
Total	239.50	5		

The calculations to derive the ANOVA table and ultimately to test the goodness of fit of the regression model can be time consuming, especially for samples with many observations. However, statistical packages, such as SAS, SPSS Statistics, and Stata, as well as software, such as Excel, R, and Python, produce the ANOVA table as part of the output for regression analysis.

EXAMPLE 5

Using ANOVA Table Results to Evaluate a Simple Linear Regression

Suppose you run a cross-sectional regression for 100 companies, where the dependent variable is the annual return on stock and the independent variable is the lagged percentage of institutional ownership (INST). The results of this simple linear regression estimation are shown in Exhibit 23. Evaluate the model by answering the questions below.

Exhibit 23 ANOVA Table for Annual Stock Return Regressed on Institutional Ownership

Source	Sum of Squares	Degrees of Freedom	Mean Square
Regression	576.1485	1	576.1485
Error	1,873.5615	98	19.1180
Total	2,449.7100		

1 What is the coefficient of determination for this regression model?

2 What is the standard error of the estimate for this regression model?

3 At a 5% level of significance, do we reject the null hypothesis of the slope coefficient equal to zero if the critical *F*-value is 3.938?

4 Based on your answers to the preceding questions, evaluate this simple linear regression model.

Solutions

1 The coefficient of determination is sum of squares regression/sum of squares total: 576.148 ÷ 2,449.71 = 0.2352, or 23.52%.

2 The standard error of the estimate is the square root of the mean square error: $\sqrt{19.1180} = 4.3724$.

3 Using a six-step process for testing hypotheses, we get the following:

Step 1	State the hypotheses.	H_0: $b_1 = 0$ versus H_a: $b_1 \neq 0$
Step 2	Identify the appropriate test statistic.	$F = \dfrac{\text{MSR}}{\text{MSE}}$ with 1 and 98 degrees of freedom.
Step 3	Specify the level of significance.	α = 5% (one tail, right side).
Step 4	State the decision rule.	Critical F-value = 3.938. Reject the null hypothesis if the calculated F-statistic is greater than 3.938.
Step 5	Calculate the test statistic.	$F = \dfrac{576.1485}{19.1180} = 30.1364$
Step 6	Make a decision.	Reject the null hypothesis because the calculated F-statistic is greater than the critical F-value. There is sufficient evidence to indicate that the slope coefficient is different from 0.0.

4 The coefficient of determination indicates that variation in the independent variable explains 23.52% of the variation in the dependent variable. Also, the F-statistic test confirms that the model's slope coefficient is different from 0 at the 5% level of significance. In sum, the model seems to fit the data reasonably well.

HYPOTHESIS TESTING OF LINEAR REGRESSION COEFFICIENTS

5

f formulate a null and an alternative hypothesis about a population value of a regression coefficient, and determine whether the null hypothesis is rejected at a given level of significance

5.1 Hypothesis Tests of the Slope Coefficient

We can use the F-statistic to test for the significance of the slope coefficient (that is, whether it is significantly different from zero), but we also may want to perform other hypothesis tests for the slope coefficient—for example, testing whether the population slope is different from a specific value or whether the slope is positive. We can use a t-distributed test statistic to test such hypotheses about a regression coefficient.

Suppose we want to check a stock's valuation using the market model; we hypothesize that the stock has an average systematic risk (i.e., risk similar to that of the market), as represented by the coefficient on the market returns variable. Or we may want to test the hypothesis that economists' forecasts of the inflation rate are unbiased (that is, on average, not overestimating or underestimating actual inflation rates). In each case, does the evidence support the hypothesis? Such questions as these can be addressed with hypothesis tests on the regression slope. To test a hypothesis about a slope, we calculate the test statistic by subtracting the hypothesized population slope (B_1) from the estimated slope coefficient ($\hat{b}_1$) and then dividing this difference by the standard error of the slope coefficient, $s_{\hat{b}_1}$:

$$t = \frac{\hat{b}_1 - B_1}{s_{\hat{b}_1}}. \tag{15}$$

This test statistic is t-distributed with $n - k - 1$ or $n - 2$ degrees of freedom because two parameters (an intercept and a slope) were estimated in the regression.

The **standard error of the slope coefficient** ($s_{\hat{b}_1}$) for a simple linear regression is the ratio of the model's standard error of the estimate (s_e) to the square root of the variation of the independent variable:

$$s_{\hat{b}_1} = \frac{s_e}{\sqrt{\sum_{i=1}^{n}(X_i - \bar{X})^2}}. \tag{16}$$

We compare the calculated t-statistic with the critical values to test hypotheses. Note that the greater the variability of the independent variable, the lower the standard error of the slope (Equation 16) and hence the greater the calculated t-statistic (Equation 15). If the calculated t-statistic is outside the bounds of the critical t-values, we reject the null hypothesis, but if the calculated t-statistic is within the bounds of the critical values, we fail to reject the null hypothesis. Similar to tests of the mean, the alternative hypothesis can be two sided or one sided.

Consider our previous simple linear regression example with ROA as the dependent variable and CAPEX as the independent variable. Suppose we want to test whether the slope coefficient of CAPEX is different from zero to confirm our intuition of a significant relationship between ROA and CAPEX. We can test the hypothesis concerning the slope using the six-step process, as we show in Exhibit 24. As a result of this test, we conclude that the slope is different from zero; that is, CAPEX is a significant explanatory variable of ROA.

Exhibit 24 Test of the Slope for the Regression of ROA on CAPEX

Step 1	State the hypotheses.	H_0: $b_1 = 0$ versus H_a: $b_1 \neq 0$
Step 2	Identify the appropriate test statistic.	$t = \frac{\hat{b}_1 - B_1}{s_{\hat{b}_1}}$ with 6 − 2 = 4 degrees of freedom.
Step 3	Specify the level of significance.	α = 5%.

Exhibit 24 (Continued)

Step 4	State the decision rule.	Critical t-values = ±2.776. We can determine this from **Excel** *Lower:* T.INV(0.025,4) *Upper:* T.INV(0.975,4) **R** qt(c(.025,.975),4) **Python** from scipy.stats import t *Lower:* t.ppf(.025,4) *Upper:* t.ppf(.975,4) We reject the null hypothesis if the calculated t-statistic is less than −2.776 or greater than +2.776.
Step 5	Calculate the test statistic.	The slope coefficient is 1.25 (Exhibit 6). The mean square error is 11.96875 (Exhibit 22). The variation of CAPEX is 122.640 (Exhibit 6). $s_e = \sqrt{11.96875} = 3.459588.$ $s_{\hat{b}_1} = \dfrac{3.459588}{\sqrt{122.640}} = 0.312398.$ $t = \dfrac{1.25 - 0}{0.312398} = 4.00131.$
Step 6	Make a decision.	Reject the null hypothesis of a zero slope. There is sufficient evidence to indicate that the slope is different from zero.

A feature of simple linear regression is that the t-statistic used to test whether the slope coefficient is equal to zero and the t-statistic to test whether the pairwise correlation is zero (that is, H_0: $\rho = 0$ versus H_a: $\rho \neq 0$) are the same value. Just as with a test of a slope, both two-sided and one-sided alternatives are possible for a test of a correlation—for example, H_0: $\rho \leq 0$ versus H_a: $\rho > 0$. The test-statistic to test whether the correlation is equal to zero is

$$t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}.$$

In our example of ROA regressed on CAPEX, the correlation (r) is 0.8945. To test whether this correlation is different from zero, we perform a test of hypothesis, shown in Exhibit 25. As you can see, we draw a conclusion similar to that for our test of the slope, but it is phrased in terms of the correlation between ROA and CAPEX: There is a significant correlation between ROA and CAPEX.

Exhibit 25 Test of the Correlation between ROA and CAPEX

Step 1	State the hypotheses.	H_0: $\rho = 0$ versus H_a: $\rho \neq 0$
Step 2	Identify the appropriate test statistic.	$t = \dfrac{r\sqrt{n-2}}{\sqrt{1-r^2}}.$ with 6 − 2 = 4 degrees of freedom.
Step 3	Specify the level of significance.	$\alpha = 5\%$.
Step 4	State the decision rule.	Critical t-values = ±2.776. Reject the null if the calculated t-statistic is less than −2.776 or greater than +2.776.

(continued)

Exhibit 25 (Continued)

Step 5	Calculate the test statistic.	$t = \dfrac{0.8945\sqrt{4}}{\sqrt{1 - 0.8001}} = 4.00131.$
Step 6	Make a decision.	Reject the null hypothesis of no correlation. There is sufficient evidence to indicate that the correlation between ROA and CAPEX is different from zero.

Another interesting feature of simple linear regression is that the test-statistic used to test the fit of the model (that is, the *F*-distributed test statistic) is related to the calculated *t*-statistic used to test whether the slope coefficient is equal to zero: $t^2 = F$; therefore, $4.00131^2 = 16.0104$.

What if instead we want to test whether there is a one-to-one relationship between ROA and CAPEX, implying a slope coefficient of 1.0. The hypotheses become H_0: $b_1 = 1$ and H_a: $b_1 \neq 1$. The calculated *t*-statistic is

$$t = \frac{1.25 - 1}{0.312398} = 0.80026.$$

This calculated test statistic falls within the bounds of the critical values, ±2.776, so we fail to reject the null hypothesis: There is not sufficient evidence to indicate that the slope is different from 1.0.

What if instead we want to test whether there is a positive slope or positive correlation, as our intuition suggests? In this case, all the steps are the same as in Exhibits 24 and 25 except the critical values because the tests are one sided. For a test of a positive slope or positive correlation, the critical value for a 5% level of significance is +2.132. We show the test of hypotheses for a positive slope and a positive correlation in Exhibit 26. Our conclusion is that there is sufficient evidence supporting both a positive slope and a positive correlation.

Exhibit 26 One-Sided Tests for the Slope and Correlation

		Test of the Slope	**Test of the Correlation**
Step 1	State the hypotheses.	H_0: $b_1 \leq 0$ versus H_a: $b_1 > 0$	H_0: $\rho \leq 0$ versus H_a: $\rho > 0$
Step 2	Identify the appropriate test statistic.	$t = \dfrac{\hat{b}_1 - B_1}{s_{\hat{b}_1}}$ with 6 − 2 = 4 degrees of freedom.	$t = \dfrac{r\sqrt{n-2}}{\sqrt{1-r^2}}.$ with 6 − 2 = 4 degrees of freedom.
Step 3	Specify the level of significance.	$\alpha = 5\%$.	$\alpha = 5\%$.
Step 4	State the decision rule.	Critical *t*-value = 2.132. Reject the null if the calculated *t*-statistic is greater than 2.132.	Critical *t*-value = 2.132. Reject the null if the calculated *t*-statistic is greater than 2.132.
Step 5	Calculate the test statistic.	$t = \dfrac{1.25 - 0}{0.312398} = 4.00131$	$t = \dfrac{0.8945\sqrt{4}}{\sqrt{1 - 0.8001}} = 4.00131$
Step 6	Make a decision.	Reject the null hypothesis. There is sufficient evidence to indicate that the slope is greater than zero.	Reject the null hypothesis. There is sufficient evidence to indicate that the correlation is greater than zero.

5.2 Hypothesis Tests of the Intercept

There are occasions when we want to test whether the population intercept is a specific value. As a reminder on how to interpret the intercept, consider the simple linear regression with a company's revenue growth rate as the dependent variable (Y) and the GDP growth rate of its home country as the independent variable (X). The intercept is the company's revenue growth rate if the GDP growth rate is 0%.

The equation for the standard error of the intercept, $s_{\hat{b}_0}$, is

$$s_{\hat{b}_0} = \sqrt{\frac{1}{n} + \frac{\bar{X}^2}{\sum_{i=1}^{n}(X_i - \bar{X})^2}}. \qquad (17)$$

We can test whether the intercept is different from the hypothesized value, B_0, by comparing the estimated intercept ($\hat{b}_0$) with the hypothesized intercept and then dividing the difference by the standard error of the intercept:

$$t_{intercept} = \frac{\hat{b}_0 - B_0}{s_{\hat{b}_0}} = \frac{\hat{b}_0 - B_0}{\sqrt{\frac{1}{n} + \frac{\bar{X}^2}{\sum_{i=1}^{n}(X_i - \bar{X})^2}}}.$$

In the ROA regression example, the intercept is 4.875%. Suppose we want to test whether the intercept is greater than 3%. The one-sided hypothesis test is shown in Exhibit 27. As you can see, we reject the null hypothesis. In other words, there is sufficient evidence that if there are no capital expenditures (CAPEX = 0), ROA is greater than 3%.

Exhibit 27 Test of Hypothesis for Intercept for Regression of ROA on CAPEX

Step 1	State the hypotheses.	H_0: $b_0 \le 3\%$ versus H_a: $b_0 > 3\%$
Step 2	Identify the appropriate test statistic.	$t_{intercept} = \frac{\hat{b}_0 - B_0}{s_{\hat{b}_0}}$ with 6 – 2 = 4 degrees of freedom.
Step 3	Specify the level of significance.	α = 5%.
Step 4	State the decision rule.	Critical *t*-value = 2.132. Reject the null if the calculated *t*-statistic is greater than 2.132.
Step 5	Calculate the test statistic.	$t_{intercept} = \frac{4.875 - 3.0}{\sqrt{\frac{1}{6} + \frac{6.1^2}{122.64}}} = \frac{1.875}{0.68562} = 2.73475$
Step 6	Make a decision.	Reject the null hypothesis. There is sufficient evidence to indicate that the intercept is greater than 3%.

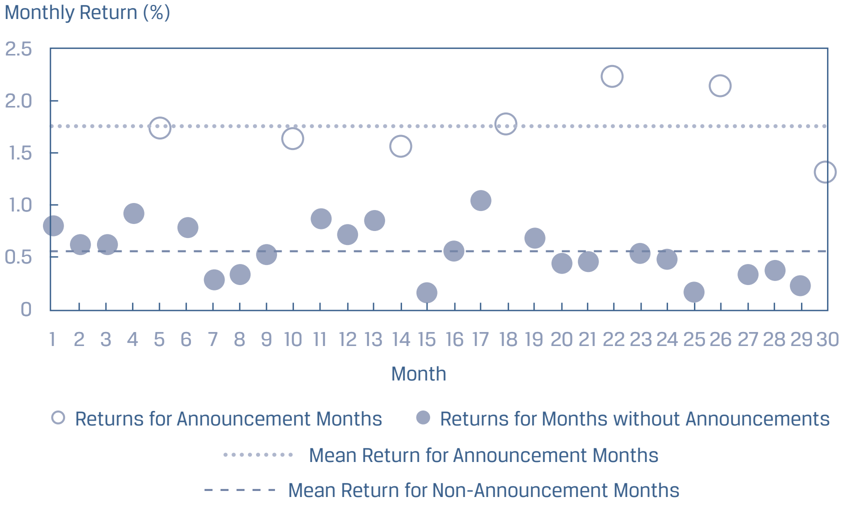
5.3 Hypothesis Tests of Slope When Independent Variable Is an Indicator Variable

Suppose we want to examine whether a company's quarterly earnings announcements influence its monthly stock returns. In this case, we could use an **indicator variable**, or dummy variable, that takes on only the values 0 or 1 as the independent variable. Consider the case of a company's monthly stock returns over a 30-month period. A simple linear regression model for investigating this question would be monthly returns, RET, regressed on the indicator variable, EARN, that takes on a value of 0 if there is no earnings announcement that month and 1 if there is an earnings announcement:

$$\text{RET}_i = b_0 + b_1\text{EARN}_i + \varepsilon_i.$$

This regression setup allows us to test whether there are different returns for earnings-announcement months versus non-earnings-announcement months. The observations and regression results are shown graphically in Exhibit 28.

Exhibit 28 Earnings Announcements, Dummy Variable, and Stock Returns



Clearly there are some months in which the returns are different from other months, and these correspond to months in which there was an earnings announcement. We estimate the simple linear regression model and perform hypothesis testing in the same manner as if the independent variable were a continuous variable. In a simple linear regression, the interpretation of the intercept is the predicted value of the dependent variable if the indicator variable is zero. Moreover, the slope, when the indicator variable is 1, is the difference in the means if we grouped the observations by the indicator variable. The results of the regression are given in Panel A of Exhibit 29.

Exhibit 29 Regression and Test of Differences Using an Indicator Variable

A. Regression Estimation Results

	Estimated Coefficients	Standard Error of Coefficients	Calculated Test Statistic
Intercept	0.5629	0.0560	10.0596
EARN	1.2098	0.1158	10.4435

Degrees of freedom = 28.
Critical *t*-values = +2.0484 (5% significance).

B. Test of Differences in Means

	RET for Earnings-Announcement Months	RET for Non-Earnings-Announcement Months	Difference in Means
Mean	1.7727	0.5629	1.2098
Variance	0.1052	0.0630	
Observations	7	23	
Pooled variance			0.07202
Calculated test statistic			10.4435

Degrees of freedom = 28.
Critical *t*-values = +2.0484 (5% significance).

We can see the following from Panel A of Exhibit 29:

- The intercept (0.5629) is the mean of the returns for non-earnings-announcement months.
- The slope coefficient (1.2098) is the difference in means of returns between earnings-announcement and non-announcement months.
- We reject the null hypothesis that the slope coefficient on EARN is equal to zero. We also reject the null hypothesis that the intercept is zero. The reason is that in both cases, the calculated test statistic exceeds the critical *t*-value.

We could also test whether the mean monthly return is the same for both the non-earnings-announcement months and the earnings-announcement months by testing the following:

$$H_0 : \mu_{RETearnings} = \mu_{RETNon-earnings} \text{ and } H_a : \mu_{RETearnings} \neq \mu_{RETNon-earnings}$$

The results of this hypothesis test are gleaned from Panel B of Exhibit 29. As you can see, we reject the null hypothesis that there is no difference in the mean RET for the earnings-announcement and non-earnings-announcements months at the 5% level of significance, since the calculated test statistic (10.4435) exceeds the critical value (2.0484).

5.4 Test of Hypotheses: Level of Significance and *p*-Values

The choice of significance level in hypothesis testing is always a matter of judgment. Analysts often choose the 0.05 level of significance, which indicates a 5% chance of rejecting the null hypothesis when, in fact, it is true (a Type I error, or false positive). Of course, decreasing the level of significance from 0.05 to 0.01 decreases the probability of Type I error, but it also increases the probability of Type II error—failing to reject the null hypothesis when, in fact, it is false (that is, a false negative).

The *p*-value is the smallest level of significance at which the null hypothesis can be rejected. The smaller the *p*-value, the smaller the chance of making a Type I error (i.e., rejecting a true null hypothesis), so the greater the likelihood the regression model is valid. For example, if the *p*-value is 0.005, we reject the null hypothesis that the true parameter is equal to zero at the 0.5% significance level (99.5% confidence). In most software packages, the *p*-values provided for regression coefficients are for a test of null hypothesis that the true parameter is equal to zero against the alternative that the parameter is not equal to zero.

In our ROA regression example, the calculated t-statistic for the test of whether the slope coefficient is zero is 4.00131. The p-value corresponding to this test statistic is 0.008, which means there is just a 0.8% chance of rejecting the null hypotheses when it is true. Comparing this p-value with the level of significance of 5% (and critical values of ±2.776) leads us to easily reject the null hypothesis of H_0: $b_1 = 0$.

How do we determine the p-values? Since this is the area in the distribution outside the calculated test statistic, we need to resort to software tools. For the p-value corresponding to the t = 4.00131 from the ROA regression example, we could use the following:

- **Excel** 1-T.DIST(4.00131,4,TRUE))*2
- **R** (1-pt(4.00131,4))*2
- **Python** from scipy.stats import t *and* (1 - t.cdf(4.00131,4))*2

EXAMPLE 6

Hypothesis Testing of Simple Linear Regression Results

An analyst is interested in interpreting the results of and performing tests of hypotheses for the market model estimation that regresses the daily return on ABC stock on the daily return on the fictitious Europe–Asia–Africa (EAA) Equity Index, his proxy for the stock market. He has generated the regression results presented in Exhibit 30.

Exhibit 30 Selected Results of Estimation of Market Model for ABC Stock

Standard error of the estimate (s_e)	1.26
Standard deviation of ABC stock returns	0.80
Standard deviation of EAA Equity Index returns	0.70
Number of observations	1,200
	Coefficients
Intercept	0.010
Slope of EAA Equity Index returns	0.982

1 If the critical t-values are ±1.96 (at the 5% significance level), is the slope coefficient different from zero?

2 If the critical t-values are ±1.96 (at the 5% significance level), is the slope coefficient different from 1.0?

Solutions

1 First, we calculate the variation of the independent variable using the standard deviation of the independent variable:

$$\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2 = \frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2}{n-1} \times (n-1).$$

So,

$$\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2 = 0.70^2 \times 1{,}199 = 587.51.$$

Next, the standard error of the estimated slope coefficient is

$$s_{\hat{b}_1} = \frac{s_e}{\sqrt{\sum_{i=1}^{n}(X_i - \bar{X})^2}} = \frac{1.26}{\sqrt{587.51}} = 0.051983,$$

and the test statistic is

$$t = \frac{\hat{b}_1 - B_1}{s_{\hat{b}_1}} = \frac{0.982 - 0}{0.051983} = 18.89079$$

The calculated test statistic is outside the bounds of ±1.96, so we reject the null hypothesis of a slope coefficient equal to zero.

2 The calculated test statistic for the test of whether the slope coefficient is equal to 1.0 is

$$t = \frac{0.982 - 1}{0.051983} = -0.3463.$$

The calculated test statistic is within the bounds of ±1.96, so we fail to reject the null hypothesis of a slope coefficient equal to 1.0, which is evidence that the true population slope may be 1.0.

PREDICTION USING SIMPLE LINEAR REGRESSION AND PREDICTION INTERVALS

6

g calculate and interpret the predicted value for the dependent variable, and a prediction interval for it, given an estimated linear regression model and a value for the independent variable

Financial analysts often want to use regression results to make predictions about a dependent variable. For example, we might ask, “How fast will the sales of XYZ Corporation grow this year if real GDP grows by 4%?” But we are not merely interested in making these forecasts; we also want to know how certain we can be about the forecasts’ results. A forecasted value of the dependent variable, $\hat{Y}_f$, is determined using the estimated intercept and slope, as well as the expected or forecasted independent variable, X_f:

$$\hat{Y}_f = \hat{b}_0 + \hat{b}_1 X_f \tag{18}$$

In our ROA regression model, if we forecast a company’s CAPEX to be 6%, the forecasted ROA based on our estimated equation is 12.375%:

$$\hat{Y}_f = 4.875 + \left(1.25 \times 6\right) = 12.375$$

However, we need to consider that the estimated regression line does not describe the relation between the dependent and independent variables perfectly; it is an average of the relation between the two variables. This is evident because the residuals are not all zero.

Therefore, an interval estimate of the forecast is needed to reflect this uncertainty. The estimated variance of the prediction error, s_f^2, of Y, given X, is

$$s_f^2 = s_e^2\left[1 + \frac{1}{n} + \frac{\left(X_f - \bar{X}\right)^2}{(n-1)s_X^2}\right] = s_e^2\left[1 + \frac{1}{n} + \frac{\left(X_f - \bar{X}\right)^2}{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2}\right],$$

and the **standard error of the forecast** is

$$s_f = s_e\sqrt{1 + \frac{1}{n} + \frac{(X_f - \bar{X})^2}{\sum_{i=1}^{n}(X_i - \bar{X})^2}}. \tag{19}$$

The standard error of the forecast depends on

- the standard error of the estimate, s_e;
- the number of observations, n;
- the forecasted value of the independent variable, X_f, used to predict the dependent variable and its deviation from the estimated mean, $\bar{X}$; and
- the variation of the independent variable.

We can see the following from the equation for the standard error of the forecast:

1 The better the fit of the regression model, the smaller the standard error of the estimate (s_e) and, therefore, the smaller standard error of the forecast.

2 The larger the sample size (n) in the regression estimation, the smaller the standard error of the forecast.

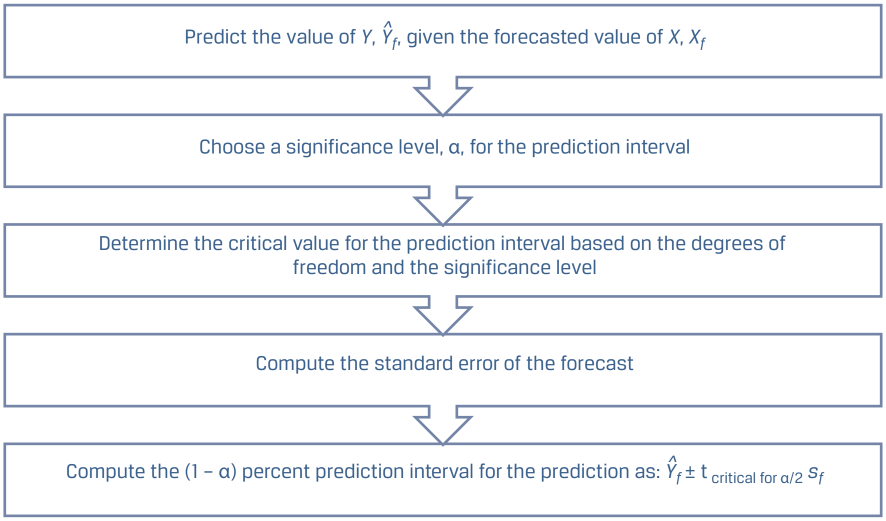
3 The closer the forecasted independent variable (X_f) is to the mean of the independent variable ($\bar{X}$) used in the regression estimation, the smaller the standard error of the forecast.

Once we have this estimate of the standard error of the forecast, determining a prediction interval around the predicted value of the dependent variable ($\hat{Y}_f$) is very similar to estimating a confidence interval around an estimated parameter. The prediction interval is

$$\hat{Y}_f \pm t_{critical\ for\ \alpha/2} s_f. \tag{20}$$

We outline the steps for developing the prediction interval in Exhibit 31.

Exhibit 31 Creating a Prediction Interval around the Predicted Dependent Variable



Predict the value of Y, $\hat{Y}_f$, given the forecasted value of X, X_f
Choose a significance level, α, for the prediction interval
Determine the critical value for the prediction interval based on the degrees of freedom and the significance level
Compute the standard error of the forecast
Compute the (1 – α) percent prediction interval for the prediction as: $\hat{Y}_f \pm t_{\text{critical for } \alpha/2}\, s_f$

For our ROA regression model, given that the forecasted value of CAPEX is 6.0, the predicted value of Y is 12.375:

$$\hat{Y}_f = 4.875 + 1.25X_f = 4.875 + (1.25 \times 6.0) = 12.375.$$

Assuming a 5% significance level (α), two sided, with n – 2 degrees of freedom (so, df = 4), the critical values for the prediction interval are ±2.776.

The standard error of the forecast is

$$s_f = 3.459588\sqrt{1 + \frac{1}{6} + \frac{(6 - 6.1)^2}{122.640}} = 3.459588\sqrt{1.166748} = 3.736912.$$

The 95% prediction interval then becomes

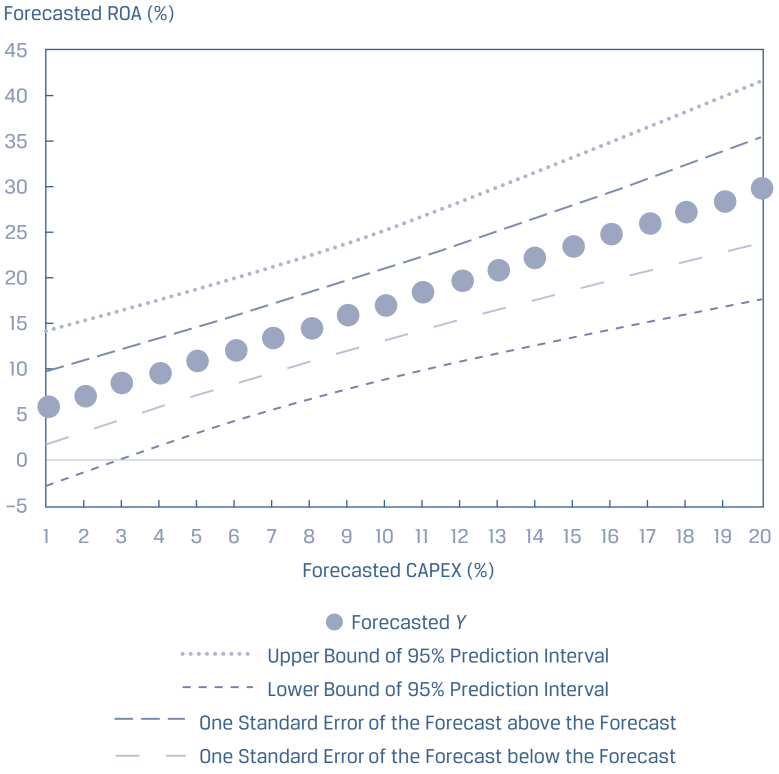
$$12.375 \pm 2.776(3.736912)$$

$$12.375 \pm 10.3737$$

$$\{2.0013 < \hat{Y}_f < 22.7487\}$$

For our ROA regression example, we can see how the standard error of the forecast (s_f) changes as our forecasted value of the independent variable gets farther from the mean of the independent variable $(X_f - \overline{X})$ in Exhibit 32. The mean of CAPEX is 6.1%, and the band that represents one standard error of the forecast, above and below the forecast, is minimized at that point and increases as the independent variable gets farther from $\overline{X}$.

Exhibit 32 ROA Forecasts and Standard Error of the Forecast



EXAMPLE 7

Predicting Net Profit Margin Using R&D Spending

Suppose we want to forecast a company's net profit margin (NPM) based on its research and development expenditures scaled by revenues (RDR), using the model estimated in Example 2 and the details provided in Exhibit 8. The regression model was estimated using data on eight companies as

$$\hat{Y}_f = 16.5 - 1.3X_f,$$

with a standard error of the estimate (s_e) of 1.8618987 and variance of RDR, $\dfrac{\sum_{i=1}^{n}(X_i - \bar{X})^2}{(n-1)}$, of 4.285714, as given.

1 What is the predicted value of NPM if the forecasted value of RDR is 5?

2 What is the standard error of the forecast (s_f) if the forecasted value of RDR is 5?

3 What is the 95% prediction interval for the predicted value of NPM using critical *t*-values (df = 6) of ±2.447?

4 What is the predicted value of NPM if the forecasted value of RDR is 15?

5 What is the standard error of the forecast if the forecasted value of RDR is 15?

6 What is the 95% prediction interval for the predicted value of NPM using critical *t*-values (df = 6) of ±2.447?

Solutions

1 The predicted value of NPM is 10: 16.5 − (1.3 × 5) = 10.

2 To derive the standard error of the forecast (s_f), we first have to calculate the variation of RDR. Then, we have the all the pieces to calculate s_f:

$$\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2 = 4.285714 \times 7 = 30.$$

$$s_f = 1.8618987\sqrt{1 + \frac{1}{8} + \frac{(5 - 7.5)^2}{30}} = 2.1499.$$

3 The 95% prediction interval for the predicted value of NPM is

$$\left\{10 \pm 2.447(2.1499)\right\}$$

$$\left\{4.7392 < \hat{Y}_f < 15.2608\right\}$$

4 The predicted value of NPM is −3: 16.5 − (1.3 × 15) = −3.

5 To derive the standard error of the forecast, we first must calculate the variation of RDR. Then, we can calculate s_f:

$$\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2 = 4.285714 \times 7 = 30.$$

$$s_f = 1.8618987\sqrt{1 + \frac{1}{8} + \frac{(15 - 7.5)^2}{30}} = 3.2249.$$

6 The 95% prediction interval for the predicted value of NPM is

$$\left\{-3 \pm 2.447(3.2249)\right\}$$

$$\left\{-10.8913 < \hat{Y}_f < 4.8913\right\}$$

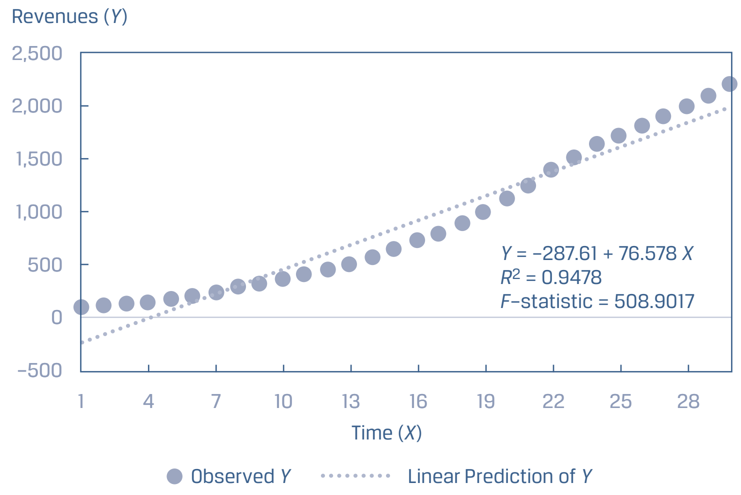
FUNCTIONAL FORMS FOR SIMPLE LINEAR REGRESSION

7

h describe different functional forms of simple linear regressions

Not every set of independent and dependent variables has a linear relation. In fact, we often see non-linear relationships in economic and financial data. Consider the revenues of a company over time illustrated in Exhibit 33, with revenues as the dependent (Y) variable and time as the independent (X) variable. Revenues grow at a rate of 15% per year for several years, but then the growth rate eventually declines to just 5% per year. Estimating this relationship as a simple linear model would understate the dependent variable, revenues, for some ranges of the independent variable, time, and would overstate it for other ranges of the independent variable.

Exhibit 33 Company Revenues over Time



We can still use the simple linear regression model, but we need to modify either the dependent or the independent variables to make it work well. This is the case with many different financial or economic data that you might use as dependent and independent variables in your regression analysis.

There are several different functional forms that can be used to potentially transform the data to enable their use in linear regression. These transformations include using the log (i.e., natural logarithm) of the dependent variable, the log of the independent variable, the reciprocal of the independent variable, the square of the independent variable, or the differencing of the independent variable. We illustrate and discuss three often-used functional forms, each of which involves log transformation:

1. the **log-lin model**, in which the dependent variable is logarithmic but the independent variable is linear;
2. the **lin-log model**, in which the dependent variable is linear but the independent variable is logarithmic; and
3. the **log-log model**, where both the dependent and independent variables are in logarithmic form.

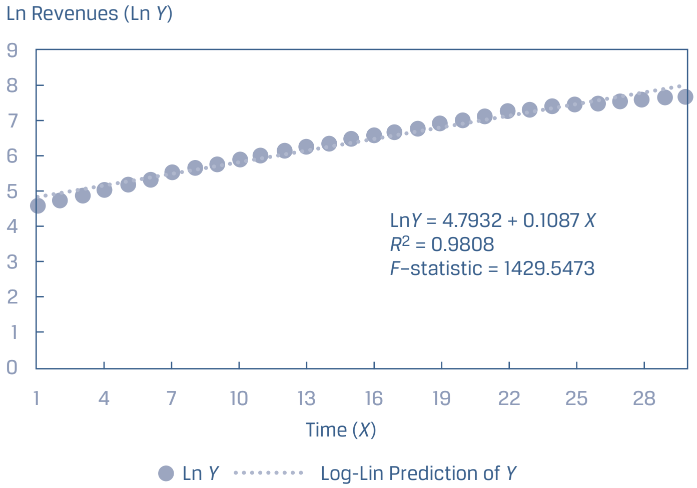
7.1 The Log-Lin Model

In the log-lin model, the dependent variable is in logarithmic form and the independent variable is not, as follows:

$$\ln Y_i = b_0 + b_1 X_i. \quad (21)$$

The slope coefficient in this model is the relative change in the dependent variable for an absolute change in the independent variable. We can transform the Y variable (revenues) in Exhibit 33 into its natural log (ln) and then fit the regression line, as we show in Exhibit 34. From this chart, we see that the log-lin model is a better fitting model than the simple linear regression model.

Exhibit 34 Log-Lin Model Applied to Company Revenues over Time



It is important to note that in working with a log-lin model, you must take care when making a forecast. For example, suppose the estimated regression model is ln $Y = -7 + 2X$. If X is 2.5%, then the forecasted value of ln Y is −2. In this case, the predicted value of Y is the antilog of −2, or $e^{-2} = 0.135335$. Another caution is that you cannot directly compare a log-lin model with a lin-lin model (that is, the regression of Y on X without any transformation) because the dependent variables are not in the same form – we would have to transform the R^2 and F-statistic to enable a comparison. However, looking at the residuals is helpful.

7.2 The Lin-Log Model

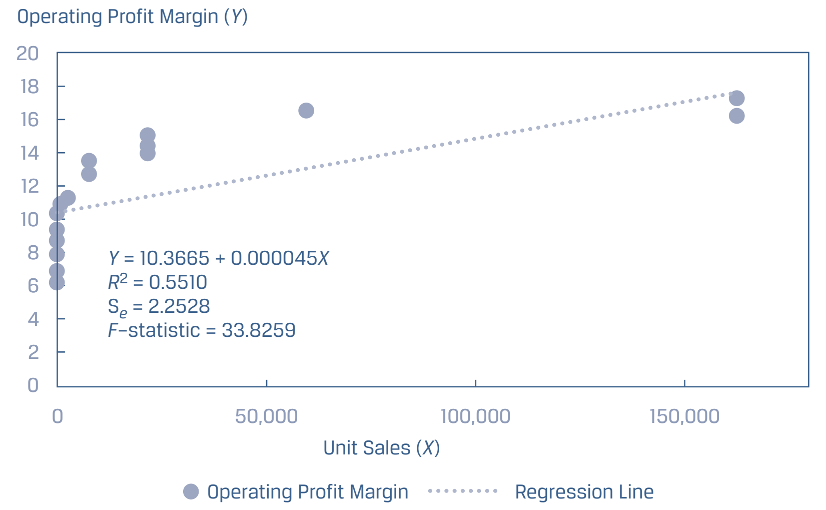
The lin-log model is similar to the log-lin model, but only the independent variable is in logarithmic form:

$$Y_i = b_0 + b_1 \ln X_i, \tag{22}$$

The slope coefficient in this regression model provides the absolute change in the dependent variable for a relative change in the independent variable.

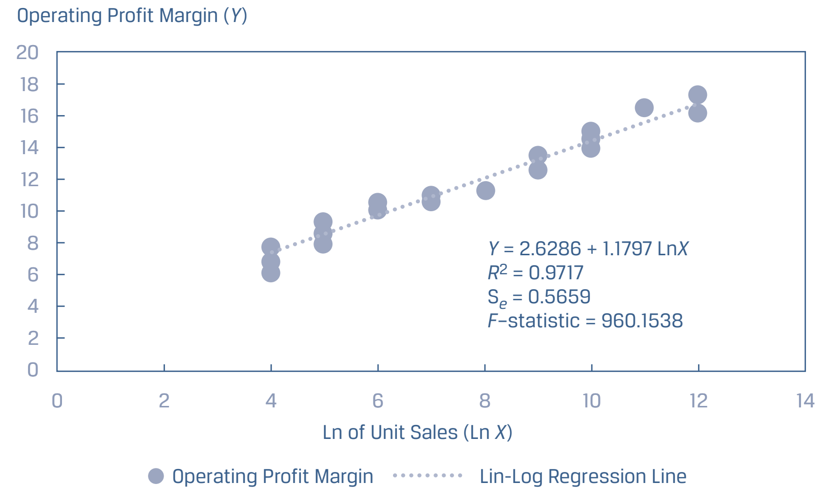
Suppose an analyst is examining the cross-sectional relationship between operating profit margin, the dependent variable (Y), and unit sales, the independent variable (X), and gathers data on a sample of 30 companies. The scatter plot and regression line for these observations are shown in Exhibit 35. Although the slope is different from zero at the 5% level (the calculated t-statistic on the slope is 5.8616, compared with critical t-values of ±2.048), given the R^2 of 55.10%, the issue is whether we can get a better fit by using a different functional form.

Exhibit 35 Relationship between Operating Profit Margin and Unit Sales



If instead we use the natural log of the unit sales as the independent variable in our model, we get a very different picture, as shown in Exhibit 36. The R^2 for the model of operating profit margin regressed on the natural log of unit sales jumps to 97.17%. Since the dependent variable is the same in both the original and transformed models, we can compare the standard error of the estimate: 2.2528 with the original independent variable and a much lower 0.5629 with the transformed independent variable. Clearly the log-transformed explanatory variable has resulted in a better fitting model.

Exhibit 36 Relationship Between Operating Profit Margin and Natural Logarithm of Unit Sales



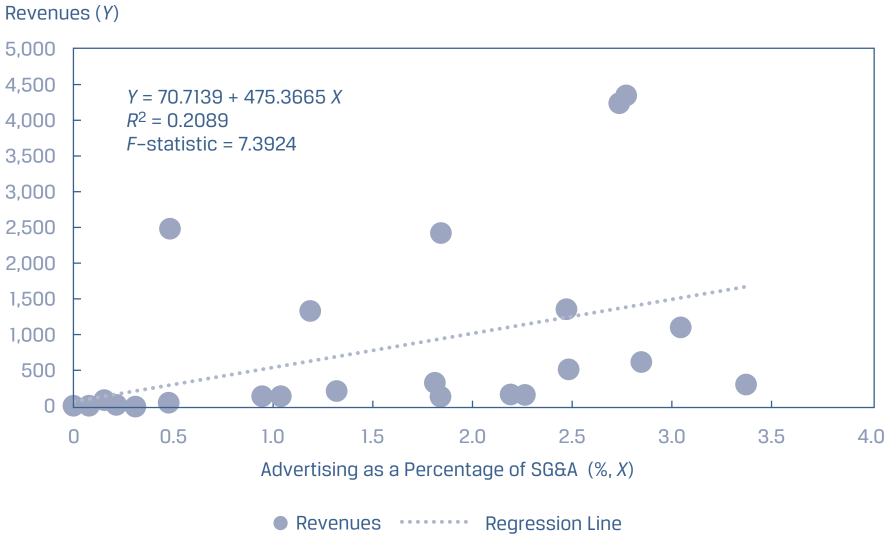
7.3 The Log-Log Model

The log-log model, in which both the dependent variable and the independent variable are linear in their logarithmic forms, is also referred to as the double-log model.

$$\ln Y_i = b_0 + b_1 \ln X_i. \quad (23)$$

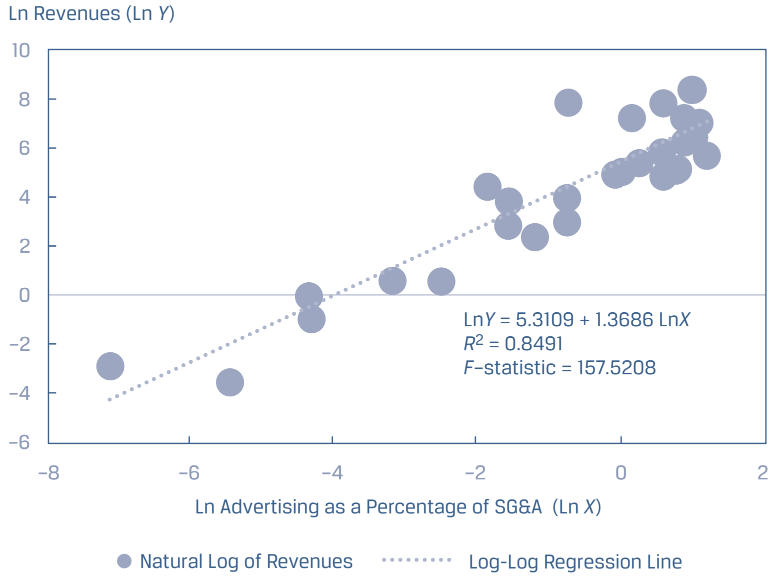
This model is useful in calculating elasticities because the slope coefficient is the relative change in the dependent variable for a relative change in the independent variable. Consider a cross-sectional model of company revenues (the *Y* variable) regressed on advertising spending as a percentage of selling, general, and administrative expenses, ADVERT (the *X* variable). As shown in Exhibit 37, a simple linear regression model results in a shallow regression line, with a coefficient of determination of just 20.89%.

Exhibit 37 Fitting a Linear Relation Between Revenues and Advertising Spending



However, if instead we use the natural logarithms of both the revenues and ADVERT, we get a much different picture of this relationship. As shown in Exhibit 38, the estimated regression line has a significant positive slope; the log-log model's R^2 increases by more than four times, from 20.89% to 84.91%; and the *F*-statistic jumps from 7.39 to 157.52. So, using the log-log transformation dramatically improves the regression model fit relative to our data.

Exhibit 38 Fitting a Log-Log Model of Revenues and Advertising Spending



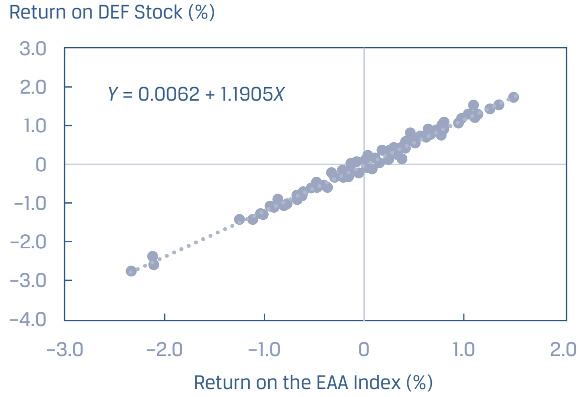
7.4 Selecting the Correct Functional Form

The key to fitting the appropriate functional form of a simple linear regression is examining the goodness of fit measures—the coefficient of determination (R^2), the F-statistic, and the standard error of the estimate (s_e)—as well as examining whether there are patterns in the residuals. In addition to fit statistics, most statistical packages provide plots of residuals as part of the regression output, which enables you to visually inspect the residuals. To reiterate an important point, what you want to see in these plots is random residuals.

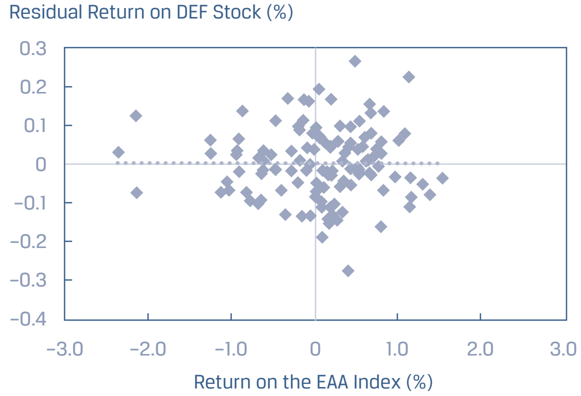
As an example, consider the relationship between the monthly returns on DEF stock and the monthly returns of the EAA Equity Index, as depicted in Panel A of Exhibit 39, with the regression line indicated. Using the equation for this regression line, we calculate the residuals and plot them against the EAA Equity Index, as shown in Panel B of Exhibit 39. The residuals appear to be random, bearing no relation to the independent variable. The distribution of the residuals, shown in Panel C of Exhibit 39, shows that the residuals are approximately normal. Using statistical software, we can investigate further by examining the distribution of the residuals, including using a normal probability plot or statistics to test for normality of the residuals.

Exhibit 39 Monthly Returns on DEF Stock Regressed on Returns on the EAA Index

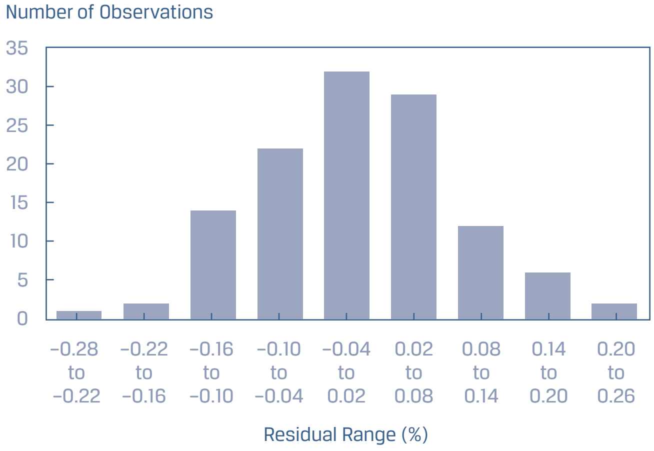
A. Scatterplot of Returns on DEF Stock and Return on the EAA Index



B. Scatterplot of Residuals and the Returns on the EAA Index



C. Histogram of Residuals



EXAMPLE 8

Comparing Functional Forms

An analyst is investigating the relationship between the annual growth in consumer spending (CONS) in a country and the annual growth in the country's GDP (GGDP). The analyst estimates the following two models:

	Model 1	Model 2
	$GGDP_i = b_0 + b_1 CONS_i + \varepsilon_i$	$GGDP_i = b_0 + b_1 \ln(CONS_i) + \varepsilon_i$
Intercept	1.040	1.006
Slope	0.669	1.994
R^2	0.788	0.867
Standard error of the estimate	0.404	0.320
F-statistic	141.558	247.040

1 Identify the functional form used in these models.

2 Explain which model has better goodness-of-fit with the sample data.

Solution

1 Model 1 is the simple linear regression with no variable transformation, whereas Model 2 is a lin-log model with the natural log of the variable CONS as the independent variable.

2 The lin-log model, Model 2, fits the data better. Since the dependent variable is the same for the two models, we can compare the fit of the models using either the relative measures (R^2 or F-statistic) or the absolute measure of fit, the standard error of the estimate. The standard error of the estimate is lower for Model 2, whereas the R^2 and F-statistic are higher for Model 2 compared with Model 1.

SUMMARY

- The dependent variable in a linear regression is the variable whose variability the regression model tries to explain. The independent variable is the variable whose variation the researcher uses to explain the variation of the dependent variable.
- If there is one independent variable in a linear regression and there are n observations of the dependent and independent variables, the regression model is $Y_i = b_0 + b_1 X_i + \varepsilon_i$, $i = 1, \ldots, n$, where Y_i is the dependent variable, X_i is the independent variable, and ε_i is the error term. In this model, the coefficients b_0 and b_1 are the population intercept and slope, respectively.

- The intercept is the expected value of the dependent variable when the independent variable has a value of zero. The slope coefficient is the estimate of the population slope of the regression line and is the expected change in the dependent variable for a one-unit change in the independent variable.
- The assumptions of the classic simple linear regression model are as follows:
  - Linearity: A linear relation exists between the dependent variable and the independent variable.
  - Homoskedasticity: The variance of the error term is the same for all observations.
  - Independence: The error term is uncorrelated across observations.
  - Normality: The error term is normally distributed.
- The estimated parameters in a simple linear regression model minimize the sum of the squared errors.
- The coefficient of determination, or R^2, measures the percentage of the total variation in the dependent variable explained by the independent variable.
- To test the fit of the simple linear regression, we can calculate an F-distributed test statistic and test the hypotheses H_0: $b_1 = 0$ versus H_a: $b_1 \neq 0$, with 1 and $n - 2$ degrees of freedom.
- The standard error of the estimate is an absolute measure of the fit of the model calculated as the square root of the mean square error.
- We can evaluate a regression model by testing whether the population value of a regression coefficient is equal to a particular hypothesized value. We do this by calculating a t-distributed test statistic that compares the estimated parameter with the hypothesized parameter, dividing this difference by the standard error of the coefficient.
- An indicator (or dummy) variable takes on only the values 0 or 1 and can be used as the independent variable in a simple linear regression. In such a model, the interpretation of the intercept is the predicted value of the dependent variable if the indicator variable is 0, and when the indicator variable is 1, the slope is the difference in the means if we grouped the observations by the indicator variable.
- We calculate a prediction interval for a regression coefficient using the estimated coefficient, the standard error of the estimated coefficient, and the critical value for the t-distributed test statistic based on the level of significance and the appropriate degrees of freedom, which are $n - 2$ for simple regression.
- We can make predictions for the dependent variable using an estimated linear regression by inserting the forecasted value of the independent variable into the estimated model.
- The standard error of the forecast is the product of the standard error of the estimate and a term that reflects the sample size of the regression, the variation of the independent variable, and the deviation between the forecasted value of the independent variable and the mean of the independent variable in the regression.

- The prediction interval for a particular forecasted value of the dependent variable is formed by using the forecasted value of the dependent variable and extending above and below this value a quantity that reflects the critical *t*-value corresponding to the degrees of freedom, the level of significance, and the standard error of the forecast.
- If the relationship between the independent variable and the dependent variable is not linear, we can often transform one or both of these variables to convert this relation to a linear form, which then allows the use of simple linear regression.

PRACTICE PROBLEMS

1 Julie Moon is an energy analyst examining electricity, oil, and natural gas consumption in different regions over different seasons. She ran a simple regression explaining the variation in energy consumption as a function of temperature. The total variation of the dependent variable was 140.58, and the explained variation was 60.16. She had 60 monthly observations.

A Calculate the coefficient of determination.

B Calculate the *F*-statistic to test the fit of the model.

C Calculate the standard error of the estimate of the regression estimation.

D Calculate the sample standard deviation of monthly energy consumption.

2 Homoskedasticity is best described as the situation in which the variance of the residuals of a regression is:

A zero.

B normally distributed.

C constant across observations.

The following information relates to Questions 3–6

An analyst is examining the annual growth of the money supply for a country over the past 30 years. This country experienced a central bank policy shift 15 years ago, which altered the approach to the management of the money supply. The analyst estimated a model using the annual growth rate in the money supply regressed on the variable (SHIFT) that takes on a value of 0 before the policy shift and 1 after. She estimated the following:

	Coefficients	Standard Error	*t*-Stat.
Intercept	5.767264	0.445229	12.95348
SHIFT	−5.13912	0.629649	−8.16188

Critical *t*-values, level of significance of 0.05:

One-sided, left side: −1.701

One-sided, right side: +1.701

Two-sided: ±2.048

3 The variable SHIFT is best described as:

A an indicator variable.

B a dependent variable.

C a continuous variable.

4 The interpretation of the intercept is the mean of the annual growth rate of the money supply:

A over the enter entire period.

© 2019 CFA Institute. All rights reserved.

- **B** after the shift in policy.
- **C** before the shift in policy.

5 The interpretation of the slope is the:

- **A** change in the annual growth rate of the money supply per year.
- **B** average annual growth rate of the money supply after the shift in policy.
- **C** difference in the average annual growth rate of the money supply from before to after the shift in policy.

6 Testing whether there is a change in the money supply growth after the shift in policy, using a 0.05 level of significance, we conclude that there is:

- **A** sufficient evidence that the money supply growth changed.
- **B** not enough evidence that the money supply growth is different from zero.
- **C** not enough evidence to indicate that the money supply growth changed.

---

7 You are examining the results of a regression estimation that attempts to explain the unit sales growth of a business you are researching. The analysis of variance output for the regression is given in the following table. The regression was based on five observations (n = 5).

Source	df	Sum of Squares	Mean Square	*F*	*p*-Value
Regression	1	88.0	88.0	36.667	0.00904
Residual	3	7.2	2.4		
Total	4	95.2			

- **A** Calculate the sample variance of the dependent variable using information in the table.
- **B** Calculate the coefficient of determination for this estimated model.
- **C** What hypothesis does the *F*-statistic test?
- **D** Is the *F*-test significant at the 0.05 significance level?
- **E** Calculate the standard error of the estimate.

8 An economist collected the monthly returns for KDL's portfolio and a diversified stock index. The data collected are shown in the following table:

Month	Portfolio Return (%)	Index Return (%)
1	1.11	−0.59
2	72.10	64.90
3	5.12	4.81
4	1.01	1.68
5	−1.72	−4.97
6	4.06	−2.06

The economist calculated the correlation between the two returns and found it to be 0.996. The regression results with the KDL return as the dependent variable and the index return as the independent variable are given as follows:

Regression Statistics	
R^2	0.9921
Standard error	2.8619
Observations	6

Source	df	Sum of Squares	Mean Square	*F*	*p*-Value
Regression	1	4,101.6205	4,101.6205	500.7921	0.0000
Residual	4	32.7611	8.1903		
Total	5	4,134.3815			

	Coefficients	Standard Error	*t*-Statistic	*p*-Value
Intercept	2.2521	1.2739	1.7679	0.1518
Index return (%)	1.0690	0.0478	22.3784	0.0000

When reviewing the results, Andrea Fusilier suspected that they were unreliable. She found that the returns for Month 2 should have been 7.21% and 6.49%, instead of the large values shown in the first table. Correcting these values resulted in a revised correlation of 0.824 and the following revised regression results:

Regression Statistics	
R^2	0.6784
Standard error	2.0624
Observations	6

Source	df	Sum of Squares	Mean Square	*F*	*p*-Value
Regression	1	35.8950	35.8950	8.4391	0.044
Residual	4	17.0137	4.2534		
Total	5	52.91			

	Coefficients	Standard Error	*t*-Statistic	*p*-Value
Intercept	2.2421	0.8635	2.5966	0.060
Slope	0.6217	0.2143	2.9050	0.044

Explain how the bad data affected the results.

The following information relates to Questions 9–12

Kenneth McCoin, CFA, is a challenging interviewer. Last year, he handed each job applicant a sheet of paper with the information in the following table, and he then asked several questions about regression analysis. Some of McCoin's questions, along with a sample of the answers he received to each, are given below. McCoin told the applicants that the independent variable is the ratio of net income to sales for restaurants with a market cap of more than $100 million and the dependent variable is the ratio of cash flow from operations to sales for those restaurants. Which of the choices provided is the best answer to each of McCoin's questions?

Regression Statistics	
R^2	0.7436
Standard error	0.0213
Observations	24

Source	**df**	**Sum of Squares**	**Mean Square**	***F***	***p*-Value**

Residual	22	0.010	0.000455		
Total	23	0.040			

	Coefficients	**Standard Error**	***t*-Statistic**	***p*-Value**
Intercept	0.077	0.007	11.328	0
Net income to sales (%)	0.826	0.103	7.988	0

9 The coefficient of determination is *closest* to:

A 0.7436.

B 0.8261.

C 0.8623.

10 The correlation between X and Y is *closest* to:

A −0.7436.

B 0.7436.

C 0.8623.

11 If the ratio of net income to sales for a restaurant is 5%, the predicted ratio of cash flow from operations (CFO) to sales is *closest* to:

A −4.054.

B 0.524.

C 4.207.

12 Is the relationship between the ratio of cash flow to operations and the ratio of net income to sales significant at the 0.05 level?

A No, because the R^2 is greater than 0.05

B No, because the p-values of the intercept and slope are less than 0.05

C Yes, because the p-values for F and t for the slope coefficient are less than 0.05

The following information relates to Questions 13–17

Howard Golub, CFA, is preparing to write a research report on Stellar Energy Corp. common stock. One of the world's largest companies, Stellar is in the business of refining and marketing oil. As part of his analysis, Golub wants to evaluate the sensitivity of the stock's returns to various economic factors. For example, a client recently asked Golub whether the price of Stellar Energy Corp. stock has tended to rise following increases in retail energy prices. Golub believes the association between the two variables is negative, but he does not know the strength of the association.

Golub directs his assistant, Jill Batten, to study the relationships between (1) Stellar monthly common stock returns and the previous month's percentage change in the US Consumer Price Index for Energy (CPIENG) and (2) Stellar monthly common stock returns and the previous month's percentage change in the US Producer Price Index for Crude Energy Materials (PPICEM). Golub wants Batten to run both a correlation and a linear regression analysis. In response, Batten compiles the summary statistics shown in Exhibit 1 for 248 months. All the data are in decimal form, where 0.01 indicates a 1% return. Batten also runs a regression analysis using Stellar monthly returns as the dependent variable and the monthly change in CPIENG as the independent variable. Exhibit 2 displays the results of this regression model.

Exhibit 1 Descriptive Statistics

	Stellar Common Stock Monthly Return	Lagged Monthly Change	
		CPIENG	PPICEM
Mean	0.0123	0.0023	0.0042
Standard deviation	0.0717	0.0160	0.0534
Covariance, Stellar vs. CPIENG	−0.00017		
Covariance, Stellar vs. PPICEM	−0.00048		
Covariance, CPIENG vs. PPICEM	0.00044		
Correlation, Stellar vs. CPIENG	−0.1452

	Coefficients	Standard Error	*t*-Statistic
Intercept	0.0138	0.0046	3.0275
CPIENG (%)	−0.6486	0.2818	−2.3014

Critical *t*-values

One-sided, left side: −1.651

One-sided, right side: +1.651

Two-sided: ±1.967

13 Which of the following best describes Batten's regression?

A Time-series regression

B Cross-sectional regression

C Time-series and cross-sectional regression

14 Based on the regression, if the CPIENG *decreases* by 1.0%, the expected return on Stellar common stock during the next period is *closest* to:

A 0.0073 (0.73%).

B 0.0138 (1.38%).

C 0.0203 (2.03%).

15 Based on Batten's regression model, the coefficient of determination indicates that:

A Stellar's returns explain 2.11% of the variability in CPIENG.

B Stellar's returns explain 14.52% of the variability in CPIENG.

C changes in CPIENG explain 2.11% of the variability in Stellar's returns.

16 For Batten's regression model, 0.0710 is the standard deviation of:

A the dependent variable.

B the residuals from the regression.

C the predicted dependent variable from the regression.

17 For the analysis run by Batten, which of the following is an *incorrect* conclusion from the regression output?

A The estimated intercept from Batten's regression is statistically different from zero at the 0.05 level of significance.

B In the month after the CPIENG declines, Stellar's common stock is expected to exhibit a positive return.

C Viewed in combination, the slope and intercept coefficients from Batten's regression are not statistically different from zero at the 0.05 level of significance.

The following information relates to Questions 18–26

Anh Liu is an analyst researching whether a company's debt burden affects investors' decision to short the company's stock. She calculates the short interest ratio (the ratio of short interest to average daily share volume, expressed in days) for 50 companies as of the end of 2016 and compares this ratio with the companies' debt ratio (the ratio of total liabilities to total assets, expressed in decimal form).

Liu provides a number of statistics in Exhibit 1. She also estimates a simple regression to investigate the effect of the debt ratio on a company's short interest ratio. The results of this simple regression, including the analysis of variance (ANOVA), are shown in Exhibit 2.

In addition to estimating a regression equation, Liu graphs the 50 observations using a scatter plot, with the short interest ratio on the vertical axis and the debt ratio on the horizontal axis.

Exhibit 1 Summary Statistics

Statistic	Debt Ratio X_i	Short Interest Ratio Y_i
Sum	19.8550	192.3000
Sum of squared deviations from the mean	$\sum_{i=1}^{n}\left(X_i - \bar{X}\right)^2 = 2.2225.$	$\sum_{i=1}^{n}\left(Y_i - \bar{Y}\right)^2 = 412.2042.$
Sum of cross-products of deviations from the mean	$\sum_{i=1}^{n}\left(X_i - \bar{X}\right)\left(Y_i - \bar{Y}\right) = -9.2430.$	

Exhibit 2 Regression of the Short Interest Ratio on the Debt Ratio

ANOVA	Degrees of Freedom (df)	Sum of Squares	Mean Square
Regression	1	38.4404	38.4404
Residual	48	373.7638	7.7867
Total	49	412.2042	

Regression Statistics	
R^2	0.0933
Standard error of estimate	2.7905
Observations	50

	Coefficients	Standard Error	*t*-Statistic
Intercept	5.4975	0.8416	6.5322
Debt ratio (%)	–4.1589	1.8718	–2.2219

Critical t-values for a 0.05 level of significance:

One-sided, left side: −1.677

One-sided, right side: +1.677

Two-sided: ±2.011

Liu is considering three interpretations of these results for her report on the relationship between debt ratios and short interest ratios:

Interpretation 1	Companies' higher debt ratios cause lower short interest ratios.
Interpretation 2	Companies' higher short interest ratios cause higher debt ratios.
Interpretation 3	Companies with higher debt ratios tend to have lower short interest ratios.

She is especially interested in using her estimation results to predict the short interest ratio for MQD Corporation, which has a debt ratio of 0.40.

18 Based on Exhibits 1 and 2, if Liu were to graph the 50 observations, the scatter plot summarizing this relation would be *best* described as:

A horizontal.

B upward sloping.

C downward sloping.

19 Based on Exhibit 1, the sample covariance is *closest to*:

A −9.2430.

B −0.1886.

C 8.4123.

20 Based on Exhibits 1 and 2, the correlation between the debt ratio and the short interest ratio is *closest to*:

A −0.3054.

B 0.0933.

C 0.3054.

21 Which of the interpretations *best* describes Liu's findings?

A Interpretation 1

B Interpretation 2

C Interpretation 3

22 The dependent variable in Liu's regression analysis is the:

A intercept.

B debt ratio.

C short interest ratio.

23 Based on Exhibit 2, the degrees of freedom for the t-test of the slope coefficient in this regression are:

A 48.

B 49.

C 50.

24 Which of the following should Liu conclude from the results shown in Exhibit 2?

A The average short interest ratio is 5.4975.

B The estimated slope coefficient is different from zero at the 0.05 level of significance.

C The debt ratio explains 30.54% of the variation in the short interest ratio.

25 Based on Exhibit 2, the short interest ratio expected for MQD Corporation is *closest* to:

A 3.8339.

B 5.4975.

C 6.2462.

26 Based on Liu's regression results in Exhibit 2, the *F*-statistic for testing whether the slope coefficient is equal to zero is *closest* to:

A −2.2219.

B 3.5036.

C 4.9367.

The following information relates to Questions 27–31

Elena Vasileva recently joined EnergyInvest as a junior portfolio analyst. Vasileva's supervisor asks her to evaluate a potential investment opportunity in Amtex, a multinational oil and gas corporation based in the United States. Vasileva's supervisor suggests using regression analysis to examine the relation between Amtex shares and returns on crude oil.

Vasileva notes the following assumptions of regression analysis:

Assumption 1	The error term is uncorrelated across observations.
Assumption 2	The variance of the error term is the same for all observations.
Assumption 3	The dependent variable is normally distributed.

Vasileva runs a regression of Amtex share returns on crude oil returns using the monthly data she collected. Selected data used in the regression are presented in Exhibit 1, and selected regression output is presented in Exhibit 2. She uses a 1% level of significance in all her tests.

Exhibit 1 Selected Data for Crude Oil Returns and Amtex Share Returns

	Oil Return (X_i)	Amtex Return (Y_i)	Cross-Product $(X_i - \bar{X})(Y_i - \bar{Y})$	Predicted Amtex Return $\hat{Y}_i$	Regression Residual $Y_i - \hat{Y}_i$	Squared Residual $(Y_i - \hat{Y}_i)^2$
Month 1	−0.032000	0.033145	−0.000388	0.002011	−0.031134	0.000969
⋮	⋮	⋮	⋮	⋮	⋮	⋮
Month 36	0.028636	0.062334	0.002663	0.016282	−0.046053	0.002121
Sum			0.085598			0.071475
Average	−0.018056	0.005293				

Exhibit 2 Selected Regression Output, Dependent Variable: Amtex Share Return

	Coefficient	Standard Error
Intercept	0.0095	0.0078
Oil return	0.2354	0.0760

Critical t-values for a 1% level of significance:

One-sided, left side: −2.441

One-sided, right side: +2.441

Two-sided: ±2.728

Vasileva expects the crude oil return next month, Month 37, to be −0.01. She computes the standard error of the forecast to be 0.0469.

27 Which of Vasileva's assumptions regarding regression analysis is *incorrect*?

A Assumption 1

B Assumption 2

C Assumption 3

28 Based on Exhibit 1, the standard error of the estimate is *closest* to:

A 0.04456.

B 0.04585.

C 0.05018.

29 Based on Exhibit 2, Vasileva should reject the null hypothesis that:

A the slope is less than or equal to 0.15.

B the intercept is less than or equal to zero.

C crude oil returns do not explain Amtex share returns.

30 Based on Exhibit 2 and Vasileva's prediction of the crude oil return for Month 37, the estimate of Amtex share return for Month 37 is *closest* to:

A −0.0024.

B 0.0071.

C 0.0119.

31 Using information from Exhibit 2, the 99% prediction interval for Amtex share return for Month 37 is *best* described as:

A $\hat{Y}_f \pm 0.0053$.

B $\hat{Y}_f \pm 0.0469$.

C $\hat{Y}_f \pm 0.1279$.

The following information relates to Questions 32–34

Doug Abitbol is a portfolio manager for Polyi Investments, a hedge fund that trades in the United States. Abitbol manages the hedge fund with the help of Robert Olabudo, a junior portfolio manager.

Abitbol looks at economists' inflation forecasts and would like to examine the relationship between the US Consumer Price Index (US CPI) consensus forecast and the actual US CPI using regression analysis. Olabudo estimates regression coefficients to test whether the consensus forecast is unbiased. If the consensus forecasts are unbiased, the intercept should be 0.0 and the slope will be equal to 1.0. Regression results are presented in Exhibit 1. Additionally, Olabudo calculates the 95% prediction interval of the actual CPI using a US CPI consensus forecast of 2.8.

Exhibit 1 Regression Output: Estimating US CPI

Regression Statistics

R^2	0.9859		
Standard error of estimate	0.0009		
Observations	60		
	Coefficients	**Standard Error**	***t*-Statistic**
Intercept	0.0001	0.0002	0.5000
US CPI consensus forecast	0.9830	0.0155	63.4194

Notes:

1 The absolute value of the critical value for the *t*-statistic is 2.002 at the 5% level of significance.

2 The standard deviation of the US CPI consensus forecast is s_x = 0.7539.

3 The mean of the US CPI consensus forecast is $\overline{X}$ = 1.3350.

Finally, Abitbol and Olabudo discuss the forecast and forecast interval:

Observation 1	For a given confidence level, the forecast interval is the same no matter the US CPI consensus forecast.
Observation 2	A larger standard error of the estimate will result in a wider confidence interval.

32 Based on Exhibit 1, Olabudo should:

- A conclude that the inflation predictions are unbiased.
- B reject the null hypothesis that the slope coefficient equals one.
- C reject the null hypothesis that the intercept coefficient equals zero.

33 Based on Exhibit 1, Olabudo should calculate a prediction interval for the actual US CPI *closest* to:

- A 2.7506 to 2.7544.
- B 2.7521 to 2.7529.
- C 2.7981 to 2.8019.

34 Which of Olabudo's observations of forecasting is correct?

A Only Observation 1

B Only Observation 2

C Both Observation 1 and Observations 2

The following information relates to Questions 35–38

Espey Jones is examining the relation between the net profit margin (NPM) of companies, in percent, and their fixed asset turnover (FATO). He collected a sample of 35 companies for the most recent fiscal year and fit several different functional forms, settling on the following model:

$$\ln\text{NPM}_i = b_0 + b_1\text{FATO}_i.$$

The results of this estimation are provided in Exhibit 1.

Exhibit 1 Results of Regressing NPM on FATO

35 The coefficient of determination is *closest* to:

A 0.0211.

B 0.9789.

C 0.9894.

36 The standard error of the estimate is *closest* to:

A 0.2631.

B 1.7849.

C 38.5579.

37 At a 0.01 level of significance, Jones should conclude that:

A the mean net profit margin is 0.5987%.

B the variation of the fixed asset turnover explains the variation of the natural log of the net profit margin.

C a change in the fixed asset turnover from 3 to 4 times is likely to result in a change in the net profit margin of 0.5987%.

38 The predicted net profit margin for a company with a fixed asset turnover of 2 times is *closest* to:

A 1.1889%.

B 1.8043%.

C 3.2835%

SOLUTIONS

1 **A** The coefficient of determination is 0.4279:

$$\frac{\text{Explained variation}}{\text{Total variation}} = \frac{60.16}{140.58} = 0.4279.$$

B $$F = \frac{60.16 \big/ 1}{(140.58 - 60.16) \big/ (60 - 2)} = \frac{60.16}{1.3866} = 43.3882.$$

C Begin with the sum of squares error of 140.58 − 60.16 = 80.42. Then calculate the mean square error of 80.42 ÷ (60 − 2) = 1.38655. The standard error of the estimate is the square root of the mean square error: $s_e = \sqrt{1.38655} = 1.1775$.

D The sample variance of the dependent variable uses the total variation of the dependent variable and divides it by the number of observations less one:

$$\sum_{i=1}^{n} \frac{\left(Y_i - \overline{Y}\right)^2}{n - 1} = \frac{\text{Total variation}}{n - 1} = \frac{140.58}{60 - 1} = 2.3827.$$

The sample standard deviation of the dependent variable is the square root of the variance, or $\sqrt{2.3827} = 1.544$.

2 C is correct. Homoskedasticity is the situation in which the variance of the residuals is constant across the observations.

3 A is correct. SHIFT is an indicator or dummy variable because it takes on only the values 0 and 1.

4 C is correct. In a simple regression with a single indicator variable, the intercept is the mean of the dependent variable when the indicator variable takes on a value of zero, which is before the shift in policy in this case.

5 C is correct. Whereas the intercept is the average of the dependent variable when the indicator variable is zero (that is, before the shift in policy), the slope is the difference in the mean of the dependent variable from before to after the change in policy.

6 A is correct. The null hypothesis of no difference in the annual growth rate is rejected at the 0.05 level: The calculated test statistic of −8.16188 is outside the bounds of ±2.048.

7 **A** The sample variance of the dependent variable is the sum of squares total divided by its degrees of freedom ($n - 1 = 5 - 1 = 4$, as given). Thus, the sample variance of the dependent variable is 95.2 ÷ 4 = 23.8.

B The coefficient of determination = 88.0 ÷ 95.2 = 0.92437.

C The F-statistic tests whether all the slope coefficients in a linear regression are equal to zero.

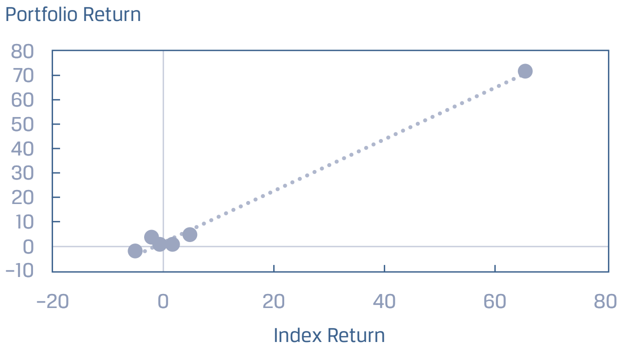
D The calculated value of the F-statistic is 36.667, as shown in the table. The corresponding p-value is less than 0.05, so you reject the null hypothesis of a slope equal to zero.

E The standard error of the estimate is the square root of the mean square error: $s_e = \sqrt{2.4} = 1.54919$.

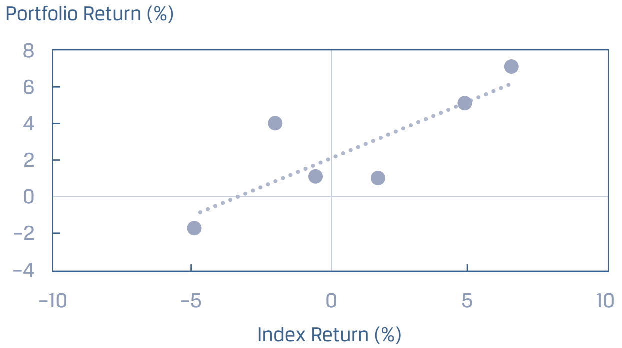
8 The Month 2 data point is an outlier, lying far away from the other data values. Because this outlier was caused by a data entry error, correcting the outlier improves the validity and reliability of the regression. In this case, revised R^2 is lower (from 0.9921 to 0.6784). The outliers created the illusion of a better fit from the higher R^2; the outliers altered the estimate of the slope. The standard error of the estimate is lower when the data error is corrected (from 2.8619 to 2.0624), as a result of the lower mean square error. However, at a 0.05 level of significance, both models fit well. The difference in the fit is illustrated in Exhibit 1.

Exhibit 1 The Fit of the Model with and without Data Errors

A. Before the Data Errors Are Corrected



B. After the Data Errors Are Corrected



9 A is correct. The coefficient of determination is the same as R^2, which is 0.7436 in the table.

10 C is correct. Because the slope is positive, the correlation between X and Y is simply the square root of the coefficient of determination: $\sqrt{0.7436} = 0.8623$.

11 C is correct. To make a prediction using the regression model, multiply the slope coefficient by the forecast of the independent variable and add the result to the intercept. Expected value of CFO to sales = 0.077 + (0.826 × 5) = 4.207.

12 C is correct. The p-value is the smallest level of significance at which the null hypotheses concerning the slope coefficient can be rejected. In this case, the p-value is less than 0.05, and thus the regression of the ratio of cash flow from operations to sales on the ratio of net income to sales is significant at the 5% level.

13 A is correct. The data are observations over time.

14 C is correct. From the regression equation, Expected return = 0.0138 + (−0.6486 × −0.01) = 0.0138 + 0.006486 = 0.0203, or 2.03%.

15 C is correct. R^2 is the coefficient of determination. In this case, it shows that 2.11% of the variability in Stellar's returns is explained by changes in CPIENG.

16 B is correct. The standard error of the estimate is the standard deviation of the regression residuals.

17 C is the correct response because it is a false statement. The slope and intercept are both statistically different from zero at the 0.05 level of significance.

18 C is correct. The slope coefficient (shown in Exhibit 2) is negative. We could also determine this by looking at the cross-product (Exhibit 1), which is negative.

19 B is correct. The sample covariance is calculated as

$$\frac{\sum_{i=1}^{n}\left(X_i - \bar{X}\right)\left(Y_i - \bar{Y}\right)}{n-1} = -9.2430 \div 49 = -0.1886$$

20 A is correct. In simple regression, the R^2 is the square of the pairwise correlation. Because the slope coefficient is negative, the correlation is the negative of the square root of 0.0933, or −0.3054.

21 C is correct. Conclusions cannot be drawn regarding causation; they can be drawn only about association; therefore, Interpretations 1 and 2 are incorrect.

22 C is correct. Liu explains the variation of the short interest ratio using the variation of the debt ratio.

23 A is correct. The degrees of freedom are the number of observations minus the number of parameters estimated, which equals 2 in this case (the intercept and the slope coefficient). The number of degrees of freedom is 50 − 2 = 48.

24 B is correct. The t-statistic is −2.2219, which is outside the bounds created by the critical t-values of ±2.011 for a two-tailed test with a 5% significance level. The value of 2.011 is the critical t-value for the 5% level of significance (2.5% in one tail) for 48 degrees of freedom. A is incorrect because the mean of the short interest ratio is 192.3 ÷ 50 = 3.846. C is incorrect because the debt ratio explains 9.33% of the variation of the short interest ratio.

25 A is correct. The predicted value of the short interest ratio = 5.4975 + (−4.1589 × 0.40) = 5.4975 − 1.6636 = 3.8339.

26 C is correct because $F = \dfrac{\text{Mean square regression}}{\text{Mean square error}} = \dfrac{38.4404}{7.7867} = 4.9367$.

27 C is correct. The assumptions of the linear regression model are that (1) the relationship between the dependent variable and the independent variable is linear in the parameters b_0 and b_1, (2) the residuals are independent of one another, (3) the variance of the error term is the same for all observations, and (4) the error term is normally distributed. Assumption 3 is incorrect because the dependent variable need not be normally distributed.

28 B is correct. The standard error of the estimate for a linear regression model with one independent variable is calculated as the square root of the mean square error:

$$s_e = \sqrt{\frac{0.071475}{34}} = 0.04585.$$

29 C is correct. Crude oil returns explain the Amtex share returns if the slope coefficient is statistically different from zero. The slope coefficient is 0.2354, and the calculated t-statistic is

$$t = \frac{0.2354 - 0.0000}{0.0760} = 3.0974,$$

which is outside the bounds of the critical values of ±2.728.

Therefore, Vasileva should reject the null hypothesis that crude oil returns do not explain Amtex share returns, because the slope coefficient is statistically different from zero.

A is incorrect because the calculated t-statistic for testing the slope against 0.15 is $t = \frac{0.2354 - 0.1500}{0.0760} = 1.1237$, which is less than the critical value of +2.441.

B is incorrect because the calculated t-statistic is $t = \frac{0.0095 - 0.0000}{0.0078} = 1.2179$, which is less than the critical value of +2.441.

30 B is correct. The predicted value of the dependent variable, Amtex share return, given the value of the independent variable, crude oil return, −0.01, is calculated as $\hat{Y} = \hat{b}_0 + \hat{b}_1 X_i = 0.0095 + \left[0.2354 \times (-0.01)\right] = 0.0071$.

31 C is correct. The predicted share return is 0.0095 + [0.2354 × (−0.01)] = 0.0071. The lower limit for the prediction interval is 0.0071 − (2.728 × 0.0469) = −0.1208, and the upper limit for the prediction interval is 0.0071 + (2.728 × 0.0469) = 0.1350.

A is incorrect because the bounds of the interval should be based on the standard error of the forecast and the critical t-value, not on the mean of the dependent variable.

B is incorrect because bounds of the interval are based on the product of the standard error of the forecast *and* the critical t-value, not simply the standard error of the forecast.

32 A is correct. We fail to reject the null hypothesis of a slope equal to one, and we fail to reject the null hypothesis of an intercept equal to zero. The test of the slope equal to 1.0 is $t = \frac{0.9830 - 1.000}{0.0155} = -1.09677$. The test of the intercept equal to 0.0 is $t = \frac{0.0001 - 0.0000}{.00002} = 0.5000$. Therefore, we conclude that the forecasts are unbiased.

33 A is correct. The forecast interval for inflation is calculated in three steps:

Step 1. Make the prediction given the US CPI forecast of 2.8:

$$\begin{aligned}\widehat{Y} &= b_0 + b_1 X \\ &= 0.0001 + (0.9830 \times 2.8) \\ &= 2.7525.\end{aligned}$$

Step 2. Compute the variance of the prediction error:

$$s_f^2 = s_e^2\left\{1 + (1/n) + \left[\left(X_f - \bar{X}\right)^2\right]\Big/\left[(n-1) \times s_x^2\right]\right\}.$$

$$s_f^2 = 0.0009^2\left\{1 + (1/60) + \left[(2.8 - 1.3350)^2\right]\Big/\left[(60 - 1) \times 0.7539^2\right]\right\}.$$

$$s_f^2 = 0.00000088.$$

$$s_f = 0.0009.$$

Step 3. Compute the prediction interval:

$$\hat{Y} \pm t_c \times s_f$$

2.7525 ± (2.0 × 0.0009)

Lower bound: 2.7525 – (2.0 × 0.0009) = 2.7506.

Upper bound: 2.7525 + (2.0 × 0.0009) = 2.7544.

So, given the US CPI forecast of 2.8, the 95% prediction interval is 2.7506 to 2.7544.

34 B is correct. The confidence level influences the width of the forecast interval through the critical *t*-value that is used to calculate the distance from the forecasted value: The larger the confidence level, the wider the interval. Therefore, Observation 1 is not correct.

Observation 2 is correct. The greater the standard error of the estimate, the greater the standard error of the forecast.

35 B is correct. The coefficient of determination is 102.9152 ÷ 105.1303 = 0.9789.

36 A is correct. The standard error is the square root of the mean square error, or $\sqrt{0.0692} = 0.2631$.

37 B is correct. The *p*-value corresponding to the slope is less than 0.01, so we reject the null hypothesis of a zero slope, concluding that the fixed asset turnover explains the natural log of the net profit margin.

38 C is correct. The predicted natural log of the net profit margin is 0.5987 + (2 × 0.2951) = 1.1889. The predicted net profit margin is $e^{1.1889} = 3.2835\%$.

For example, to find the *z*-value leaving 2.5 percent of the area/probability in the lower tail, find the element 0.0250 in the body of the table. Read −1.90 at the left end of the element's row and 0.06 at the top of the element's column, to give −1.90 − 0.06 = −1.96. *Table generated with Excel.*

To find a critical t-value, enter the table with df and a specified value for α, the significance level. For example, with 5 df, $\alpha = 0.05$ and a one-tailed test, the desired probability in the tail would be $p = 0.05$ and the critical t-value would be $t(5, 0.05) = 2.015$. With $\alpha = 0.05$ and a two-tailed test, the desired probability in each tail would be $p = 0.025 = \alpha/2$, giving $t(0.025) = 2.571$. *Table generated using Excel.*

Glossary

A priori probability A probability based on logical analysis rather than on observation or personal judgment.

Abandonment option The ability to terminate an investment at some future time if the financial results are disappointing.

Abnormal return The amount by which a security's actual return differs from its expected return, given the security's risk and the market's return.

Absolute advantage A country's ability to produce a good or service at a lower absolute cost than its trading partner.

Absolute dispersion The amount of variability present without comparison to any reference point or benchmark.

Absolute frequency The actual number of observations counted for each unique value of the variable (also called raw frequency).

Accelerated book build An offering of securities by an investment bank acting as principal that is accomplished in only one or two days.

Accelerated methods Depreciation methods that allocate a relatively large proportion of the cost of an asset to the early years of the asset's useful life.

Accounting costs Monetary value of economic resources used in performing an activity. These can be explicit, out-of-pocket, current payments, or an allocation of historical payments (depreciation) for resources. They do not include implicit opportunity costs.

Accounting profit Income as reported on the income statement, in accordance with prevailing accounting standards, before the provisions for income tax expense. Also called *income before taxes* or *pretax income*.

Accounts payable Amounts that a business owes to its vendors for goods and services that were purchased from them but which have not yet been paid.

Accrued expenses Liabilities related to expenses that have been incurred but not yet paid as of the end of an accounting period—an example of an accrued expense is rent that has been incurred but not yet paid, resulting in a liability "rent payable." Also called *accrued liabilities*.

Accrued interest Interest earned but not yet paid.

Acquisition method A method of accounting for a business combination where the acquirer is required to measure each identifiable asset and liability at fair value. This method was the result of a joint project of the IASB and FASB aiming at convergence in standards for the accounting of business combinations.

Action lag Delay from policy decisions to implementation.

Active investment An approach to investing in which the investor seeks to outperform a given benchmark.

Active return The return on a portfolio minus the return on the portfolio's benchmark.

Activity ratios Ratios that measure how efficiently a company performs day-to-day tasks, such as the collection of receivables and management of inventory. Also called *asset utilization ratios* or *operating efficiency ratios*.

Add-on rates Bank certificates of deposit, repos, and indexes such as Libor and Euribor are quoted on an add-on rate basis (bond equivalent yield basis).

Addition rule for probabilities A principle stating that the probability that *A* or *B* occurs (both occur) equals the probability that *A* occurs, plus the probability that *B* occurs, minus the probability that both *A* and *B* occur.

Agency bond See *quasi-government bond*.

Agency costs Costs associated with the conflict of interest present between principals and agents when a company is managed by non-owners. Agency costs result from the inherent conflicts of interest between managers, bondholders, and equity owners.

Agency costs of debt Costs arising from conflicts of interest between managers and debtholders.

Agency costs of equity The smaller the stake managers have in the company, the less their share in bearing the cost of excessive perquisite consumption—consequently, the less their desire to give their best efforts in running the company.

Agency RMBS In the United States, securities backed by residential mortgage loans and guaranteed by a federal agency or guaranteed by either of the two GSEs (Fannie Mae and Freddie Mac).

Aggregate demand The quantity of goods and services that households, businesses, government, and non-domestic customers want to buy at any given level of prices.

Aggregate demand curve Inverse relationship between the price level and real output.

Aggregate income The value of all the payments earned by the suppliers of factors used in the production of goods and services.

Aggregate output The value of all the goods and services produced during a specified period.

Aggregate supply The quantity of goods and services producers are willing to supply at any given level of price.

Aggregate supply curve The level of domestic output that companies will produce at each price level.

All-or-nothing (AON) orders An order that includes the instruction to trade only if the trade fills the entire quantity (size) specified.

Allocationally efficient A characteristic of a market, a financial system, or an economy that promotes the allocation of resources to their highest value uses.

Alternative data Non-traditional data types generated by the use of electronic devices, social media, satellite and sensor networks, and company exhaust.

Alternative hypothesis The hypothesis that is accepted if the null hypothesis is rejected.

Alternative investment markets Market for investments other than traditional securities investments (i.e., traditional common and preferred shares and traditional fixed income instruments). The term usually encompasses direct and indirect investment in real estate (including timberland and farmland) and commodities (including precious metals); hedge funds, private equity, and other investments requiring specialized due diligence.

Alternative trading systems Trading venues that function like exchanges but that do not exercise regulatory authority over their subscribers except with respect to the conduct

of the subscribers' trading in their trading systems. Also called *electronic communications networks* or *multilateral trading facilities*.

American depository receipt A US dollar-denominated security that trades like a common share on US exchanges.

American depository share The underlying shares on which American depository receipts are based. They trade in the issuing company's domestic market.

American-style Type of option contract that can be exercised at any time up to the option's expiration date.

Amortisation The process of allocating the cost of intangible long-term assets having a finite useful life to accounting periods; the allocation of the amount of a bond premium or discount to the periods remaining until bond maturity.

Amortised cost The historical cost (initially recognised cost) of an asset, adjusted for amortisation and impairment.

Amortizing bond Bond with a payment schedule that calls for periodic payments of interest and repayments of principal.

Amortizing loans Loans with a payment schedule that calls for periodic payments of interest and repayments of principal.

Analysis of variance (ANOVA) The analysis that breaks the total variability of a dataset (such as observations on the dependent variable in a regression) into components representing different sources of variation. With reference to regression, ANOVA provides the inputs for an *F*-test of the significance of the regression as a whole, as well as the inputs for the coefficient of determination and the standard error of the estimate.

Analytical duration The use of mathematical formulas to estimate the impact of benchmark yield-to-maturity changes on bond prices.

Anchoring and adjustment bias An information-processing bias in which the use of a psychological heuristic influences the way people estimate probabilities.

Annual percentage rate The cost of borrowing expressed as a yearly rate.

Annuity A finite set of level sequential cash flows.

Annuity due An annuity having a first cash flow that is paid immediately.

Anomalies Apparent deviations from market efficiency.

Antidilutive With reference to a transaction or a security, one that would increase earnings per share (EPS) or result in EPS higher than the company's basic EPS—antidilutive securities are not included in the calculation of diluted EPS.

Arbitrage 1) The simultaneous purchase of an undervalued asset or portfolio and sale of an overvalued but equivalent asset or portfolio, in order to obtain a riskless profit on the price differential. Taking advantage of a market inefficiency in a risk-free manner. 2) The condition in a financial market in which equivalent assets or combinations of assets sell for two different prices, creating an opportunity to profit at no risk with no commitment of money. In a well-functioning financial market, few arbitrage opportunities are possible. 3) A risk-free operation that earns an expected positive net profit but requires no net investment of money.

Arbitrage-free pricing The overall process of pricing derivatives by arbitrage and risk neutrality. Also called the *principle of no arbitrage*.

Arbitrageurs Traders who engage in arbitrage. See *arbitrage*.

Arithmetic mean The sum of the observations divided by the number of observations.

Artificial intelligence Computer systems that exhibit cognitive and decision-making ability comparable (or superior) to that of humans.

Ask The price at which a dealer or trader is willing to sell an asset, typically qualified by a maximum quantity (ask size). See *offer*.

Ask size The maximum quantity of an asset that pertains to a specific ask price from a trader. For example, if the ask for a share issue is $30 for a size of 1,000 shares, the trader is offering to sell at $30 up to 1,000 shares.

Asset allocation The process of determining how investment funds should be distributed among asset classes.

Asset-backed securities A type of bond issued by a legal entity called a *special purpose entity* (SPE) on a collection of assets that the SPE owns. Also, securities backed by receivables and loans other than mortgages.

Asset-based valuation models Valuation based on estimates of the market value of a company's assets.

Asset beta The unlevered beta; which reflects the business risk of the assets; the assets' systematic risk.

Asset class A group of assets that have similar characteristics, attributes, and risk–return relationships.

Asset swap Converts the periodic fixed coupon of a specific bond to an MRR plus or minus a spread.

Asset utilization ratios Ratios that measure how efficiently a company performs day-to-day tasks, such as the collection of receivables and management of inventory.

Assets Resources controlled by an enterprise as a result of past events and from which future economic benefits to the enterprise are expected to flow.

Assignment of accounts receivable The use of accounts receivable as collateral for a loan.

Asymmetric information The differential of information between corporate insiders and outsiders regarding the company's performance and prospects. Managers typically have more information about the company's performance and prospects than owners and creditors.

At the money An option in which the underlying's price equals the exercise price.

Auction A type of bond issuing mechanism often used for sovereign bonds that involves bidding.

Autarkic price The price of a good or service in an autarkic economy.

Autarky A state in which a country does not trade with other countries.

Automatic stabilizer A countercyclical factor that automatically comes into play as an economy slows and unemployment rises.

Availability bias An information-processing bias in which people take a heuristic approach to estimating the probability of an outcome based on how easily the outcome comes to mind.

Available-for-sale Under US GAAP, debt securities not classified as either held-to-maturity or held-for-trading securities. The investor is willing to sell but not actively planning to sell. In general, available-for-sale debt securities are reported at fair value on the balance sheet, with unrealized gains included as a component of other comprehensive income.

Average fixed cost Total fixed cost divided by quantity produced.

Average life See *weighted average life*.

Average product Measures the productivity of inputs on average and is calculated by dividing total product by the total number of units for a given input that is used to generate that output.

Average revenue Total revenue divided by quantity sold.

Average total cost Total cost divided by quantity produced.

Average variable cost Total variable cost divided by quantity produced.

Back-testing With reference to portfolio strategies, the application of a strategy's portfolio selection rules to historical data to assess what would have been the strategy's historical performance.

Backfill bias A bias introduced if a fund backfills its past performance data to the database when it first starts reporting actual performance.

Backtesting With reference to portfolio strategies, the application of a strategy's portfolio selection rules to historical data to assess what would have been the strategy's historical performance.

Backup line of credit A type of credit enhancement provided by a bank to an issuer of commercial paper to ensure that the issuer will have access to sufficient liquidity to repay maturing commercial paper if issuing new paper is not a viable option.

Backwardation A condition in the futures markets in which the spot price exceeds the futures price, the forward curve is downward sloping, and the convenience yield is high.

Balance of payments A double-entry bookkeeping system that summarizes a country's economic transactions with the rest of the world for a particular period of time, typically a calendar quarter or year.

Balance of trade deficit When the domestic economy is spending more on non-domestic goods and services than non-domestic economies are spending on domestic goods and services.

Balance sheet The financial statement that presents an entity's current financial position by disclosing resources the entity controls (its assets) and the claims on those resources (its liabilities and equity claims), as of a particular point in time (the date of the balance sheet). Also called *statement of financial position* or *statement of financial condition.*

Balance sheet ratios Financial ratios involving balance sheet items only.

Balanced With respect to a government budget, one in which spending and revenues (taxes) are equal.

Balloon payment Large payment required at maturity to retire a bond's outstanding principal amount.

Bar chart A chart for plotting the frequency distribution of categorical data, where each bar represents a distinct category and each bar's height is proportional to the frequency of the corresponding category. In technical analysis, a bar chart that plots four bits of data for each time interval—the high, low, opening, and closing prices. A vertical line connects the high and low prices. A cross-hatch left indicates the opening price and a cross-hatch right indicates the closing price.

Barter economy An economy where economic agents as house-holds, corporations, and governments "pay" for goods and services with another good or service.

Base-rate neglect A type of representativeness bias in which the base rate or probability of the categorization is not adequately considered.

Base rates The reference rate on which a bank bases lending rates to all other customers.

Basic EPS Net earnings available to common shareholders (i.e., net income minus preferred dividends) divided by the weighted average number of common shares outstanding.

Basis point Used in stating yield spreads, one basis point equals one-hundredth of a percentage point, or 0.01%.

Basket of listed depository receipts An exchange-traded fund (ETF) that represents a portfolio of depository receipts.

Bayes' formula The rule for updating the probability of an event of interest—given a set of prior probabilities for the event, information, and information given the event—if you receive new information.

Bearer bonds Bonds for which ownership is not recorded; only the clearing system knows who the bond owner is.

Bearish crossover A technical analysis term that describes a situation where a short-term moving average crosses a longer-term moving average from above; this movement is considered bearish. A **death cross** is a bearish crossover based on 50-day and 200-day moving averages.

Behavioral finance A field of finance that examines the psychological variables that affect and often distort the investment decision making of investors, analysts, and portfolio managers.

Behind the market Said of prices specified in orders that are worse than the best current price; e.g., for a limit buy order, a limit price below the best bid.

Benchmark A comparison portfolio; a point of reference or comparison.

Benchmark issue The latest sovereign bond issue for a given maturity. It serves as a benchmark against which to compare bonds that have the same features but that are issued by another type of issuer.

Benchmark rate Typically the yield-to-maturity on a government bond having the same or close to the same time-to-maturity.

Benchmark spread The yield spread over a specific benchmark, usually measured in basis points.

Bernoulli random variable A random variable having the outcomes 0 and 1.

Bernoulli trial An experiment that can produce one of two outcomes.

Best bid The highest bid in the market.

Best effort offering An offering of a security using an investment bank in which the investment bank, as agent for the issuer, promises to use its best efforts to sell the offering but does not guarantee that a specific amount will be sold.

Best-efforts offering An offering of a security using an investment bank in which the investment bank, as agent for the issuer, promises to use its best efforts to sell the offering but does not guarantee that a specific amount will be sold.

Best-in-class An ESG implementation approach that seeks to identify the most favorable companies in an industry based on ESG considerations.

Best offer The lowest offer (ask price) in the market.

Beta A measure of the sensitivity of a given investment or portfolio to movements in the overall market.

Bid The price at which a dealer or trader is willing to buy an asset, typically qualified by a maximum quantity.

Bid–ask spread The difference between the prices at which dealers will buy from a customer (bid) and sell to a customer (offer or ask). It is often used as an indicator of liquidity.

Bid–offer spread The difference between the prices at which dealers will buy from a customer (bid) and sell to a customer (offer or ask). It is often used as an indicator of liquidity.

Bid size The maximum quantity of an asset that pertains to a specific bid price from a trader.

Big Data The vast amount of data being generated by industry, governments, individuals, and electronic devices that arises from both traditional and non-traditional data sources.

Bilateral loan A loan from a single lender to a single borrower.

Bimodal A distribution that has two most frequently occurring values.

Binomial model A model for pricing options in which the underlying price can move to only one of two possible new prices.

Binomial random variable The number of successes in n Bernoulli trials for which the probability of success is constant for all trials and the trials are independent.

Binomial tree The graphical representation of a model of asset price dynamics in which, at each period, the asset moves up with probability p or down with probability $(1 - p)$.

Bitcoin A cryptocurrency using blockchain technology that was created in 2009.

Bivariate correlation See *Pearson correlation*.

Block brokers A broker (agent) that provides brokerage services for large-size trades.

Blockchain A type of digital ledger in which information is recorded sequentially and then linked together and secured using cryptographic methods.

Blue chip Widely held large market capitalization companies that are considered financially sound and are leaders in their respective industry or local stock market.

Bollinger Bands A price-based technical analysis indicator consisting of a line representing the moving average, a higher line representing the moving average plus a set number of standard deviations from the average (for the same number of periods as was used to calculate the moving average), and a lower line representing the moving average minus the same number of standard deviations.

Bond Contractual agreement between the issuer and the bondholders.

Bond equivalent yield A calculation of yield that is annualized using the ratio of 365 to the number of days to maturity. Bond equivalent yield allows for the restatement and comparison of securities with different compounding periods.

Bond indenture The governing legal credit agreement, typically incorporated by reference in the prospectus. Also called *trust deed*.

Bond market vigilantes Bond market participants who might reduce their demand for long-term bonds, thus pushing up their yields.

Bond yield plus risk premium approach An estimate of the cost of common equity that is produced by summing the before-tax cost of debt and a risk premium that captures the additional yield on a company's stock relative to its bonds. The additional yield is often estimated using historical spreads between bond yields and stock yields.

Bonus issue of shares A type of dividend in which a company distributes additional shares of its common stock to shareholders instead of cash.

Book building Investment bankers' process of compiling a "book" or list of indications of interest to buy part of an offering.

Book value The net amount shown for an asset or liability on the balance sheet; book value may also refer to the company's excess of total assets over total liabilities. Also called *carrying value*.

Boom An expansionary phase characterized by economic growth "testing the limits" of the economy.

Bootstrap A resampling method that repeatedly draws samples with replacement of the selected elements from the original observed sample. Bootstrap is usually conducted by using computer simulation and is often used to find standard error or construct confidence intervals of population parameters.

Bottom-up analysis An investment selection approach that focuses on company-specific circumstances rather than emphasizing economic cycles or industry analysis.

Box and whisker plot A graphic for visualizing the dispersion of data across quartiles. It consists of a "box" with "whiskers" connected to the box.

Breakdown A breakdown occurs when the price of an asset moves below a support level.

Breakeven point The number of units produced and sold at which the company's net income is zero (Revenues = Total cost); in the case of perfect competition, the quantity at which price, average revenue, and marginal revenue equal average total cost.

Breakout A breakout occurs when the price of an asset moves above a resistance level.

Bridge financing Interim financing that provides funds until permanent financing can be arranged.

Broad money Encompasses narrow money plus the entire range of liquid assets that can be used to make purchases.

Broker 1) An agent who executes orders to buy or sell securities on behalf of a client in exchange for a commission. 2) See *futures commission merchants*.

Broker–dealer A financial intermediary (often a company) that may function as a principal (dealer) or as an agent (broker) depending on the type of trade.

Brokered market A market in which brokers arrange trades among their clients.

Brownfield investment Investing in *existing* infrastructure assets.

Bubble line chart A line chart that uses varying-sized bubbles to represent a third dimension of the data. The bubbles are sometimes color-coded to present additional information.

Budget surplus/deficit The difference between government revenue and expenditure for a stated fixed period of time.

Bullet bond Bond in which the principal repayment is made entirely at maturity.

Bullish crossover A technical analysis term that describes a situation where a short-term moving average crosses a longer-term moving average from below; this movement is considered bullish. A **golden cross** is a bullish crossover based on 50-day and 200-day moving averages.

Business cycles Are recurrent expansions and contractions in economic activity affecting broad segments of the economy.

Business risk The risk associated with operating earnings. Operating earnings are uncertain because total revenues and many of the expenditures contributed to produce those revenues are uncertain.

Buy-side firm An investment management company or other investor that uses the services of brokers or dealers (i.e., the client of the sell side firms).

Buyback A transaction in which a company buys back its own shares. Unlike stock dividends and stock splits, share repurchases use corporate cash.

Call An option that gives the holder the right to buy an underlying asset from another party at a fixed price over a specific period of time.

Call market A market in which trades occur only at a particular time and place (i.e., when the market is called).

Call money rate The interest rate that buyers pay for their margin loan.

Call option An option that gives the holder the right to buy an underlying asset from another party at a fixed price over a specific period of time.

Call protection The time during which the issuer of the bond is not allowed to exercise the call option.

Callable bond A bond containing an embedded call option that gives the issuer the right to buy the bond back from the investor at specified prices on pre-determined dates.

Calmar ratio A comparison of the average annual compounded return to the maximum drawdown risk.

Candlestick chart A price chart with four bits of data for each time interval. A candle indicates the opening and closing price for the interval. The body of the candle is shaded if the opening price was higher than the closing price, and the body is white (or clear) if the opening price was lower than the closing price. Vertical lines known as wicks or shadows extend from the top and bottom of the candle to indicate, respectively, the high and low prices for the interval.

Cannibalization Cannibalization occurs when an investment takes customers and sales away from another part of the company.

Cap rate A metric by which real estate managers are often judged; the annual rent actually earned (net of any vacancies) divided by the price originally paid for the property.

Capacity The ability of the borrower to make its debt payments on time.

Capital account A component of the balance of payments account that measures transfers of capital.

Capital allocation line (CAL) A graph line that describes the combinations of expected return and standard deviation of return available to an investor from combining the optimal portfolio of risky assets with the risk-free asset.

Capital allocation process The process that companies use for decision making on capital investments—those projects with a life of one year or longer.

Capital asset pricing model (CAPM) An equation describing the expected return on any asset (or portfolio) as a linear function of its beta relative to the market portfolio.

Capital consumption allowance A measure of the wear and tear (depreciation) of the capital stock that occurs in the production of goods and services.

Capital deepening investment Increases the stock of capital relative to labor.

Capital expenditure Expenditure on physical capital (fixed assets).

Capital light Capital light businesses require little incremental investment in fixed assets or working capital to enable revenue growth.

Capital loss ratio The percentage of capital in deals that have been realized below cost, net of any recovered proceeds, divided by total invested capital.

Capital market expectations An investor's expectations concerning the risk and return prospects of asset classes.

Capital market line (CML) The line with an intercept point equal to the risk-free rate that is tangent to the efficient frontier of risky assets; represents the efficient frontier when a risk-free asset is available for investment.

Capital market securities Securities with maturities at issuance longer than one year.

Capital markets Financial markets that trade securities of longer duration, such as bonds and equities.

Capital rationing A capital rationing environment assumes that the company has a fixed amount of funds to invest.

Capital restrictions Controls placed on foreigners' ability to own domestic assets and/or domestic residents' ability to own foreign assets.

Capital stock The accumulated amount of buildings, machinery, and equipment used to produce goods and services.

Capital structure The mix of debt and equity that a company uses to finance its business; a company's specific mixture of long-term financing.

Carry The net of the costs and benefits of holding, storing, or "carrying" an asset.

Carrying amount The amount at which an asset or liability is valued according to accounting principles.

Carrying value The net amount shown for an asset or liability on the balance sheet; book value may also refer to the company's excess of total assets over total liabilities. For a bond, the purchase price plus (or minus) the amortized amount of the discount (or premium).

Cartel Participants in collusive agreements that are made openly and formally.

Cash collateral account Form of external credit enhancement whereby the issuer immediately borrows the credit-enhancement amount and then invests that amount, usually in highly rated short-term commercial paper.

Cash conversion cycle A financial metric that measures the length of time required for a company to convert cash invested in its operations to cash received as a result of its operations; equal to days of inventory on hand + days of sales outstanding – number of days of payables. Also called *net operating cycle*.

Cash flow additivity principle The principle that dollar amounts indexed at the same point in time are additive.

Cash flow from operating activities The net amount of cash provided from operating activities.

Cash flow from operations The net amount of cash provided from operating activities.

Cash flow yield The internal rate of return on a series of cash flows.

Cash market securities Money market securities settled on a "same day" or "cash settlement" basis.

Cash markets See *spot markets*.

Cash prices See *spot prices*.

Cash-settled forwards See *non-deliverable forwards*.

Catch-up clause A clause in an agreement that favors the GP. For a GP who earns a 20% performance fee, a catch-up clause allows the GP to receive 100% of the distributions above the hurdle rate *until* she receives 20% of the profits generated, and then every excess dollar is split 80/20 between the LPs and GP.

Categorical data Values that describe a quality or characteristic of a group of observations and therefore can be used as labels to divide a dataset into groups to summarize and visualize (also called **qualitative data**).

CBOE Volatility Index (VIX) A measure of near-term market volatility as conveyed by S&P 500 stock index option prices.

Central bank funds market The market in which deposit-taking banks that have an excess reserve with their national central bank can lend money to banks that need funds for maturities ranging from overnight to one year. Called the Federal or Fed funds market in the United States.

Central bank funds rate Interest rate at which central bank funds are bought (borrowed) and sold (lent) for maturities ranging from overnight to one year. Called Federal or Fed funds rate in the United States.

Central banks The dominant bank in a country, usually with official or semi-official governmental status.

Central limit theorem The theorem that states the sum (and the mean) of a set of independent, identically distributed random variables with finite variances is normally distributed, whatever distribution the random variables follow.

Certificate of deposit An instrument that represents a specified amount of funds on deposit with a bank for a specified maturity and interest rate. CDs are issued in various denominations and can be negotiable or non-negotiable.

Change in polarity principle A tenet of technical analysis that states that once a support level is breached, it becomes a resistance level. The same holds true for resistance levels: Once breached, they become support levels.

Change of control put A covenant giving bondholders the right to require the issuer to buy back their debt, often at par or at some small premium to par value, in the event that the borrower is acquired.

Character The quality of a debt issuer's management.

Chartist An individual who uses charts or graphs of a security's historical prices or levels to forecast its future trends.

Chi-square test of independence A statistical test for detecting a potential association between categorical variables.

Classical cycle Refers to fluctuations in the level of economic activity when measured by GDP in volume terms.

Classified balance sheet A balance sheet organized so as to group together the various assets and liabilities into subcategories (e.g., current and noncurrent).

Clawback A requirement that the general partner return any funds distributed as incentive fees until the limited partners have received back their initial investment and a percentage of the total profit.

Clearing The process by which the exchange verifies the execution of a transaction and records the participants' identities.

Clearing instructions Instructions that indicate how to arrange the final settlement ("clearing") of a trade.

Clearinghouse An entity associated with a futures market that acts as middleman between the contracting parties and guarantees to each party the performance of the other.

Closed economy An economy that does not trade with other countries; an *autarkic economy*.

Closed-end fund A mutual fund in which no new investment money is accepted. New investors invest by buying existing shares, and investors in the fund liquidate by selling their shares to other investors.

Cluster sampling A procedure that divides a population into subpopulation groups (clusters) representative of the population and then randomly draws certain clusters to form a sample.

Clustered bar chart See *grouped bar chart*.

Co-investing In co-investing, the investor invests in assets *indirectly* through the fund but also possesses rights (known as co-investment rights) to invest *directly* in the same assets. Through co-investing, an investor is able to make an investment *alongside* a fund when the fund identifies deals.

Code of ethics An established guide that communicates an organization's values and overall expectations regarding member behavior. A code of ethics serves as a general guide for how community members should act.

Coefficient of determination The percentage of the variation of the dependent variable that is explained by the independent variable. Also referred to as the "R-squared" or "R^2."

Coefficient of variation The ratio of a set of observations' standard deviation to the observations' mean value.

Cognitive cost The effort involved in processing new information and updating beliefs.

Cognitive dissonance The mental discomfort that occurs when new information conflicts with previously held beliefs or cognitions.

Cognitive errors Behavioral biases resulting from faulty reasoning; cognitive errors stem from basic statistical, information-processing, or memory errors.

Coincident economic indicators Turning points that are usually close to those of the overall economy; they are believed to have value for identifying the economy's present state.

Collateral Assets or financial guarantees underlying a debt obligation that are above and beyond the issuer's promise to pay.

Collateral manager Buys and sells debt obligations for and from the CDO's portfolio of assets (i.e., the collateral) to generate sufficient cash flows to meet the obligations to the CDO bondholders.

Collateral trust bonds Bonds secured by securities, such as common shares, other bonds, or other financial assets.

Collateralized bond obligations A structured asset-backed security that is collateralized by a pool of bonds.

Collateralized debt obligation Generic term used to describe a security backed by a diversified pool of one or more debt obligations.

Collateralized loan obligations A structured asset-backed security that is collateralized by a pool of loans.

Collateralized mortgage obligation A security created through the securitization of a pool of mortgage-related products (mortgage pass-through securities or pools of loans).

Collateralized mortgage obligations Securities created through the securitization of a pool of mortgage-related products (mortgage pass-through securities or pools of loans).

Collaterals Assets or financial guarantees underlying a debt obligation that are above and beyond the issuer's promise to pay.

Combination A listing in which the order of the listed items does not matter.

Combination formula (binomial formula) The number of ways that we can choose r objects from a total of n objects, when the order in which the r objects are listed does not matter, is ${}_nC_r = \binom{n}{r} = \dfrac{n!}{(n-r)!r!}$.

Commercial paper A short-term, negotiable, unsecured promissory note that represents a debt obligation of the issuer.

Committed (Regular) lines of credit A bank commitment to extend credit up to a pre-specified amount; the commitment is considered a short-term liability and is usually in effect for 364 days (one day short of a full year).

Committed capital The amount that the limited partners have agreed to provide to the private equity fund.

Commodity swap A swap in which the underlying is a commodity such as oil, gold, or an agricultural product.

Common market Level of economic integration that incorporates all aspects of the customs union and extends it by allowing free movement of factors of production among members.

Common shares A type of security that represent an ownership interest in a company.

Common-size analysis The restatement of financial statement items using a common denominator or reference item that allows one to identify trends and major differences; an example is an income statement in which all items are expressed as a percent of revenue.

Common stock See *common shares.*

Company analysis Analysis of an individual company.

Comparable company A company that has similar business risk, usually in the same industry and preferably with a single line of business.

Comparative advantage A country's ability to produce a good or service at a lower relative cost, or opportunity cost, than its trading partner.

Competitive strategy A company's plans for responding to the threats and opportunities presented by the external environment.

Complement The event not-S, written S^C, given the event S. Note that $P(S) + P(S^C) = 1$.

Complements Goods that tend to be used together; technically, two goods whose cross-price elasticity of demand is negative.

Complete markets Informally, markets in which the variety of distinct securities traded is so broad that any desired payoff in a future state-of-the-world is achievable.

Component cost of capital The rate of return required by suppliers of capital for an individual source of a company's funding, such as debt or equity.

Compounding The process of accumulating interest on interest.

Comprehensive income The change in equity of a business enterprise during a period from nonowner sources; includes all changes in equity during a period except those resulting from investments by owners and distributions to owners; comprehensive income equals net income plus other comprehensive income.

Conditional expected value The expected value of a stated event given that another event has occurred.

Conditional pass-through covered bonds Covered bonds that convert to pass-through securities after the original maturity date if all bond payments have not yet been made and the sponsor is in default.

Conditional probability The probability of an event given (conditioned on) another event.

Conditional variances The variance of one variable, given the outcome of another.

Confidence level The complement of the level of significance.

Confirmation bias A belief perseverance bias in which people tend to look for and notice what confirms their beliefs, to ignore or undervalue what contradicts their beliefs, and to misinterpret information as support for their beliefs.

Confusion matrix A type of contingency table used for evaluating the performance of a classification model.

Conservatism bias A belief perseverance bias in which people maintain their prior views or forecasts by inadequately incorporating new information.

Consolidation The movement of a stock's price within a well-defined range of trading levels for a period of time. The price consolidates between a support level and a resistance level.

Constant-yield price trajectory A graph that illustrates the change in the price of a fixed-income bond over time assuming no change in yield-to-maturity. The trajectory shows the "pull to par" effect on the price of a bond trading at a premium or a discount to par value.

Constituent securities With respect to an index, the individual securities within an index.

Consumer surplus The difference between the value that a consumer places on units purchased and the amount of money that was required to pay for them.

Contango A condition in the futures markets in which the spot price is lower than the futures price, the forward curve is upward sloping, and there is little or no convenience yield.

Contingency provision Clause in a legal document that allows for some action if a specific event or circumstance occurs.

Contingency table A tabular format that displays the frequency distributions of two or more categorical variables simultaneously and is used for finding patterns between the variables. A contingency table for two categorical variables is also known as a two-way table.

Contingent claim A security whose value is based on some other underlying security.

Contingent claims Derivatives in which the payoffs occur if a specific event occurs; generally referred to as options.

Contingent convertible bonds Bonds that automatically convert into equity if a specific event or circumstance occurs, such as the issuer's equity capital falling below the minimum requirement set by the regulators. Also called *CoCos.*

Continuation pattern A type of pattern used in technical analysis to predict the resumption of a market trend that was in place prior to the formation of a pattern.

Continuous data Data that can be measured and can take on any numerical value in a specified range of values.

Continuous random variable A random variable for which the range of possible outcomes is the real line (all real numbers between $-\infty$ and $+\infty$) or some subset of the real line.

Continuous trading market A market in which trades can be arranged and executed any time the market is open.

Continuously compounded return The natural logarithm of 1 plus the holding period return, or equivalently, the natural logarithm of the ending price over the beginning price.

Contra account An account that offsets another account.

Contract rate See *mortgage rate.*

Contraction The period of a business cycle after the peak and before the trough; often called a *recession* or, if exceptionally severe, called a *depression*.

Contraction risk The risk that when interest rates decline, the security will have a shorter maturity than was anticipated at the time of purchase because borrowers refinance at the new, lower interest rates.

Contractionary Tending to cause the real economy to contract.

Contractionary fiscal policy A fiscal policy that has the objective to make the real economy contract.

Contracts for differences See *non-deliverable forwards.*

Contribution margin The amount available for fixed costs and profit after paying variable costs; revenue minus variable costs.

Controlling shareholders A particular shareholder or block of shareholders holding a percentage of shares that gives them significant voting power.

Convenience sampling A procedure of selecting an element from a population on the basis of whether or not it is accessible to a researcher or how easy it is for a researcher to access the element.

Convenience yield A non-monetary advantage of holding an asset.

Conventional bond See *plain vanilla bond*.

Conventional cash flows A conventional cash flow pattern is one with an initial outflow followed by a series of inflows.

Convergence The tendency for differences in output per capita across countries to diminish over time. In technical analysis, the term describes the case when an indicator moves in the same manner as the security being analyzed.

Conversion premium The difference between the convertible bond's price and its conversion value.

Conversion price For a convertible bond, the price per share at which the bond can be converted into shares.

Conversion ratio For a convertible bond, the number of common shares that each bond can be converted into.

Conversion value For a convertible bond, the current share price multiplied by the conversion ratio.

Convertible bond Bond that gives the bondholder the right to exchange the bond for a specified number of common shares in the issuing company.

Convertible preference shares A type of equity security that entitles shareholders to convert their shares into a specified number of common shares.

Convexity adjustment For a bond, one half of the annual or approximate convexity statistic multiplied by the change in the yield-to-maturity squared.

Core inflation Refers to the inflation rate calculated based on a price index of goods and services except food and energy.

Corporate governance The system of internal controls and procedures by which individual companies are managed.

Correlation A measure of the linear relationship between two random variables.

Correlation coefficient A number between −1 and +1 that measures the consistency or tendency for two investments to act in a similar way. It is used to determine the effect on portfolio risk when two assets are combined.

Cost averaging The periodic investment of a fixed amount of money.

Cost of capital The cost of financing to a company; the rate of return that suppliers of capital require as compensation for their contribution of capital.

Cost of carry See *carry*.

Cost of debt The cost of debt financing to a company, such as when it issues a bond or takes out a bank loan; the rate of return required by a company's bondholders.

Cost of equity The rate of return required by a company's common stockholders.

Cost of preferred stock The cost to a company of issuing preferred stock; the dividend yield that a company must commit to pay preferred stockholders.

Cost structure The mix of a company's variable costs and fixed costs.

Counterparty risk The risk that the other party to a contract will fail to honor the terms of the contract.

Coupon rate The interest rate promised in a contract; this is the rate used to calculate the periodic interest payments.

Cournot assumption Assumption in which each firm determines its profit-maximizing production level assuming that the other firms' output will not change.

Covariance A measure of the co-movement (linear association) between two random variables.

Covariance matrix A matrix or square array whose entries are covariances; also known as a variance–covariance matrix.

Covenants The terms and conditions of lending agreements that the issuer must comply with; they specify the actions that an issuer is obligated to perform (affirmative covenant) or prohibited from performing (negative covenant).

Covered bond Debt obligation secured by a segregated pool of assets called the cover pool. The issuer must maintain the value of the cover pool. In the event of default, bondholders have recourse against both the issuer and the cover pool.

Covered bonds Senior debt obligations issued by a financial institution and backed by a segregated pool of assets. Covered bond investors have recourse to both the underlying assets and the financial institution.

Credit analysis The evaluation of credit risk; the evaluation of the creditworthiness of a borrower or counterparty.

Credit default swap (CDS) A type of credit derivative in which one party, the credit protection buyer who is seeking credit protection against a third party, makes a series of regularly scheduled payments to the other party, the credit protection seller. The seller makes no payments until a credit event occurs.

Credit derivatives A contract in which one party has the right to claim a payment from another party in the event that a specific credit event occurs over the life of the contract.

Credit enhancements Provisions that may be used to reduce the credit risk of a bond issue.

Credit-linked coupon bond Bond for which the coupon changes when the bond's credit rating changes.

Credit-linked note (CLN) Fixed-income security in which the holder of the security has the right to withhold payment of the full amount due at maturity if a credit event occurs.

Credit migration risk The risk that a bond issuer's creditworthiness deteriorates, or migrates lower, leading investors to believe the risk of default is higher. Also called *downgrade risk*.

Credit risk The risk of loss caused by a counterparty's or debtor's failure to make a promised payment. Also called *default risk*.

Credit spread option An option on the yield spread on a bond.

Credit tranching A structure used to redistribute the credit risk associated with the collateral; a set of bond classes created to allow investors a choice in the amount of credit risk that they prefer to bear.

Creditworthiness The perceived ability of the borrower to pay its debt obligations in a timely manner; it represents the ability of a company to withstand adverse impacts on its cash flows.

Critical values Values of the test statistic at which the decision changes from fail to reject the null hypothesis to reject the null hypothesis.

Cross-default Covenant or contract clause that specifies a borrower is considered in default if they default on another debt obligation.

Cross-default provisions Provisions whereby events of default, such as non-payment of interest on one bond, trigger default on all outstanding debt; implies the same default probability for all issues.

Cross-price elasticity of demand The percentage change in quantity demanded for a given percentage change in the price of another good; the responsiveness of the demand for Product A that is associated with the change in price of Product B.

Cross-sectional analysis Analysis that involves comparisons across individuals in a group over a given time period or at a given point in time.

Cross-sectional data A list of the observations of a specific variable from multiple observational units at a given point in time. The observational units can be individuals, groups, companies, trading markets, regions, etc.

Crossing networks Trading systems that match buyers and sellers who are willing to trade at prices obtained from other markets.

Crowding out The thesis that government borrowing may divert private sector investment from taking place.

Cryptocurrency An electronic medium of exchange that lacks physical form.

Cryptography An algorithmic process to encrypt data, making the data unusable if received by unauthorized parties.

Cumulative absolute frequency Cumulates (i.e., adds up) in a frequency distribution the absolute frequencies as one moves from the first bin to the last bin.

Cumulative distribution function A function giving the probability that a random variable is less than or equal to a specified value.

Cumulative frequency distribution chart A chart that plots either the cumulative absolute frequency or the cumulative relative frequency on the y-axis against the upper limit of the interval and allows one to see the number or the percentage of the observations that lie below a certain value.

Cumulative preference shares Preference shares for which any dividends that are not paid accrue and must be paid in full before dividends on common shares can be paid.

Cumulative relative frequency A sequence of partial sums of the relative frequencies in a frequency distribution.

Cumulative voting A voting process whereby shareholders can accumulate and vote all their shares for a single candidate in an election, as opposed to having to allocate their voting rights evenly among all candidates.

Currencies Monies issued by national monetary authorities.

Currency option bonds Bonds that give bondholders the right to choose the currency in which they want to receive interest payments and principal repayments.

Currency swap A swap in which each party makes interest payments to the other in different currencies.

Current account A component of the balance of payments account that measures the flow of goods and services.

Current assets Assets that are expected to be consumed or converted into cash in the near future, typically one year or less. *Also called liquid assets.*

Current cost With reference to assets, the amount of cash or cash equivalents that would have to be paid to buy the same or an equivalent asset today; with reference to liabilities, the undiscounted amount of cash or cash equivalents that would be required to settle the obligation today.

Current government spending With respect to government expenditures, spending on goods and services that are provided on a regular, recurring basis including health, education, and defense.

Current liabilities Short-term obligations, such as accounts payable, wages payable, or accrued liabilities, that are expected to be settled in the near future, typically one year or less.

Current yield The sum of the coupon payments received over the year divided by the flat price; also called the *income* or *interest yield* or *running yield*.

Curve duration The sensitivity of the bond price (or the market value of a financial asset or liability) with respect to a benchmark yield curve.

Customs union Extends the free trade area (FTA) by not only allowing free movement of goods and services among members, but also creating a common trade policy against nonmembers.

CVaR Conditional VaR, a tail loss measure. The weighted average of all loss outcomes in the statistical distribution that exceed the VaR loss.

Cyclical A cyclical company is one whose profits are strongly correlated with the strength of the overall economy.

Cyclical companies Companies with sales and profits that regularly expand and contract with the business cycle or state of economy.

Daily settlement See *mark to market* and *marking to market.*

Dark pools Alternative trading systems that do not display the orders that their clients send to them.

Data A collection of numbers, characters, words, and text—as well as images, audio, and video—in a raw or organized format to represent facts or information.

Data mining The practice of determining a model by extensive searching through a dataset for statistically significant patterns. Also called *data snooping.*

Data science An interdisciplinary field that brings computer science, statistics, and other disciplines together to analyze and produce insights from Big Data.

Data snooping The practice of determining a model by extensive searching through a dataset for statistically significant patterns.

Data table see **two-dimensional rectangular array**.

Day order An order that is good for the day on which it is submitted. If it has not been filled by the close of business, the order expires unfilled.

Days of inventory on hand An activity ratio equal to the number of days in the period divided by inventory turnover over the period.

Dealers A financial intermediary that acts as a principal in trades.

Dealing securities Securities held by banks or other financial intermediaries for trading purposes.

Death cross See **Bearish crossover**.

Debentures Type of bond that can be secured or unsecured.

Debt rating An independent measure of the quality and safety of a company's debt based upon an analysis of the company's ability to pay the promised cash flows in full and on time. It includes an analysis of any indentures.

Debt-rating approach A method for estimating a company's before-tax cost of debt based on the yield on comparably rated bonds for maturities that closely match that of the company's existing debt.

Debt tax shield The tax benefit from interest paid on debt being tax deductible from income, equal to the marginal tax rate multiplied by the value of the debt.

Debt-to-assets ratio A solvency ratio calculated as total debt divided by total assets.

Debt-to-capital ratio A solvency ratio calculated as total debt divided by total debt plus total shareholders' equity.

Debt-to-equity ratio A solvency ratio calculated as total debt divided by total shareholders' equity.

Deciles Quantiles that divide a distribution into 10 equal parts.

Declaration date The day that the corporation issues a statement declaring a specific dividend.

Decreasing returns to scale When a production process leads to increases in output that are proportionately smaller than the increase in inputs.

Deductible temporary differences Temporary differences that result in a reduction of or deduction from taxable income in a future period when the balance sheet item is recovered or settled.

Deep learning Machine learning using neural networks with many hidden layers.

Deep learning nets Machine learning using neural networks with many hidden layers.

Default probability The probability that a borrower defaults or fails to meet its obligation to make full and timely payments of principal and interest, according to the terms of the debt security. Also called *default risk*.

Default risk The probability that a borrower defaults or fails to meet its obligation to make full and timely payments of principal and interest, according to the terms of the debt security. Also called *default probability*.

Default risk premium An extra return that compensates investors for the possibility that the borrower will fail to make a promised payment at the contracted time and in the contracted amount.

Defensive companies Companies with sales and profits that have little sensitivity to the business cycle or state of the economy.

Defensive interval ratio A liquidity ratio that estimates the number of days that an entity could meet cash needs from liquid assets; calculated as (cash + short-term marketable investments + receivables) divided by daily cash expenditures.

Deferred coupon bond Bond that pays no coupons for its first few years but then pays a higher coupon than it otherwise normally would for the remainder of its life. Also called *split coupon bond*.

Deferred income A liability account for money that has been collected for goods or services that have not yet been delivered; payment received in advance of providing a good or service.

Deferred revenue A liability account for money that has been collected for goods or services that have not yet been delivered; payment received in advance of providing a good or service.

Deferred tax assets A balance sheet asset that arises when an excess amount is paid for income taxes relative to accounting profit. The taxable income is higher than accounting profit and income tax payable exceeds tax expense. The company expects to recover the difference during the course of future operations when tax expense exceeds income tax payable.

Deferred tax liabilities A balance sheet liability that arises when a deficit amount is paid for income taxes relative to accounting profit. The taxable income is less than the accounting profit and income tax payable is less than tax expense. The company expects to eliminate the liability over the course of future operations when income tax payable exceeds tax expense.

Defined benefit pension plans Plans in which the company promises to pay a certain annual amount (defined benefit) to the employee after retirement. The company bears the investment risk of the plan assets.

Defined contribution pension plans Individual accounts to which an employee and typically the employer makes contributions during their working years and expect to draw on the accumulated funds at retirement. The employee bears the investment and inflation risk of the plan assets.

Deflation Negative inflation.

Degree of confidence The probability that a confidence interval includes the unknown population parameter.

Degree of financial leverage (DFL) The ratio of the percentage change in net income to the percentage change in operating income; the sensitivity of the cash flows available to owners when operating income changes.

Degree of operating leverage (DOL) The ratio of the percentage change in operating income to the percentage change in units sold; the sensitivity of operating income to changes in units sold.

Degree of total leverage The ratio of the percentage change in net income to the percentage change in units sold; the sensitivity of the cash flows to owners to changes in the number of units produced and sold.

Degrees of freedom The number of independent variables used in defining sample statistics, such as variance, and the probability distributions they measure.

Delta The sensitivity of the derivative price to a small change in the value of the underlying asset.

Demand curve Graph of the inverse demand function. A graph showing the demand relation, either the highest quantity willingly purchased at each price or the highest price willingly paid for each quantity.

Demand function A relationship that expresses the quantity demanded of a good or service as a function of own-price and possibly other variables.

Demand shock A typically unexpected disturbance to demand, such as an unexpected interruption in trade or transportation.

Dependent With reference to events, the property that the probability of one event occurring depends on (is related to) the occurrence of another event.

Dependent variable The variable whose variation about its mean is to be explained by the regression; the left-side variable in a regression equation. Also referred to as the *explained variable*.

Depository bank A bank that raises funds from depositors and other investors and lends it to borrowers.

Depository institutions Commercial banks, savings and loan banks, credit unions, and similar institutions that raise funds from depositors and other investors and lend it to borrowers.

Depository receipt A security that trades like an ordinary share on a local exchange and represents an economic interest in a foreign company.

Depreciation The process of systematically allocating the cost of long-lived (tangible) assets to the periods during which the assets are expected to provide economic benefits.

Derivative pricing rule A pricing rule used by crossing networks in which a price is taken (derived) from the price that is current in the asset's primary market.

Derivatives A financial instrument whose value depends on the value of some underlying asset or factor (e.g., a stock price, an interest rate, or exchange rate).

Descriptive statistics Measures that summarize central tendency and spread variation in the data's distribution.

Diffuse prior The assumption of equal prior probabilities.

Diffusion index Reflects the proportion of the index's components that are moving in a pattern consistent with the overall index.

Diluted EPS The EPS that would result if all dilutive securities were converted into common shares.

Diluted shares The number of shares that would be outstanding if all potentially dilutive claims on common shares (e.g., convertible debt, convertible preferred stock, and employee stock options) were exercised.

Diminishing balance method An accelerated depreciation method, i.e., one that allocates a relatively large proportion of the cost of an asset to the early years of the asset's useful life.

Diminishing marginal productivity Describes a state in which each additional unit of input produces less output than previously.

Direct format With reference to the cash flow statement, a format for the presentation of the statement in which cash flow from operating activities is shown as operating cash receipts less operating cash disbursements. Also called *direct method*.

Direct investing Occurs when an investor makes a direct investment in an asset without the use of an intermediary.

Direct method See *direct format*.

Direct taxes Taxes levied directly on income, wealth, and corporate profits.

Direct write-off method An approach to recognizing credit losses on customer receivables in which the company waits until such time as a customer has defaulted and only then recognizes the loss.

Discount To reduce the value of a future payment in allowance for how far away it is in time; to calculate the present value of some future amount. Also, the amount by which an instrument is priced below its face (par) value.

Discount margin See *required margin*.

Discount rates In general, the interest rates used to calculate present values. In the money market, however, a discount rate is a specific type of quoted rate.

Discounted cash flow models Valuation models that estimate the intrinsic value of a security as the present value of the future benefits expected to be received from the security.

Discouraged worker A person who has stopped looking for a job or has given up seeking employment.

Discrete data Numerical values that result from a counting process; therefore, practically speaking, the data are limited to a finite number of values.

Discrete random variable A random variable that can take on at most a countable number of possible values.

Discriminatory pricing rule A pricing rule used in continuous markets in which the limit price of the order or quote that first arrived determines the trade price.

Diseconomies of scale Increase in cost per unit resulting from increased production.

Dispersion The variability of a population or sample of observations around the central tendency.

Display size The size of an order displayed to public view.

Disposition effect As a result of loss aversion, an emotional bias whereby investors are reluctant to dispose of losers. This reluctance results in an inefficient and gradual adjustment to deterioration in fundamental value.

Distributed ledger A type of database that may be shared among entities in a network.

Distributed ledger technology Technology based on a distributed ledger.

Divergence In technical analysis, a term that describes the case when an indicator moves differently from the security being analyzed.

Diversification ratio The ratio of the standard deviation of an equally weighted portfolio to the standard deviation of a randomly selected security.

Dividend A distribution paid to shareholders based on the number of shares owned.

Dividend discount model (DDM) A present value model that estimates the intrinsic value of an equity share based on the present value of its expected future dividends.

Dividend payout ratio The ratio of cash dividends paid to earnings for a period.

Divisor A number (denominator) used to determine the value of a price return index. It is initially chosen at the inception of an index and subsequently adjusted by the index provider, as necessary, to avoid changes in the index value that are unrelated to changes in the prices of its constituent securities.

Doji In the Japanese terminology used in candlestick charting, the doji signifies that after a full day of trading, the positive price influence of buyers and the negative price influence of sellers exactly counteracted each other—with opening and closing prices that are virtually equal—which suggests that the market under analysis is in balance.

Domestic content provisions Stipulate that some percentage of the value added or components used in production should be of domestic origin.

Double bottom In technical analysis, a reversal pattern that is formed when the price reaches a low, rebounds, and then declines back to the first low level. A double bottom is used to predict a change from a downtrend to an uptrend.

Double coincidence of wants A prerequisite to barter trades, in particular that both economic agents in the transaction want what the other is selling.

Double declining balance depreciation An accelerated depreciation method that involves depreciating the asset at double the straight-line rate. This rate is multiplied by the book value of the asset at the beginning of the period (a declining balance) to calculate depreciation expense.

Double top In technical analysis, a reversal pattern that is formed when an uptrend reverses twice at roughly the same high price level. A double top is used to predict a change from an uptrend to a downtrend.

Down transition probability The probability that an asset's value moves down in a model of asset price dynamics.

Downgrade risk The risk that a bond issuer's creditworthiness deteriorates, or migrates lower, leading investors to believe the risk of default is higher. Also called *credit migration risk*.

Downside risk Risk of incurring returns below a specified value.

Downtrend A pattern that occurs when the price of an asset moves lower over a period of time.

Drag on liquidity When receipts lag, creating pressure from the decreased available funds.

Drawdown A percentage peak-to-trough reduction in net asset value.

Dual-currency bonds Bonds that make coupon payments in one currency and pay the par value at maturity in another currency.

DuPont analysis An approach to decomposing return on investment, e.g., return on equity, as the product of other financial ratios.

Duration A measure of the approximate sensitivity of a security to a change in interest rates (i.e., a measure of interest rate risk).

Duration gap A bond's Macaulay duration minus the investment horizon.

Dutch Book Theorem A result in probability theory stating that inconsistent probabilities create profit opportunities.

Early repayment option See *prepayment option*.

Earnings per share The amount of income earned during a period per share of common stock.

Earnings surprise The portion of a company's earnings that is unanticipated by investors and, according to the efficient market hypothesis, merits a price adjustment.

Economic costs All the remuneration needed to keep a productive resource in its current employment or to acquire the resource for productive use; the sum of total accounting costs and implicit opportunity costs.

Economic indicator A variable that provides information on the state of the overall economy.

Economic loss The amount by which accounting profit is less than normal profit.

Economic profit Equal to accounting profit less the implicit opportunity costs not included in total accounting costs; the difference between total revenue (TR) and total cost (TC). Also called *abnormal profit* or *supernormal profit*.

Economic stabilization Reduction of the magnitude of economic fluctuations.

Economic union Incorporates all aspects of a common market and in addition requires common economic institutions and coordination of economic policies among members.

Economies of scale Reduction in cost per unit resulting from increased production.

Effective annual rate The amount by which a unit of currency will grow in a year with interest on interest included.

Effective convexity A *curve convexity* statistic that measures the secondary effect of a change in a benchmark yield curve on a bond's price.

Effective duration The sensitivity of a bond's price to a change in a benchmark yield curve.

Effective interest rate The borrowing rate or market rate that a company incurs at the time of issuance of a bond.

Efficient market A market in which asset prices reflect new information quickly and rationally.

Elastic Said of a good or service when the magnitude of elasticity is greater than one.

Elasticity The percentage change in one variable for a percentage change in another variable; a general measure of how sensitive one variable is to a change in the value of another variable.

Elasticity of demand A measure of the sensitivity of quantity demanded to a change in a product's own price: $\%\Delta Q^D/\%\Delta P$.

Elasticity of supply A measure of the sensitivity of quantity supplied to a change in price: $\%\Delta Q^S/\%\Delta P$.

Electronic communications networks See *alternative trading systems*.

Embedded option Contingency provisions that provide the issuer or the bondholders the right, but not the obligation, to take action. These options are not part of the security and cannot be traded separately.

Embedded options Contingency provisions that provide the issuer or the bondholders the right, but not the obligation, to take action. These options are not part of the security and cannot be traded separately.

Emotional biases Behavioral biases resulting from reasoning influenced by feelings; emotional biases stem from impulse or intuition.

Empirical duration The use of statistical methods and historical bond prices to estimate the price–yield relationship for a specific bond or portfolio of bonds.

Empirical probability The probability of an event estimated as a relative frequency of occurrence.

Employed The number of people with a job.

Endowment bias An emotional bias in which people value an asset more when they hold rights to it than when they do not.

Engagement/active ownership An ESG investment approach that uses shareholder power to influence corporate behavior through direct corporate engagement (i.e., communicating with senior management and/or boards of companies), filing or co-filing shareholder proposals, and proxy voting that is directed by ESG guidelines.

Enterprise risk management An overall assessment of a company's risk position. A centralized approach to risk management sometimes called firmwide risk management.

Enterprise value A measure of a company's total market value from which the value of cash and short-term investments have been subtracted.

Equal weighting An index weighting method in which an equal weight is assigned to each constituent security at inception.

Equipment trust certificates Bonds secured by specific types of equipment or physical assets.

Equity Assets less liabilities; the residual interest in the assets after subtracting the liabilities.

Equity risk premium The expected return on equities minus the risk-free rate; the premium that investors demand for investing in equities.

Equity swap A swap transaction in which at least one cash flow is tied to the return to an equity portfolio position, often an equity index.

Error term The difference between an observation and its expected value, where the expected value is based on the true underlying population relation between the dependent and independent variables. Also known simply as the *error*.

ESG An acronym that encompasses environmental, social, and governance.

ESG integration An ESG investment approach that focuses on systematic consideration of material ESG factors in asset allocation, security selection, and portfolio construction decisions for the purpose of achieving the product's stated investment objectives. Used interchangeably with **ESG investing**.

ESG investing The consideration of environmental, social, and governance factors in the investment process. Used interchangeably with **ESG integration**.

Estimate The particular value calculated from sample observations using an estimator.

Estimated parameters With reference to a regression analysis, the estimated values of the population intercept and population slope coefficients in a regression.

Estimator An estimation formula; the formula used to compute the sample mean and other sample statistics are examples of estimators.

Ethical principles Beliefs regarding what is good, acceptable, or obligatory behavior and what is bad, unacceptable, or forbidden behavior.

Ethics The study of moral principles or of making good choices. Ethics encompasses a set of moral principles and rules of conduct that provide guidance for our behavior.

Eurobonds Type of bond issued internationally, outside the jurisdiction of the country in whose currency the bond is denominated.

European-style Said of an option contract that can only be exercised on the option's expiration date.

Event Any outcome or specified set of outcomes of a random variable.

Ex-dividend date The first date that a share trades without (i.e., "ex") the dividend.

Excess kurtosis Degree of kurtosis (fatness of tails) relative to the kurtosis of the normal distribution.

Exchanges Places where traders can meet to arrange their trades.

Execution instructions Instructions that indicate how to fill an order.

Exercise The process of using an option to buy or sell the underlying.

Exercise price The fixed price at which an option holder can buy or sell the underlying. Also called *strike price*, *striking price*, or *strike*.

Exercise value The value obtained if an option is exercised based on current conditions. Also known as *intrinsic value*.

Exhaustive Covering or containing all possible outcomes.

Expansion The period of a business cycle after its lowest point and before its highest point.

Expansionary Tending to cause the real economy to grow.

Expansionary fiscal policy Fiscal policy aimed at achieving real economic growth.

Expected inflation The level of inflation that economic agents expect in the future.

Expected loss Default probability times loss severity given default.

Expected return on the portfolio ($E(R_p)$) The weighted average of the expected returns (R_1 to R_n) on the component securities using their respective weights (w_1 to w_n).

Expected value The probability-weighted average of the possible outcomes of a random variable.

Expenses Outflows of economic resources or increases in liabilities that result in decreases in equity (other than decreases because of distributions to owners); reductions in net assets associated with the creation of revenues.

Export subsidy Paid by the government to the firm when it exports a unit of a good that is being subsidized.

Exports Goods and services that an economy sells to other countries.

Extension risk The risk that when interest rates rise, fewer prepayments will occur because homeowners are reluctant to give up the benefits of a contractual interest rate that now looks low. As a result, the security becomes longer in maturity than anticipated at the time of purchase.

Externalities Spillover effects of production and consumption activities onto others who are not directly involved in a particular transaction, activity, or decision.

Externality An effect of a market transaction that is borne by parties other than those who transacted.

Extra dividend A dividend paid by a company that does not pay dividends on a regular schedule, or a dividend that supplements regular cash dividends with an extra payment.

Extreme value theory A branch of statistics that focuses primarily on extreme outcomes.

Face value The amount of cash payable by a company to the bondholders when the bonds mature; the promised payment at maturity separate from any coupon payment.

Factoring arrangement When a company sells its accounts receivable to a lender (known as a factor) who assumes responsibility for the credit granting and collection process.

Fair value The amount at which an asset could be exchanged, or a liability settled, between knowledgeable, willing parties in an arm's-length transaction; the price that would be received to sell an asset or paid to transfer a liability in an orderly transaction between market participants.

False discovery approach An adjustment in the *p*-values for tests performed multiple times.

False discovery rate The rate of Type I errors in testing a null hypothesis multiple times for a given level of significance.

Fat-Tailed Describes a distribution that has fatter tails than a normal distribution (also called leptokurtic).

Fed funds rate The US interbank lending rate on overnight borrowings of reserves.

Federal funds rate The US interbank lending rate on overnight borrowings of reserves.

Fiat money Money that is not convertible into any other commodity.

Fiduciary An entity designated to represent the rights and responsibilities of a beneficiary whose assets they are managing, such as a bond trustee acting on behalf of fixed-income investors.

Fiduciary call A combination of a European call and a risk-free bond that matures on the option expiration day and has a face value equal to the exercise price of the call.

FIFO method The first in, first out, method of accounting for inventory, which matches sales against the costs of items of inventory in the order in which they were placed in inventory.

Fill or kill See *immediate or cancel order*.

Finance lease From the lessee perspective, under US GAAP, a type of lease which is more akin to the purchase of an asset by the lessee. From the lessor perspective, under IFRS, a lease which "transfers substantially all the risks and rewards incidental to ownership of an underlying asset."

Financial account A component of the balance of payments account that records investment flows.

Financial distress Heightened uncertainty regarding a company's ability to meet its various obligations because of diminished earnings power or actual current losses.

Financial flexibility The ability to react and adapt to financial adversity and opportunities.

Financial leverage The extent to which a company can effect, through the use of debt, a proportional change in the return on common equity that is greater than a given proportional change in operating income; also, short for the financial leverage ratio.

Financial leverage ratio A measure of financial leverage calculated as average total assets divided by average total equity.

Financial risk The risk that environmental, social, or governance risk factors will result in significant costs or other losses to a company and its shareholders; the risk arising from a company's obligation to meet required payments under its financing agreements.

Financing activities Activities related to obtaining or repaying capital to be used in the business (e.g., equity and long-term debt).

Fintech Technological innovation in the design and delivery of financial services and products in the financial industry.

Firm commitment offering See *underwritten offering*.

First-degree price discrimination Where a monopolist is able to charge each customer the highest price the customer is willing to pay.

First lien debt Debt secured by a pledge of certain assets that could include buildings, but it may also include property and equipment, licenses, patents, brands, etc.

First mortgage debt Debt secured by a pledge of a specific property.

Fiscal multiplier The ratio of a change in national income to a change in government spending.

Fiscal policy The use of taxes and government spending to affect the level of aggregate expenditures.

Fisher effect The thesis that the real rate of interest in an economy is stable over time so that changes in nominal interest rates are the result of changes in expected inflation.

Fixed charge coverage A solvency ratio measuring the number of times interest and lease payments are covered by operating income, calculated as (EBIT + lease payments) divided by (interest payments + lease payments).

Fixed costs Costs that remain at the same level regardless of a company's level of production and sales.

Fixed-for-floating interest rate swap An interest rate swap in which one party pays a fixed rate and the other pays a floating rate, with both sets of payments in the same currency. Also called *plain vanilla swap* or *vanilla swap*.

Fixed-rate perpetual preferred stock Nonconvertible, noncallable preferred stock that has a fixed dividend rate and no maturity date.

Flag A technical analysis continuation pattern formed by parallel trendlines, typically over a short period.

Flat price The full price of a bond minus the accrued interest; also called the *quoted* or *clean* price.

Float-adjusted market-capitalization weighting An index weighting method in which the weight assigned to each constituent security is determined by adjusting its market capitalization for its market float.

Floaters See *floating-rate notes*.

Floating-rate notes Notes on which interest payments are not fixed but instead vary from period to period depending on the current level of a reference interest rate.

Flotation cost Fees charged to companies by investment bankers and other costs associated with raising new capital.

Foreclosure Allows the lender to take possession of a mortgaged property if the borrower defaults and then sell it to recover funds.

Foreign currency reserves Holding by the central bank of non-domestic currency deposits and non-domestic bonds.

Foreign direct investment Direct investment by a firm in one country (the source country) in productive assets in a foreign country (the host country).

Foreign exchange gains (or losses) Gains (or losses) that occur when the exchange rate changes between the investor's currency and the currency that foreign securities are denominated in.

Foreign portfolio investment Shorter-term investment by individuals, firms, and institutional investors (e.g., pension funds) in foreign financial instruments such as foreign stocks and foreign government bonds.

Forward commitments Class of derivatives that provides the ability to lock in a price to transact in the future at a previously agreed-upon price.

Forward contract An agreement between two parties in which one party, the buyer, agrees to buy from the other party, the seller, an underlying asset at a later date for a price established at the start of the contract.

Forward curve A series of forward rates, each having the same time frame.

Forward market For future delivery, beyond the usual settlement time period in the cash market.

Forward price The fixed price or rate at which the transaction scheduled to occur at the expiration of a forward contract will take place. This price is agreed on at the initiation date of the contract.

Forward rate The interest rate on a bond or money market instrument traded in a forward market. A forward rate can be interpreted as an incremental, or marginal, return for extending the time-to-maturity for an additional time period.

Forward rate agreements A forward contract calling for one party to make a fixed interest payment and the other to make an interest payment at a rate to be determined at the contract expiration.

Fractile A value at or below which a stated fraction of the data lies. Also called quantile.

Fractional reserve banking Banking in which reserves constitute a fraction of deposits.

Framing bias An information-processing bias in which a person answers a question differently based on the way in which it is asked (framed).

Free cash flow The actual cash that would be available to the company's investors after making all investments necessary to maintain the company as an ongoing enterprise (also referred to as free cash flow to the firm); the internally generated funds that can be distributed to the company's investors (e.g., shareholders and bondholders) without impairing the value of the company.

Free cash flow hypothesis The hypothesis that higher debt levels discipline managers by forcing them to make fixed debt service payments and by reducing the company's free cash flow.

Free-cash-flow-to-equity models Valuation models based on discounting expected future free cash flow to equity.

Free float The number of shares that are readily and freely tradable in the secondary market.

Free trade When there are no government restrictions on a country's ability to trade.

Free trade areas One of the most prevalent forms of regional integration, in which all barriers to the flow of goods and services among members have been eliminated.

Frequency distribution A tabular display of data constructed either by counting the observations of a variable by distinct values or groups or by tallying the values of a numerical variable into a set of numerically ordered bins (also called a one-way table).

Frequency polygon A graph of a frequency distribution obtained by drawing straight lines joining successive points representing the class frequencies.

Frequency table A representation of the frequency of occurrence of two discrete variables.

Full price The price of a security with accrued interest; also called the *invoice* or *dirty* price.

Fund investing In fund investing, the investor invests in assets indirectly by contributing capital to a fund as part of a group of investors. Fund investing is available for all major alternative investment types.

Fundamental analysis The examination of publicly available information and the formulation of forecasts to estimate the intrinsic value of assets.

Fundamental value The underlying or true value of an asset based on an analysis of its qualitative and quantitative characteristics. Also called *intrinsic value*.

Fundamental weighting An index weighting method in which the weight assigned to each constituent security is based on its underlying company's size. It attempts to address the disadvantages of market-capitalization weighting by using measures that are independent of the constituent security's price.

Funds of hedge funds Funds that hold a portfolio of hedge funds, more commonly shortened to *funds of funds*.

Fungible Freely exchangeable, interchangeable, or substitutable with other things of the same type. Money and commodities are the most common examples.

Future value (FV) The amount to which a payment or series of payments will grow by a stated future date.

Futures contract A variation of a forward contract that has essentially the same basic definition but with some additional features, such as a clearinghouse guarantee against credit losses, a daily settlement of gains and losses, and an organized electronic or floor trading facility.

Futures price The agreed-upon price of a futures contract.

FX swap The combination of a spot and a forward FX transaction.

G-spread The yield spread in basis points over an actual or interpolated government bond.

Gains Asset inflows not directly related to the ordinary activities of the business.

Game theory The set of tools decision makers use to incorporate responses by rival decision makers into their strategies.

Gamma A numerical measure of how sensitive an option's delta (the sensitivity of the derivative's price) is to a change in the value of the underlying.

Gap opening A gap is an area of a chart where a security's price either rises or falls from the previous day's close with no trading occurring in between. A gap opening is the start of a new trading session with a gap.

GDP deflator A gauge of prices and inflation that measures the aggregate changes in prices across the overall economy.

General partner (GP) The partner that runs the business and theoretically bears unlimited liability for the business's debts and obligations.

Geometric mean A measure of central tendency computed by taking the nth root of the product of n non-negative values.

Giffen goods Goods that are consumed more as the price of the good rises because it is a very inferior good whose income effect overwhelms its substitution effect when price changes.

Gilts Bonds issued by the UK government.

Global depository receipt A depository receipt that is issued outside of the company's home country and outside of the United States.

Global minimum-variance portfolio The portfolio on the minimum-variance frontier with the smallest variance of return.

Global registered share A common share that is traded on different stock exchanges around the world in different currencies.

Gold standard With respect to a currency, if a currency is on the gold standard a given amount can be converted into a prespecified amount of gold.

Golden Cross See **Bullish crossover**.

Good-on-close An execution instruction specifying that an order can only be filled at the close of trading. Also called *market on close*.

Good-on-open An execution instruction specifying that an order can only be filled at the opening of trading.

Good-till-cancelled order An order specifying that it is valid until the entity placing the order has cancelled it (or, commonly, until some specified amount of time such as 60 days has elapsed, whichever comes sooner).

Goodwill An intangible asset that represents the excess of the purchase price of an acquired company over the value of the net assets acquired.

Government equivalent yield A yield that restates a yield-to-maturity based on a 30/360 day count to one based on actual/actual.

Green bonds Bonds used in green finance whereby the proceeds are earmarked toward environmental-related products.

Green finance A type of finance that addresses environmental concerns while achieving economic growth.

Green loans Any loan instruments made available exclusively to finance or re-finance, in whole or in part, new and/or existing eligible green projects. Green loans are commonly aligned in the market with the Green Loan Principles.

Greenfield investment Investing in infrastructure assets *that are to be constructed*.

Grey market The forward market for bonds about to be issued. Also called "when issued" market.

Gross domestic product The market value of all final goods and services produced within the economy during a given period (output definition) or, equivalently, the aggregate income earned by all households, all companies, and the government within the economy during a given period (income definition).

Gross margin Sales minus the cost of sales (i.e., the cost of goods sold for a manufacturing company).

Gross profit Sales minus the cost of sales (i.e., the cost of goods sold for a manufacturing company).

Gross profit margin The ratio of gross profit to revenues.

Grouped bar chart A bar chart for showing joint frequencies for two categorical variables (also known as a **clustered bar chart**).

Grouping by function With reference to the presentation of expenses in an income statement, the grouping together of expenses serving the same function, e.g. all items that are costs of goods sold.

Grouping by nature With reference to the presentation of expenses in an income statement, the grouping together of expenses by similar nature, e.g., all depreciation expenses.

Growth cycle Refers to fluctuations in economic activity around the long-term potential trend growth level, focusing on how much actual economic activity is below or above trend growth in economic activity.

Growth cyclical A term sometimes used to describe companies that are growing rapidly on a long-term basis but that still experience above-average fluctuation in their revenues and profits over the course of a business cycle.

Growth investors With reference to equity investors, investors who seek to invest in high-earnings-growth companies.

Growth option The ability to make additional investments in a project at some future time if the financial results are strong. Also called *expansion option*.

Growth rate cycle Refers to fluctuations in the growth rate of economic activity.

Guarantee certificate A type of structured financial instrument that provides investors with capital protection. It combines a zero-coupon bond and a call option on some underlying asset.

Haircut See *repo margin*.

Halo effect An emotional bias that extends a favorable evaluation of some characteristics to other characteristics.

Hard-bullet covered bonds Covered bonds for which a bond default is triggered and bond payments are accelerated in the event of sponsor default if payments do not occur according to the original maturity schedule.

Harmonic mean A type of weighted mean computed as the reciprocal of the arithmetic average of the reciprocals.

Head and shoulders pattern In technical analysis, a reversal pattern that is formed in three parts: a left shoulder, a head, and a right shoulder. A head and shoulders pattern is used to predict a change from an uptrend to a downtrend.

Headline inflation Refers to the inflation rate calculated based on the price index that includes all goods and services in an economy.

Heat map A type of graphic that organizes and summarizes data in a tabular format and represents it using a color spectrum.

Hedge funds Private investment vehicles that typically use leverage, derivatives, and long and short investment strategies.

Hedge portfolio A hypothetical combination of the derivative and its underlying that eliminates risk.

Held-to-maturity Debt (fixed-income) securities that a company intends to hold to maturity; these are presented at their original cost, updated for any amortisation of discounts or premiums.

Herding Clustered trading that may or may not be based on information.

Heteroskedasticity A violation of the simple linear regression assumption of homoskedasticity; with heteroskedasticity, the variability of the residuals is not equal across all observations.

Hidden order An order that is exposed not to the public but only to the brokers or exchanges that receive it.

High-frequency trading A form of algorithmic trading that makes use of vast quantities of data to execute trades on ultra-high-speed networks in fractions of a second.

High-water mark The highest value, net of fees, which a fund has reached in history. It reflects the highest cumulative return used to calculate an incentive fee.

Hindsight bias A bias with selective perception and retention aspects in which people may see past events as having been predictable and reasonable to expect.

Histogram A chart that presents the distribution of numerical data by using the height of a bar or column to represent the absolute frequency of each bin or interval in the distribution.

Historical cost In reference to assets, the amount paid to purchase an asset, including any costs of acquisition and/or preparation; with reference to liabilities, the amount of proceeds received in exchange in issuing the liability.

Historical equity risk premium approach An estimate of a country's equity risk premium that is based on the historical averages of the risk-free rate and the rate of return on the market portfolio.

Holder-of-record date The date that a shareholder listed on the corporation's books will be deemed to have ownership of the shares for purposes of receiving an upcoming dividend.

Holding period return The return that an investor earns during a specified holding period; a synonym for total return.

Home bias A preference for securities listed on the exchanges of one's home country.

Homogeneity of expectations The assumption that all investors have the same economic expectations and thus have the same expectations of prices, cash flows, and other investment characteristics.

Homoskedasticity An assumption of simple linear regression such that the variability of the residuals is equal across all observations.

Horizon yield The internal rate of return between the total return (the sum of reinvested coupon payments and the sale price or redemption amount) and the purchase price of the bond.

Horizontal analysis Common-size analysis that involves comparing a specific financial statement with that statement in prior or future time periods; also, cross-sectional analysis of one company with another.

Horizontal demand schedule Implies that at a given price, the response in the quantity demanded is infinite.

Hostile takeover An attempt by one entity to acquire a company without the consent of the company's management.

Household A person or a group of people living in the same residence, taken as a basic unit in economic analysis.

Human capital The accumulated knowledge and skill that workers acquire from education, training, or life experience and the corresponding present value of future earnings to be generated by said skilled individual.

Hurdle rate The minimum rate of return on investment that a fund must reach before a GP receives carried interest.

Hypothesis A proposed explanation or theory that can be tested.

Hypothesis testing The process of testing of hypotheses about one or more populations using statistical inference.

I-spread The yield spread of a specific bond over the standard swap rate in that currency of the same tenor.

Iceberg order An order in which the display size is less than the order's full size.

If-converted method A method for accounting for the effect of convertible securities on earnings per share (EPS) that specifies what EPS would have been if the convertible securities had been converted at the beginning of the period, taking account of the effects of conversion on net income and the weighted average number of shares outstanding.

Illusion of control bias A bias in which people tend to believe that they can control or influence outcomes when, in fact, they cannot.

Immediate or cancel order An order that is valid only upon receipt by the broker or exchange. If such an order cannot be filled in part or in whole upon receipt, it cancels immediately. Also called *fill or kill*.

Impact investing Investments made with the intention to generate positive, measurable social and environmental impact alongside a financial return.

Impact lag The lag associated with the result of actions affecting the economy with delay.

Implicit price deflator for GDP A gauge of prices and inflation that measures the aggregate changes in prices across the overall economy.

Implicit selection bias One type of selection bias introduced through the presence of a threshold that filters out some unqualified members.

Implied forward rates Calculated from spot rates, an implied forward rate is a breakeven reinvestment rate that links the return on an investment in a shorter-term zero-coupon bond to the return on an investment in a longer-term zero-coupon bond.

Implied volatility The volatility that option traders use to price an option, implied by the price of the option and a particular option-pricing model.

Import license Specifies the quantity of a good that can be imported into a country.

Imports Goods and services that a domestic economy (i.e., house-holds, firms, and government) purchases from other countries.

In the money Options that, if exercised, would result in the value received being worth more than the payment required to exercise.

Income Increases in economic benefits in the form of inflows or enhancements of assets, or decreases of liabilities that result in an increase in equity (other than increases resulting from contributions by owners).

Income elasticity of demand A measure of the responsiveness of demand to changes in income, defined as the percentage change in quantity demanded divided by the percentage change in income.

Income tax paid The actual amount paid for income taxes in the period; not a provision, but the actual cash outflow.

Income tax payable The income tax owed by the company on the basis of taxable income.

Increasing marginal returns When the marginal product of a resource increases as additional units of that input are employed.

Increasing returns to scale When a production process leads to increases in output that are proportionately larger than the increase in inputs.

Incremental cash flow The cash flow that is realized because of a decision; the changes or increments to cash flows resulting from a decision or action.

Indenture Legal contract that describes the form of a bond, the obligations of the issuer, and the rights of the bondholders. Also called the *trust deed*.

Independent With reference to events, the property that the occurrence of one event does not affect the probability of another event occurring. With reference to two random variables X and Y, they are independent if and only if $P(X,Y) = P(X)P(Y)$.

Independent projects Independent projects are capital investments whose cash flows are independent of each other.

Independent variable A variable used to explain the dependent variable in a regression; a right-side variable in a regression equation. Also referred to as the *explanatory variable*.

Independently and identically distributed With respect to random variables, the property of random variables that are independent of each other but follow the identical probability distribution.

Index-linked bond Bond for which coupon payments and/or principal repayment are linked to a specified index.

Indexing An investment strategy in which an investor constructs a portfolio to mirror the performance of a specified index.

Indicator variable A variable that takes on only one of two values, 0 or 1, based on a condition. In simple linear regression, the slope is the difference in the dependent variable for the two conditions. Also referred to as a *dummy variable*.

Indifference curve A curve representing all the combinations of two goods or attributes such that the consumer is entirely indifferent among them.

Indirect format With reference to cash flow statements, a format for the presentation of the statement which, in the operating cash flow section, begins with net income then shows additions and subtractions to arrive at operating cash flow. Also called *indirect method*.

Indirect method See *indirect format*.

Indirect taxes Taxes such as taxes on spending, as opposed to direct taxes.

Industry A group of companies offering similar products and/or services.

Industry analysis The analysis of a specific branch of manufacturing, service, or trade.

Inelastic Said of a good or service when the magnitude of elasticity is less than one. Insensitive to price changes.

Inferior goods A good whose consumption decreases as income increases.

Inflation The percentage increase in the general price level from one period to the next; a sustained rise in the overall level of prices in an economy.

Inflation-linked bond Type of index-linked bond that offers investors protection against inflation by linking the bond's coupon payments and/or the principal repayment to an index of consumer prices. Also called *linkers*.

Inflation premium An extra return that compensates investors for expected inflation.

Inflation reports A type of economic publication put out by many central banks.

Inflation uncertainty The degree to which economic agents view future rates of inflation as difficult to forecast.

Information cascade The transmission of information from those participants who act first and whose decisions influence the decisions of others.

Information-motivated traders Traders that trade to profit from information that they believe allows them to predict future prices.

Informationally efficient market A market in which asset prices reflect new information quickly and rationally.

Initial coin offering An unregulated process whereby companies raise capital by selling crypto tokens to investors in exchange for fiat money or another agreed-upon cryptocurrency.

Initial margin The amount that must be deposited in a clearinghouse account when entering into a futures contract.

Initial margin requirement The margin requirement on the first day of a transaction as well as on any day in which additional margin funds must be deposited.

Initial public offering (IPO) The first issuance of common shares to the public by a formerly private corporation.

Input productivity The amount of output produced by workers in a given period of time—for example, output per hour worked; measures the efficiency of labor.

Intangible assets Assets lacking physical substance, such as patents and trademarks.

Interbank market The market of loans and deposits between banks for maturities ranging from overnight to one year.

Intercept The expected value of the dependent variable when the independent variable in a simple linear regression is equal to zero.

Interest Payment for lending funds.

Interest coverage A solvency ratio calculated as EBIT divided by interest payments.

Interest-only mortgage A loan in which no scheduled principal repayment is specified for a certain number of years.

Interest rate A rate of return that reflects the relationship between differently dated cash flows; a discount rate.

Interest rate effect The effect through which price level changes, through demand for money, impact interest rate, which in turn impacts investment and consumption.

Interest rate swap A swap in which the underlying is an interest rate. Can be viewed as a currency swap in which both currencies are the same and can be created as a combination of currency swaps.

Intermarket analysis A field within technical analysis that combines analysis of the major categories of securities—namely, equities, bonds, currencies, and commodities—to identify market trends and possible inflections in trends.

Internal rate of return The discount rate that makes net present value equal 0; the discount rate that makes the present value of an investment's costs (outflows) equal to the present value of the investment's benefits (inflows).

Internet of Things A network arrangement of structures and devices whereby the objects on the network are able to interact and share information.

Interpolated spread The yield spread of a specific bond over the standard swap rate in that currency of the same tenor.

Interquartile range The difference between the third and first quartiles of a dataset.

Interval With reference to grouped data, a set of values within which an observation falls.

Intrinsic value See *exercise value*.

Inventory investment Net change in business inventory.

Inventory turnover An activity ratio calculated as cost of goods sold divided by average inventory.

Inverse demand function A restatement of the demand function in which price is stated as a function of quantity.

Inverse floater A type of leveraged structured financial instrument. The cash flows are adjusted periodically and move in the opposite direction of changes in the reference rate.

Inverse transformation method A method using randomly generated numbers from the continuous uniform distribution to generate random observations from any distribution.

Investing activities Activities associated with the acquisition and disposal of property, plant, and equipment; intangible assets; other long-term assets; and both long-term and short-term investments in the equity and debt (bonds and loans) issued by other companies.

Investment banks Financial intermediaries that provide advice to their mostly corporate clients and help them arrange transactions such as initial and seasoned securities offerings.

Investment policy statement (IPS) A written planning document that describes a client's investment objectives and risk tolerance over a relevant time horizon, along with constraints that apply to the client's portfolio.

Investment property Property used to earn rental income or capital appreciation (or both).

Jackknife A resampling method that repeatedly draws samples by taking the original observed data sample and leaving out one observation at a time (without replacement) from the set.

January effect Calendar anomaly that stock market returns in January are significantly higher compared to the rest of the months of the year, with most of the abnormal returns reported during the first five trading days in January. Also called *turn-of-the-year effect*.

Joint frequencies The entry in the cells of the contingency table that represent the joining of one variable from a row and the other variable from a column to count observations.

Joint probability The probability of the joint occurrence of stated events.

Joint probability function A function giving the probability of joint occurrences of values of stated random variables.

Judgmental Sampling A procedure of selectively handpicking elements from the population based on a researcher's knowledge and professional judgment.

Key rate duration A method of measuring the interest rate sensitivities of a fixed-income instrument or portfolio to shifts in key points along the yield curve.

Keynesians Economists who believe that fiscal policy can have powerful effects on aggregate demand, output, and employment when there is substantial spare capacity in an economy.

Kurtosis The statistical measure that indicates the combined weight of the tails of a distribution relative to the rest of the distribution.

Labor force The portion of the working age population (over the age of 16) that is employed or is available for work but not working (unemployed).

Labor productivity The quantity of goods and services (real GDP) that a worker can produce in one hour of work.

Lagging economic indicators Turning points that take place later than those of the overall economy; they are believed to have value in identifying the economy's past condition.

Law of demand The principle that as the price of a good rises, buyers will choose to buy less of it, and as its price falls, they will buy more.

Law of diminishing marginal returns The observation that a variable factor's marginal product must eventually fall as more of it is added to a fixed amount of the other factors.

Law of diminishing returns The smallest output that a firm can produce such that its long run average costs are minimized.

Law of one price The condition in a financial market in which two equivalent financial instruments or combinations of financial instruments can sell for only one price. Equivalent to the principle that no arbitrage opportunities are possible.

Lead underwriter The lead investment bank in a syndicate of investment banks and broker–dealers involved in a securities underwriting.

Leading economic indicators Turning points that usually precede those of the overall economy; they are believed to have value for predicting the economy's future state, usually near-term.

Lease A contract that conveys the right to use an asset for a period of time in exchange for consideration.

Legal tender Something that must be accepted when offered in exchange for goods and services.

Lender of last resort An entity willing to lend money when no other entity is ready to do so.

Leptokurtic Describes a distribution that has fatter tails than a normal distribution (also called fat-tailed).

Lessee The party obtaining the use of an asset through a lease.

Lessor The owner of an asset that grants the right to use the asset to another party.

Letter of credit Form of external credit enhancement whereby a financial institution provides the issuer with a credit line to reimburse any cash flow shortfalls from the assets backing the issue.

Level of significance The probability of a Type I error in testing a hypothesis.

Leverage In the context of corporate finance, leverage refers to the use of fixed costs within a company's cost structure. Fixed costs that are operating costs (such as depreciation or rent) create operating leverage. Fixed costs that are financial costs (such as interest expense) create financial leverage.

Leveraged buyout A transaction whereby the target company's management team converts the target to a privately held company by using heavy borrowing to finance the purchase of the target company's outstanding shares.

Liabilities Present obligations of an enterprise arising from past events, the settlement of which is expected to result in an outflow of resources embodying economic benefits; creditors' claims on the resources of a company.

LIFO layer liquidation With respect to the application of the LIFO inventory method, the liquidation of old, relatively low-priced inventory; happens when the volume of sales rises above the volume of recent purchases so that some sales are made from relatively old, low-priced inventory. Also called *LIFO liquidation*.

LIFO method The last in, first out, method of accounting for inventory, which matches sales against the costs of items of inventory in the reverse order the items were placed in inventory (i.e., inventory produced or acquired last are assumed to be sold first).

LIFO reserve The difference between the reported LIFO inventory carrying amount and the inventory amount that would have been reported if the FIFO method had been used (in other words, the FIFO inventory value less the LIFO inventory value).

Likelihood The probability of an observation, given a particular set of conditions.

Limit down A limit move in the futures market in which the price at which a transaction would be made is at or below the lower limit.

Limit order Instructions to a broker or exchange to obtain the best price immediately available when filling an order, but in no event accept a price higher than a specified (limit) price when buying or accept a price lower than a specified (limit) price when selling.

Limit order book The book or list of limit orders to buy and sell that pertains to a security.

Limit up A limit move in the futures market in which the price at which a transaction would be made is at or above the upper limit.

Limitations on liens Meant to put limits on how much secured debt an issuer can have.

Limited partners Partners with limited liability. Limited partnerships in hedge and private equity funds are typically restricted to investors who are expected to understand and to be able to assume the risks associated with the investments.

Limited partnership agreement (LPA) A legal document that outlines the rules of the partnership and establishes the framework that ultimately guides the fund's operations throughout its life.

Lin-log model A regression model in which the independent variable is in logarithmic form.

Line chart A type of graph used to visualize ordered observations. In technical analysis, a plot of price data, typically closing prices, with a line connecting the points.

Linear interpolation The estimation of an unknown value on the basis of two known values that bracket it, using a straight line between the two known values.

Linear regression Regression that models the straight-line relationship between the dependent and independent variables. Also known as *least squares regression* and *ordinary least squares regression*.

Linear scale A scale in which equal distances correspond to equal absolute amounts. Also called an *arithmetic scale*.

Linker See *inflation-linked bond*.

Liquid market Said of a market in which traders can buy or sell with low total transaction costs when they want to trade.

Liquidation To sell the assets of a company, division, or subsidiary piecemeal, typically because of bankruptcy; the form of bankruptcy that allows for the orderly satisfaction of creditors' claims after which the company ceases to exist.

Liquidity The extent to which a company is able to meet its short-term obligations using cash flows and those assets that can be readily transformed into cash.

Liquidity premium An extra return that compensates investors for the risk of loss relative to an investment's fair value if the investment needs to be converted to cash quickly.

Liquidity ratios Financial ratios measuring the company's ability to meet its short-term obligations to creditors.

Liquidity risk The risk that a financial instrument cannot be purchased or sold without a significant concession in price due to the size of the market.

Liquidity trap A condition in which the demand for money becomes infinitely elastic (horizontal demand curve) so that injections of money into the economy will not lower interest rates or affect real activity.

Load fund A mutual fund in which, in addition to the annual fee, a percentage fee is charged to invest in the fund and/or for redemptions from the fund.

Loan-to-value ratio The amount of the property's mortgage divided by the purchase price

Locked limit A condition in the futures markets in which a transaction cannot take place because the price would be beyond the limits.

Lockup period The minimum holding period before investors are allowed to make withdrawals or redeem shares from a fund.

Log-lin model A regression model in which the dependent variable is in logarithmic form.

Log-log model A regression model in which both the dependent and independent variables are in logarithmic form. Also known as the *double-log model*.

Logarithmic scale A scale in which equal distances represent equal proportional changes in the underlying quantity.

London interbank offered rate (Libor) Collective name for multiple rates at which a select set of banks believes they could borrow unsecured funds from other banks in the London interbank market for different currencies and different borrowing periods ranging from overnight to one year.

Long The buyer of a derivative contract. Also refers to the position of owning a derivative.

Long-lived assets Assets that are expected to provide economic benefits over a future period of time, typically greater than one year. Also called *long-term assets*.

Long position A position in an asset or contract in which one owns the asset or has an exercisable right under the contract.

Long-run average total cost The curve describing average total cost when no costs are considered fixed.

Look-ahead bias A bias caused by using information that was unavailable on the test date.

Loss aversion The tendency of people to dislike losses more than they like comparable gains.

Loss-aversion bias A bias in which people tend to strongly prefer avoiding losses as opposed to achieving gains.

Loss severity Portion of a bond's value (including unpaid interest) an investor loses in the event of default.

Losses Asset outflows not directly related to the ordinary activities of the business.

Lower bound The lowest possible value of an option.

M^2 A measure of what a portfolio would have returned if it had taken on the same total risk as the market index.

M^2 alpha Difference between the risk-adjusted performance of the portfolio and the performance of the benchmark.

Macaulay duration The approximate amount of time a bond would have to be held for the market discount rate at purchase to be realized if there is a single change in interest rate. It indicates the point in time when the coupon reinvestment and price effects of a change in yield-to-maturity offset each other.

Machine learning Computer based techniques that seek to extract knowledge from large amounts of data by "learning" from known examples and then generating structure or predictions. ML algorithms aim to "find the pattern, apply the pattern."

Macroeconomics The branch of economics that deals with aggregate economic quantities, such as national output and national income.

Maintenance covenants Covenants in bank loan agreements that require the borrower to satisfy certain financial ratio tests while the loan is outstanding.

Maintenance margin The minimum amount that is required by a futures clearinghouse to maintain a margin account and to protect against default. Participants whose margin balances drop below the required maintenance margin must replenish their accounts.

Maintenance margin requirement The margin requirement on any day other than the first day of a transaction.

Management buy-in Leveraged buyout in which the current management team is being replaced and the acquiring team will be involved in managing the company.

Management buyout A leveraged buyout event in which a group of investors consisting primarily of the company's existing management purchases at least controlling interest in its outstanding shares. At the extreme, they may purchase all shares and take the company private.

Management fee A fee based on assets under management or committed capital, as applicable—also called a *base fee*.

MAR ratio A variation of the Calmar ratio that uses a full investment history and the average drawdown.

Margin The amount of money that a trader deposits in a margin account. The term is derived from the stock market practice in which an investor borrows a portion of the money required to purchase a certain amount of stock. In futures markets, there is no borrowing so the margin is more of a down payment or performance bond.

Margin bond A cash deposit required by the clearinghouse from the participants to a contract to provide a credit guarantee. Also called a *performance bond*.

Margin call A request for the short to deposit additional funds to bring their balance up to the initial margin.

Margin loan Money borrowed from a broker to purchase securities.

Marginal cost The cost of producing an additional unit of a good.

Marginal frequencies The sums determined by adding joint frequencies across rows or across columns in a contingency table.

Marginal product Measures the productivity of each unit of input and is calculated by taking the difference in total product from adding another unit of input (assuming other resource quantities are held constant).

Marginal propensity to consume The proportion of an additional unit of disposable income that is consumed or spent; the change in consumption for a small change in income.

Marginal propensity to save The proportion of an additional unit of disposable income that is saved (not spent).

Marginal revenue The change in total revenue divided by the change in quantity sold; simply, the additional revenue from selling one more unit.

Marginal value curve A curve describing the highest price consumers are willing to pay for each additional unit of a good.

Mark to market The revaluation of a financial asset or liability to its current market value or fair value.

Mark-to-market Refers to the current expected fair market value for which a given security would likely be available for purchase or sale if traded in current market conditions.

Market anomaly Change in the price or return of a security that cannot directly be linked to current relevant information known in the market or to the release of new information into the market.

Market bid–ask spread The difference between the best bid and the best offer.

Market-capitalization weighting An index weighting method in which the weight assigned to each constituent security is determined by dividing its market capitalization by the total market capitalization (sum of the market capitalization) of all securities in the index. Also called *value weighting*.

Market discount rate The rate of return required by investors given the risk of the investment in a bond; also called the *required yield* or the *required rate of return*.

Market float The number of shares that are available to the investing public.

Market liquidity risk The risk that the price at which investors can actually transact—buying or selling—may differ from the price indicated in the market.

Market model A regression equation that specifies a linear relationship between the return on a security (or portfolio) and the return on a broad market index.

Market multiple models Valuation models based on share price multiples or enterprise value multiples.

Market-on-close An execution instruction specifying that an order can only be filled at the close of trading.

Market order Instructions to a broker or exchange to obtain the best price immediately available when filling an order.

Market-oriented investors With reference to equity investors, investors whose investment disciplines cannot be clearly categorized as value or growth.

Market rate of interest The rate demanded by purchasers of bonds, given the risks associated with future cash payment obligations of the particular bond issue.

Market reference rate (MRR) Collective name for a set of rates covering different currencies for different maturities, ranging from overnight to one year.

Market risk The risk that arises from movements in interest rates, stock prices, exchange rates, and commodity prices.

Market value The price at which an asset or security can currently be bought or sold in an open market.

Marketable limit order A buy limit order in which the limit price is placed above the best offer, or a sell limit order in which the limit price is placed below the best bid. Such orders generally will partially or completely fill right away.

Markowitz efficient frontier The graph of the set of portfolios offering the maximum expected return for their level of risk (standard deviation of return).

Matching principle The accounting principle that expenses should be recognized in the same period in which the associated revenue is recognized.

Matrix pricing Process of estimating the market discount rate and price of a bond based on the quoted or flat prices of more frequently traded comparable bonds.

Maturity premium An extra return that compensates investors for the increased sensitivity of the market value of debt to a change in market interest rates as maturity is extended.

Maturity structure A factor explaining the differences in yields on similar bonds; also called *term structure*.

Mean absolute deviation With reference to a sample, the mean of the absolute values of deviations from the sample mean.

Mean square error (MSE) The sum of squares error divided by the degrees of freedom, $n - k - 1$; in a simple linear regression, $n - k - 1 = n - 2$.

Mean square regression (MSR) The sum of squares regression divided by the number of independent variables k; in a simple linear regression, $k = 1$.

Mean–variance analysis An approach to portfolio analysis using expected means, variances, and covariances of asset returns.

Measure of central tendency A quantitative measure that specifies where data are centered.

Measure of value A standard for measuring value; a function of money.

Measures of location Quantitative measures that describe the location or distribution of data. They include not only measures of central tendency but also other measures, such as percentiles.

Median The value of the middle item of a set of items that has been sorted into ascending or descending order (i.e., the 50th percentile).

Medium of exchange Any asset that can be used to purchase goods and services or to repay debts; a function of money.

Medium-term note A corporate bond offered continuously to investors by an agent of the issuer, designed to fill the funding gap between commercial paper and long-term bonds.

Mental accounting bias An information-processing bias in which people treat one sum of money differently from another equal-sized sum based on which mental account the money is assigned to.

Menu costs A cost of inflation in which businesses constantly have to incur the costs of changing the advertised prices of their goods and services.

Mesokurtic Describes a distribution with kurtosis equal to that of the normal distribution, namely, kurtosis equal to three.

Microeconomics The branch of economics that deals with markets and decision making of individual economic units, including consumers and businesses.

Minimum efficient scale The smallest output that a firm can produce such that its long-run average total cost is minimized.

Minimum-variance portfolio The portfolio with the minimum variance for each given level of expected return.

Minority shareholders Particular shareholders or a block of shareholders holding a small proportion of a company's outstanding shares, resulting in a limited ability to exercise control in voting activities.

Minsky moment Named for Hyman Minksy. A point in a business cycle when, after individuals become overextended in borrowing to finance speculative investments, people start realizing that something is likely to go wrong and a panic ensues, leading to asset sell-offs.

Modal interval With reference to grouped data, the interval containing the greatest number of observations (i.e., highest frequency).

Mode The most frequently occurring value in a distribution.

Modern portfolio theory (MPT) The analysis of rational portfolio choices based on the efficient use of risk.

Modified duration A measure of the percentage price change of a bond given a change in its yield-to-maturity.

Momentum oscillator A graphical representation of market sentiment that is constructed from price data and calculated so that it oscillates either between a low and a high or around some number.

Monetarists Economists who believe that the rate of growth of the money supply is the primary determinant of the rate of inflation.

Monetary policy Actions taken by a nation's central bank to affect aggregate output and prices through changes in bank reserves, reserve requirements, or its target interest rate.

Monetary transmission mechanism The process whereby a central bank's interest rate gets transmitted through the economy and ultimately affects the rate of increase of prices.

Monetary union An economic union in which the members adopt a common currency.

Money A generally accepted medium of exchange and unit of account.

Money convexity For a bond, the annual or approximate convexity multiplied by the full price.

Money creation The process by which changes in bank reserves translate into changes in the money supply.

Money duration A measure of the price change in units of the currency in which the bond is denominated given a change in its yield-to-maturity.

Money market The market for short-term debt instruments (one-year maturity or less).

Money market securities Fixed-income securities with maturities at issuance of one year or less.

Money multiplier Describes how a change in reserves is expected to affect the money supply; in its simplest form, 1 divided by the reserve requirement.

Money neutrality The thesis that an increase in the money supply leads in the long-run to an increase in the price level, while leaving real variables like output and employment unaffected.

Money-weighted return The internal rate of return on a portfolio, taking account of all cash flows.

Moneyness The relationship between the price of the underlying and an option's exercise price.

Monopolistic competition Highly competitive form of imperfect competition; the competitive characteristic is a notably large number of firms, while the monopoly aspect is the result of product differentiation.

Monopoly In pure monopoly markets, there are no substitutes for the given product or service. There is a single seller, which exercises considerable power over pricing and output decisions.

Monte Carlo simulation A technique involving the use of computer software to represent the operation of a complex financial system. A characteristic feature is the generation of a large number of random samples from a specified probability distribution or distributions to represent the role of risk in the system.

Moral principles Beliefs regarding what is good, acceptable, or obligatory behavior and what is bad, unacceptable, or forbidden behavior.

Mortgage-backed securities Debt obligations that represent claims to the cash flows from pools of mortgage loans, most commonly on residential property.

Mortgage loan A loan secured by the collateral of some specified real estate property that obliges the borrower to make a predetermined series of payments to the lender.

Mortgage pass-through security A security created when one or more holders of mortgages form a pool of mortgages and sell shares or participation certificates in the pool.

Mortgage rate The interest rate on a mortgage loan; also called *contract rate* or *note rate*.

Moving average The average of the closing price of a security over a specified number of periods. With each new period, the average is recalculated.

Moving-average convergence/divergence oscillator A momentum oscillator that is based on the difference between short-term and long-term moving averages of a security's price.

Multi-factor model A model that explains a variable in terms of the values of a set of factors.

Multi-market indexes Comprised of indexes from different countries, designed to represent multiple security markets.

Multi-step format With respect to the format of the income statement, a format that presents a subtotal for gross profit (revenue minus cost of goods sold).

Multilateral trading facilities See *alternative trading systems*.

Multinational corporation A company operating in more than one country or having subsidiary firms in more than one country.

Multinomial formula (general formula for labeling problems) The number of ways that n objects can be labeled with k different labels, with n_1 of the first type, n_2 of the second type, and so on, with $n_1 + n_2 + \ldots + n_k = n$, is given by $\dfrac{n!}{n_1!n_2!\ldots n_k!}$.

Multiple of invested capital (MOIC) A simplified calculation that measures the total value of all distributions and residual asset values relative to an initial total investment; also known as a *money multiple*.

Multiple testing problem The risk of getting statistically significant test results when performing a test multiple times.

Multiplication rule for counting If one task can be done in n_1 ways, and a second task, given the first, can be done in n_2 ways, and a third task, given the first two tasks, can be done in n_3 ways, and so on for k tasks, then the number of ways the k tasks can be done is $(n_1)(n_2)(n_3) \ldots (n_k)$.

Multiplication rule for expected value of the product of uncorrelated random variables This rule is $E(XY) = E(X)E(Y)$ if X and Y are uncorrelated.

Multiplication rule for independent events The rule that when two events are independent, the joint probability of A and B equals the product of the individual probabilities of A and B.

Multiplication rule for probability The rule that the joint probability of events A and B equals the probability of A given B times the probability of B.

Multiplier models Valuation models based on share price multiples or enterprise value multiples.

Multivariate distribution A probability distribution that specifies the probabilities for a group of related random variables.

Multivariate normal distribution A probability distribution for a group of random variables that is completely defined by the means and variances of the variables plus all the correlations between pairs of the variables.

Muni See *municipal bond*.

Municipal bond A type of non-sovereign bond issued by a state or local government in the United States. It very often (but not always) offers income tax exemptions.

Mutual fund A comingled investment pool in which investors in the fund each have a pro-rata claim on the income and value of the fund.

Mutually exclusive Indicates that only one event can occur at a time.

Mutually exclusive projects Mutually exclusive projects compete directly with each other. For example, if Projects A and B are mutually exclusive, you can choose A or B but you cannot choose both.

***n* Factorial** For a positive integer n, the product of the first n positive integers; 0 factorial equals 1 by definition. n factorial is written as $n!$.

Narrow money The notes and coins in circulation in an economy, plus other very highly liquid deposits.

Nash equilibrium When two or more participants in a non-coop-erative game have no incentive to deviate from their respective equilibrium strategies given their opponent's strategies.

National income The income received by all factors of production used in the generation of final output. National income equals gross domestic product (or, in some countries, gross national product) minus the capital consumption allowance and a statistical discrepancy.

Natural language processing Computer programs developed to analyze and interpret human language.

Natural rate of unemployment Effective unemployment rate, below which pressure emerges in labor markets.

Negative screening An ESG investment style that focuses on the exclusion of certain sectors, companies, or practices in a fund or portfolio on the basis of specific ESG criteria.

Net book value The remaining (undepreciated) balance of an asset's purchase cost. For liabilities, the face value of a bond minus any unamortized discount, or plus any unamortized premium.

Net exports The difference between the value of a country's exports and the value of its imports (i.e., value of exports minus imports).

Net income The difference between revenue and expenses; what remains after subtracting all expenses (including depreciation, interest, and taxes) from revenue.

Net present value The present value of an investment's cash inflows (benefits) minus the present value of its cash outflows (costs).

Net profit margin An indicator of profitability, calculated as net income divided by revenue; indicates how much of each dollar of revenues is left after all costs and expenses. Also called *profit margin* or *return on sales*.

Net realisable value Estimated selling price in the ordinary course of business less the estimated costs necessary to make the sale.

Net revenue Revenue after adjustments (e.g., for estimated returns or for amounts unlikely to be collected).

Net tax rate The tax rate net of transfer payments.

Neural networks Computer programs based on how our own brains learn and process information.

Neutral rate of interest The rate of interest that neither spurs on nor slows down the underlying economy.

No-load fund A mutual fund in which there is no fee for investing in the fund or for redeeming fund shares, although there is an annual fee based on a percentage of the fund's net asset value.

Node Each value on a binomial tree from which successive moves or outcomes branch.

Nominal data Categorical values that are not amenable to being organized in a logical order. An example of nominal data is the classification of publicly listed stocks into sectors.

Nominal GDP The value of goods and services measured at current prices.

Nominal risk-free interest rate The sum of the real risk-free interest rate and the inflation premium.

Non-accelerating inflation rate of unemployment Effective unemployment rate below which pressure emerges in labor markets.

Non-agency RMBS In the United States, securities issued by private entities that are not guaranteed by a federal agency or a GSE.

Non-Bank lender Unlike typical banks, which make loans and take deposits, these lenders only make loans. Although they lend money to companies, they usually specialize in issuing mortgages to first-time homebuyers and parties looking to refinance an existing mortgage.

Non-cumulative preference shares Preference shares for which dividends that are not paid in the current or subsequent periods are forfeited permanently (instead of being accrued and paid at a later date).

Non-current assets Assets that are expected to benefit the company over an extended period of time (usually more than one year).

Non-current liabilities Obligations that broadly represent a probable sacrifice of economic benefits in periods generally greater than one year in the future.

Non-cyclical A company whose performance is largely independent of the business cycle. Also known as defensive.

Non-deliverable forwards Cash-settled forward contracts, used predominately with respect to foreign exchange forwards. Also called *contracts for differences*.

Non-financial risks Risks that arise from sources other than changes in the external financial markets, such as changes in accounting rules, legal environment, or tax rates.

Non-participating preference shares Preference shares that do not entitle shareholders to share in the profits of the company. Instead, shareholders are only entitled to receive a fixed dividend payment and the par value of the shares in the event of liquidation.

Non-probability sampling A sampling plan dependent on factors other than probability considerations, such as a sampler's judgment or the convenience to access data.

Non-recourse loan A loan in which the lender does not have a shortfall claim against the borrower, so the lender can look only to the property to recover the outstanding mortgage balance.

Non-renewable resources Finite resources that are depleted once they are consumed, such as oil and coal.

Non-sovereign bond A bond issued by a government below the national level, such as a province, region, state, or city.

Nonconventional cash flows In a nonconventional cash flow pattern, the initial outflow is not followed by inflows only, but the cash flows can flip from positive (inflows) to negative (outflows) again or even change signs several times.

Nonparametric test A test that is not concerned with a parameter or that makes minimal assumptions about the population from which a sample comes.

Nonsystematic risk Unique risk that is local or limited to a particular asset or industry that need not affect assets outside of that asset class.

Normal distribution A continuous, symmetric probability distribution that is completely described by its mean and its variance.

Normal goods Goods that are consumed in greater quantities as income increases.

Normal profit The level of accounting profit needed to just cover the implicit opportunity costs ignored in accounting costs.

Notching Ratings adjustment methodology where specific issues from the same borrower may be assigned different credit ratings.

Note rate See *mortgage rate*.

Notice period The length of time (typically 30 to 90 days) in advance that investors may be required to notify a fund of their intent to redeem some or all of their investment.

Notional principal An imputed principal amount.

Null hypothesis The hypothesis that is tested.

Numerical data Values that represent measured or counted quantities as a number. Also called **quantitative data**.

Objective probabilities Probabilities that generally do not vary from person to person; includes a priori and empirical probabilities.

Observation The value of a specific variable collected at a point in time or over a specified period of time.

Odds against *E* The reciprocal of odds for *E*.

Odds for *E* The probability of *E* divided by 1 minus the probability of *E*.

Off-the-run Seasoned government bonds are off-the-run securities; they are not the most recently issued or the most actively traded.

Offer The price at which a dealer or trader is willing to sell an asset, typically qualified by a maximum quantity (ask size).

Official interest rate An interest rate that a central bank sets and announces publicly; normally the rate at which it is willing to lend money to the commercial banks. Also called *official policy rate* or *policy rate*.

Official policy rate An interest rate that a central bank sets and announces publicly; normally the rate at which it is willing to lend money to the commercial banks.

Oligopoly Market structure with a relatively small number of firms supplying the market.

On-the-run The most recently issued and most actively traded sovereign securities.

One-dimensional array The simplest format for representing a collection of data of the same data type.

One-sided hypothesis test A test in which the null hypothesis is rejected only if the evidence indicates that the population parameter is greater than or less than the hypothesized parameter; occurs when the alternative hypothesis is stated either as greater than or less than the hypothesized population parameter.

Open economy An economy that trades with other countries.

Open-end fund A mutual fund that accepts new investment money and issues additional shares at a value equal to the net asset value of the fund at the time of investment.

Open interest The number of outstanding contracts in a clearinghouse at any given time. The open interest figure changes daily as some parties open up new positions, while other parties offset their old positions.

Open market operations The purchase or sale of bonds by the national central bank to implement monetary policy. The bonds traded are usually sovereign bonds issued by the national government.

Operating activities Activities that are part of the day-to-day business functioning of an entity, such as selling inventory and providing services.

Operating breakeven The number of units produced and sold at which the company's operating profit is zero (revenues = operating costs).

Operating cash flow The net amount of cash provided from operating activities.

Operating efficiency ratios Ratios that measure how efficiently a company performs day-to-day tasks, such as the collection of receivables and management of inventory.

Operating lease A type of lease which is more akin to the rental of the underlying asset.

Operating leverage The use of fixed costs in operations.

Operating profit A company's profits on its usual business activities before deducting taxes. Also called *operating income*.

Operating profit margin A profitability ratio calculated as operating income (i.e., income before interest and taxes) divided by revenue. Also called *operating margin*.

Operating risk The risk attributed to the operating cost structure, in particular the use of fixed costs in operations; the risk arising from the mix of fixed and variable costs; the risk that a company's operations may be severely affected by environmental, social, and governance risk factors.

Operational independence A bank's ability to execute monetary policy and set interest rates in the way it thought would best meet the inflation target.

Operational risk The risk that arises from inadequate or failed people, systems, and internal policies, procedures, and processes, as well as from external events that are beyond the control of the organization but that affect its operations.

Operationally efficient Said of a market, a financial system, or an economy that has relatively low transaction costs.

Opportunity cost The value that investors forgo by choosing a particular course of action; the value of something in its best alternative use.

Optimal capital structure The capital structure at which the value of the company is maximized.

Option A financial instrument that gives one party the right, but not the obligation, to buy or sell an underlying asset from or to another party at a fixed price over a specific period of time. Also referred to as *contingent claim* or *option contract.*

Option-adjusted price The value of the embedded option plus the flat price of the bond.

Option-adjusted spread OAS = Z-spread – Option value (in basis points per year).

Option-adjusted yield The required market discount rate whereby the price is adjusted for the value of the embedded option.

Option contract See *option*.

Option premium The amount of money a buyer pays and seller receives to engage in an option transaction.

Order A specification of what instrument to trade, how much to trade, and whether to buy or sell.

Order-driven markets A market (generally an auction market) that uses rules to arrange trades based on the orders that traders submit; in their pure form, such markets do not make use of dealers.

Order precedence hierarchy With respect to the execution of orders to trade, a set of rules that determines which orders execute before other orders.

Ordinal data Categorical values that can be logically ordered or ranked.

Ordinary annuity An annuity with a first cash flow that is paid one period from the present.

Ordinary shares Equity shares that are subordinate to all other types of equity (e.g., preferred equity). Also called *common stock* or *common shares.*

Organized exchange A securities marketplace where buyers and seller can meet to arrange their trades.

Other comprehensive income Items of comprehensive income that are not reported on the income statement; comprehensive income minus net income.

Out-of-sample test A test of a strategy or model using a sample outside the period on which the strategy or model was developed.

Out of the money Options that, if exercised, would require the payment of more money than the value received and therefore would not be currently exercised.

Outcome A possible value of a random variable.

Over-the-counter (OTC) market A decentralized market where buy and sell orders initiated from various locations are matched through a communications network.

Overbought A market condition in which market sentiment is thought to be unsustainably bullish.

Overcollateralization Form of internal credit enhancement that refers to the process of posting more collateral than needed to obtain or secure financing.

Overconfidence bias A bias in which people demonstrate unwarranted faith in their own intuitive reasoning, judgments, and/or cognitive abilities.

Overfitting An undesirable result from fitting a model so closely to a dataset that it does not perform well on new data.

Oversold A market condition in which market sentiment is thought to be unsustainably bearish.

Own price The price of a good or service itself (as opposed to the price of something else).

Own-price elasticity of demand The percentage change in quantity demanded for a percentage change in good's own price, holding all other things constant.

Owners' equity The excess of assets over liabilities; the residual interest of shareholders in the assets of an entity after deducting the entity's liabilities. Also called *shareholders' equity* or *shareholders' funds*.

***p*-Value** The smallest level of significance at which the null is rejected.

Paired comparisons test See *test of the mean of the differences*.

Panel data A mix of time-series and cross-sectional data that contains observations through time on characteristics of across multiple observational units.

Par curve A sequence of yields-to-maturity such that each bond is priced at par value. The bonds are assumed to have the same currency, credit risk, liquidity, tax status, and annual yields stated for the same periodicity.

Par value The amount of principal on a bond.

Parallel shift A parallel yield curve shift implies that all rates change by the same amount in the same direction.

Parameter A descriptive measure computed from or used to describe a population of data, conventionally represented by Greek letters.

Parametric test Any test (or procedure) concerned with parameters or whose validity depends on assumptions concerning the population generating the sample.

Pari passu Covenant or contract clause that ensures a debt obligation is treated the same as the borrower's other senior debt instruments and is not subordinated to similar obligations.

Partial duration See *key rate duration*.

Participating preference shares Preference shares that entitle shareholders to receive the standard preferred dividend plus the opportunity to receive an additional dividend if the company's profits exceed a pre-specified level.

Pass-through rate The coupon rate of a mortgage pass-through security.

Passive investment A buy and hold approach in which an investor does not make portfolio changes based on short-term expectations of changing market or security performance.

Payable date The day that the company actually mails out (or electronically transfers) a dividend payment.

Payment date The day that the company actually mails out (or electronically transfers) a dividend payment.

Payments system The system for the transfer of money.

Pearson correlation A parametric measure of the relationship between two variables.

Pecking order theory The theory that managers consider how their actions might be interpreted by outsiders and thus order their preferences for various forms of corporate financing. Forms of financing that are least visible to outsiders (e.g., internally generated funds) are most preferable to managers, and those that are most visible (e.g., equity) are least preferable.

Peer company See *comparable company*.

Peer group A group of companies engaged in similar business activities whose economics and valuation are influenced by closely related factors.

Pennant A technical analysis continuation pattern formed by trendlines that converge to form a triangle, typically over a short period.

Per capita real GDP Real GDP divided by the size of the population, often used as a measure of a country's average standard of living.

Per unit contribution margin The amount that each unit sold contributes to covering fixed costs—that is, the difference between the price per unit and the variable cost per unit.

Percentiles Quantiles that divide a distribution into 100 equal parts that sum to 100.

Perfect capital markets Markets in which, by assumption, there are no taxes, transaction costs, or bankruptcy costs and in which all investors have equal ("symmetric") information.

Perfect competition A market structure in which the individual firm has virtually no impact on market price, because it is assumed to be a very small seller among a very large number of firms selling essentially identical products.

Perfectly elastic When the quantity demanded or supplied of a given good is infinitely sensitive to a change in the value of a specified variable (e.g., price).

Perfectly inelastic When the quantity demanded or supplied of a given good is completely insensitive to a change in the value of a specified variable (e.g., price).

Performance bond See *margin bond*.

Performance evaluation The measurement and assessment of the outcomes of investment management decisions.

Performance fee Fees paid to the general partner from the limited partner(s) based on realized net profits.

Period costs Costs (e.g., executives' salaries) that cannot be directly matched with the timing of revenues and which are thus expensed immediately.

Periodicity The assumed number of periods in the year; typically matches the frequency of coupon payments.

Permanent differences Differences between tax and financial reporting of revenue (expenses) that will not be reversed at some future date. These result in a difference between the company's effective tax rate and statutory tax rate and do not result in a deferred tax item.

Permissioned networks Networks that are fully open only to select participants on a DLT network.

Permissionless networks Networks that are fully open to any user on a DLT network.

Permutation An ordered listing.

Permutation formula The number of ways that we can choose r objects from a total of n objects, when the order in which the r objects are listed does matter, is ${}_nP_r = \dfrac{n!}{(n-r)!}$.

Perpetual bonds Bonds with no stated maturity date.

Perpetuity A perpetual annuity, or a set of never-ending level sequential cash flows, with the first cash flow occurring one period from now. A bond that does not mature.

Personal income A broad measure of household income that includes all income received by households, whether earned or unearned; measures the ability of consumers to make purchases.

Pet projects Investments in which influential managers want the corporation to invest. Often, unfortunately, pet projects are selected without undergoing normal capital allocation analysis.

Plain vanilla bond Bond that makes periodic, fixed coupon payments during the bond's life and a lump-sum payment of principal at maturity. Also called *conventional bond*.

Platykurtic Describes a distribution that has relatively less weight in the tails than the normal distribution (also called thin-tailed).

Point estimate A single numerical estimate of an unknown quantity, such as a population parameter.

Policy rate An interest rate that a central bank sets and announces publicly; normally the rate at which it is willing to lend money to the commercial banks.

Population All members of a specified group.

Portfolio company In private equity, the company in which the private equity fund is investing.

Portfolio demand for money The demand to hold speculative money balances based on the potential opportunities or risks that are inherent in other financial instruments.

Portfolio planning The process of creating a plan for building a portfolio that is expected to satisfy a client's investment objectives.

Position The quantity of an asset that an entity owns or owes.

Positive screening The process of including sectors or companies based on specific ESG criteria, typically ESG performance relative to industry peers

Posterior probability An updated probability that reflects or comes after new information.

Potential GDP The level of real GDP that can be produced at full employment; measures the productive capacity of the economy.

Power of a test The probability of correctly rejecting the null—that is, rejecting the null hypothesis when it is false.

Precautionary money balances Money held to provide a buffer against unforeseen events that might require money.

Preference shares A type of equity interest which ranks above common shares with respect to the payment of dividends and the distribution of the company's net assets upon liquidation. They have characteristics of both debt and equity securities. Also called *preferred stock*.

Preferred stock See *preference shares*.

Premium In the case of bonds, premium refers to the amount by which a bond is priced above its face (par) value. In the case of an option, the amount paid for the option contract.

Prepaid expense A normal operating expense that has been paid in advance of when it is due.

Prepayment option Contractual provision that entitles the borrower to prepay all or part of the outstanding mortgage principal prior to the scheduled due date when the principal must be repaid. Also called *early repayment option*.

Prepayment penalty mortgages Mortgages that stipulate a monetary penalty if a borrower prepays within a certain time period after the mortgage is originated.

Prepayment risk The uncertainty that the timing of the actual cash flows will be different from the scheduled cash flows as set forth in the loan agreement due to the borrowers' ability to alter payments, usually to take advantage of interest rate movements.

Present value (PV) The present discounted value of future cash flows: For assets, the present discounted value of the future net cash inflows that the asset is expected to generate; for liabilities, the present discounted value of the future net cash outflows that are expected to be required to settle the liabilities.

Present value models Valuation models that estimate the intrinsic value of a security as the present value of the future benefits expected to be received from the security. Also called *discounted cash flow models*.

Pretax margin A profitability ratio calculated as earnings before taxes divided by revenue.

Price elasticity of demand Measures the percentage change in the quantity demanded, given a percentage change in the price of a given product.

Price index Represents the average prices of a basket of goods and services.

Price limits Limits imposed by a futures exchange on the price change that can occur from one day to the next.

Price multiple A ratio that compares the share price with some sort of monetary flow or value to allow evaluation of the relative worth of a company's stock.

Price priority The principle that the highest priced buy orders and the lowest priced sell orders execute first.

Price relative A ratio of an ending price over a beginning price; it is equal to 1 plus the holding period return on the asset.

Price return Measures *only* the price appreciation or percentage change in price of the securities in an index or portfolio.

Price return index An index that reflects *only* the price appreciation or percentage change in price of the constituent securities. Also called *price index*.

Price-setting option The option to adjust prices when demand varies from what is forecast.

Price stability In economics, refers to an inflation rate that is low on average and not subject to wide fluctuation.

Price takers Producers that must accept whatever price the market dictates.

Price to book value A valuation ratio calculated as price per share divided by book value per share.

Price to cash flow A valuation ratio calculated as price per share divided by cash flow per share.

Price to earnings ratio (P/E ratio or P/E) The ratio of share price to earnings per share.

Price to sales A valuation ratio calculated as price per share divided by sales per share.

Price value of a basis point A version of money duration, it is an estimate of the change in the full price of a bond given a 1 basis point change in the yield-to-maturity.

Price weighting An index weighting method in which the weight assigned to each constituent security is determined by dividing its price by the sum of all the prices of the constituent securities.

Priced risk Risk for which investors demand compensation for bearing (e.g., equity risk, company-specific factors, macroeconomic factors).

Primary bond market A market in which issuers first sell bonds to investors to raise capital.

Primary capital markets (primary markets) The market where securities are first sold and the issuers receive the proceeds.

Primary dealer Financial institution that is authorized to deal in new issues of sovereign bonds and that serves primarily as a trading counterparty of the office responsible for issuing sovereign bonds.

Primary market The market where securities are first sold and the issuers receive the proceeds.

Prime brokers Brokers that provide services that commonly include custody, administration, lending, short borrowing, and trading.

Principal The amount of funds originally invested in a project or instrument; the face value to be paid at maturity.

Principal–agent relationship A relationship in which a principal hires an agent to perform a particular task or service; also known as an *agency relationship*.

Principal amount Amount that an issuer agrees to repay the debtholders on the maturity date.

Principal business activity The business activity from which a company derives a majority of its revenues and/or earnings.

Principal value Amount that an issuer agrees to repay the debtholders on the maturity date.

Principle of no arbitrage See *arbitrage-free pricing*.

Prior probabilities Probabilities reflecting beliefs prior to the arrival of new information.

Priority of claims Priority of payment, with the most senior or highest ranking debt having the first claim on the cash flows and assets of the issuer.

Private equity fund A hedge fund that seeks to buy, optimize, and ultimately sell portfolio companies to generate profits. See *venture capital fund*.

Private equity funds Funds that seek to invest in, optimize, and eventually exit portfolio companies to generate profits. See *venture capital funds*.

Private equity securities Securities that are not listed on public exchanges and have no active secondary market. They are issued primarily to institutional investors via non-public offerings, such as private placements.

Private investment in public equity (PIPE) An investment in the equity of a publicly traded firm that is made at a discount to the market value of the firm's shares.

Private placement Typically, a non-underwritten, unregistered offering of securities that are sold only to an investor or a small group of investors. It can be accomplished directly between the issuer and the investor(s) or through an investment bank.

Probability A number between 0 and 1 describing the chance that a stated event will occur.

Probability density function A function with non-negative values such that probability can be described by areas under the curve graphing the function.

Probability distribution A distribution that specifies the probabilities of a random variable's possible outcomes.

Probability function A function that specifies the probability that the random variable takes on a specific value.

Probability sampling A sampling plan that allows every member of the population to have an equal chance of being selected.

Probability tree diagram A diagram with branches emanating from nodes representing either mutually exclusive chance events or mutually exclusive decisions.

Production-flexibility options The options to alter production when demand varies from what is forecast.

Production function Provides the quantitative link between the levels of output that the economy can produce and the inputs used in the production process.

Productivity The amount of output produced by workers during a given period—for example, output per hour worked measures the efficiency of labor.

Profession An occupational group that has specific education, expert knowledge, and a framework of practice and behavior that underpins community trust, respect, and recognition.

Profit The return that owners of a company receive for the use of their capital and the assumption of financial risk when making their investments.

Profit and loss (P&L) statement A financial statement that provides information about a company's profitability over a stated period of time. Also called the *income statement*.

Profit margin An indicator of profitability, calculated as net income divided by revenue; indicates how much of each dollar of revenues is left after all costs and expenses.

Profitability ratios Ratios that measure a company's ability to generate profitable sales from its resources (assets).

Project sequencing To defer the decision to invest in a future project until the outcome of some or all of a current investment is known. Investments are sequenced over time, so that making an investment creates the option to invest in future projects.

Promissory note A written promise to pay a certain amount of money on demand.

Property, plant, and equipment Tangible assets that are expected to be used for more than one period in either the production or supply of goods or services, or for administrative purposes.

Prospectus The document that describes the terms of a new bond issue and helps investors perform their analysis on the issue.

Protective put An option strategy in which a long position in an asset is combined with a long position in a put.

Proxy contest Corporate takeover mechanism in which shareholders are persuaded to vote for a group seeking a controlling position on a company's board of directors.

Proxy voting A process that enables shareholders who are unable to attend a meeting to authorize another individual to vote on their behalf.

Public offer See *public offering*.

Public offering An offering of securities in which any member of the public may buy the securities. Also called *public offer*.

Public–private partnership (PPP) An agreement between the public sector and the private sector to finance, build, and operate public infrastructure, such as hospitals and toll roads.

Pull on liquidity When disbursements are paid too quickly or trade credit availability is limited, requiring companies to expend funds before they receive funds from sales that could cover the liability.

Pure discount bonds See *zero-coupon bond*.

Put An option that gives the holder the right to sell an underlying asset to another party at a fixed price over a specific period of time.

Put–call–forward parity The relationship among puts, calls, and forward contracts.

Put–call parity An equation expressing the equivalence (parity) of a portfolio of a call and a bond with a portfolio of a put and the underlying, which leads to the relationship between put and call prices.

Put/call ratio A technical analysis indicator that evaluates market sentiment based on the volume of put options traded divided by the volume of call options traded for a particular financial instrument.

Put option An option that gives the holder the right to sell an underlying asset to another party at a fixed price over a specific period of time.

Putable bonds Bonds that give the bondholder the right to sell the bond back to the issuer at a predetermined price on specified dates.

Qualitative data see **categorical data**.

Quantile A value at or below which a stated fraction of the data lies. Also referred to as a fractile.

Quantitative data see **numerical data**.

Quantitative easing An expansionary monetary policy based on aggressive open market purchase operations.

Quantity equation of exchange An expression that over a given period, the amount of money used to purchase all goods and services in an economy, $M \times V$, is equal to monetary value of this output, $P \times Y$.

Quantity theory of money Asserts that total spending (in money terms) is proportional to the quantity of money.

Quartiles Quantiles that divide a distribution into four equal parts.

Quasi-fixed cost A cost that stays the same over a range of production but can change to another constant level when production moves outside of that range.

Quasi-government bond A bond issued by an entity that is either owned or sponsored by a national government. Also called *agency bond*.

Quintiles Quantiles that divide a distribution into five equal parts.

Quota rents Profits that foreign producers can earn by raising the price of their goods higher than they would without a quota.

Quotas Government policies that restrict the quantity of a good that can be imported into a country, generally for a specified period of time.

Quote-driven market A market in which dealers acting as principals facilitate trading.

Quoted interest rate A quoted interest rate that does not account for compounding within the year. Also called *stated annual interest rate*.

Quoted margin The specified yield spread over the reference rate, used to compensate an investor for the difference in the credit risk of the issuer and that implied by the reference rate.

Random number An observation drawn from a uniform distribution.

Random number generator An algorithm that produces uniformly distributed random numbers between 0 and 1.

Random variable A quantity whose future outcomes are uncertain.

Range The difference between the maximum and minimum values in a dataset.

Raw data Data available in their original form as collected.

Real exchange rate effect The effect through which changing price level impacts real exchange rate which in turn impacts net exports and aggregate demand.

Real GDP The value of goods and services produced, measured at base year prices.

Real income Income adjusted for the effect of inflation on the purchasing power of money. Also known as the *purchasing power of income*. If income remains constant and a good's price falls, real income is said to rise, even though the number of monetary units (e.g., dollars) remains unchanged.

Real interest rate Nominal interest rate minus the expected rate of inflation.

Real risk-free interest rate The single-period interest rate for a completely risk-free security if no inflation were expected.

Realizable (settlement) value With reference to assets, the amount of cash or cash equivalents that could currently be obtained by selling the asset in an orderly disposal; with reference to liabilities, the undiscounted amount of cash or cash equivalents expected to be paid to satisfy the liabilities in the normal course of business.

Rebalancing Adjusting the weights of the constituent securities in an index.

Rebalancing policy The set of rules that guide the process of restoring a portfolio's asset class weights to those specified in the strategic asset allocation.

Recession A period during which real GDP decreases (i.e., negative growth) for at least two successive quarters, or a period of significant decline in total output, income, employment, and sales usually lasting from six months to a year.

Recognition lag The lag in government response to an economic problem resulting from the delay in confirming a change in the state of the economy.

Recourse loan A loan in which the lender has a claim against the borrower for any shortfall between the outstanding mortgage balance and the proceeds received from the sale of the property.

Redemption yield See *yield-to-maturity*.

Redemptions Withdrawals of funds by investors, as allowed by the notice period and other terms in the partnership agreement.

Refinancing rate A type of central bank policy rate.

Registered bonds Bonds for which ownership is recorded by either name or serial number.

Regression analysis A tool for examining whether a variable is useful for explaining another variable.

Regression coefficients The intercept and slope coefficient of a regression.

Regret The feeling that an opportunity has been missed; typically, an expression of *hindsight bias*.

Regret-aversion bias An emotional bias in which people tend to avoid making decisions that will result in action out of fear that the decision will turn out poorly.

Relative dispersion The amount of dispersion relative to a reference value or benchmark.

Relative frequency The absolute frequency of each unique value of the variable divided by the total number of observations of the variable.

Relative price The price of a specific good or service in comparison with those of other goods and services.

Relative strength analysis A comparison of the performance of one asset with the performance of another asset or a benchmark, based on changes in the ratio of the two assets' prices over time.

Relative strength index (RSI) A technical analysis momentum oscillator that compares a security's gains with its losses over a set period.

Renewable resources Resources that can be replenished, such as a forest.

Rent Payment for the use of property.

Reorganization Agreements made by a company in bankruptcy under which a company's capital structure is altered and/or alternative arrangements are made for debt repayment; US Chapter 11 bankruptcy. The company emerges from bankruptcy as a going concern.

Replication The creation of an asset or portfolio from another asset, portfolio, and/or derivative.

Repo A form of collateralized loan involving the sale of a security with a simultaneous agreement by the seller to buy back the same security from the purchaser at an agreed-on price and future date. The party who sells the

security at the inception of the repurchase agreement and buys it back at maturity is borrowing money from the other party, and the security sold and subsequently repurchased represents the collateral.

Repo margin The difference between the market value of the security used as collateral and the value of the loan. Also called *haircut*.

Repo rate The interest rate on a repurchase agreement.

Representativeness bias A belief perseverance bias in which people tend to classify new information based on past experiences and classifications.

Repurchase agreement A form of collateralized loan involving the sale of a security with a simultaneous agreement by the seller to buy the same security back from the purchaser at an agreed-on price and future date. The party who sells the security at the inception of the repurchase agreement and buys it back at maturity is borrowing money from the other party, and the security sold and subsequently repurchased represents the collateral.

Repurchase date The date when the party who sold the security at the inception of a repurchase agreement buys back the security from the cash lending counterparty.

Repurchase price The price at which the party who sold the security at the inception of the repurchase agreement buys back the security from the cash lending counterparty.

Required margin The yield spread over or under the reference rate such that an FRN is priced at par value on a rate reset date.

Required rate of return See *market discount rate*.

Required yield See *market discount rate*.

Required yield spread The difference between the yield-to-maturity on a new bond and the benchmark rate; additional compensation required by investors for the difference in risk and tax status of a bond relative to a government bond. Sometimes called the *spread over the benchmark*.

Resampling A statistical method that repeatedly draws samples from the original observed data sample for the statistical inference of population parameters.

Reserve accounts Form of internal credit enhancement that relies on creating accounts and depositing in these accounts cash that can be used to absorb losses. Also called *reserve funds*.

Reserve funds See *reserve accounts*.

Reserve requirement The requirement for banks to hold reserves in proportion to the size of deposits.

Residual The difference between an observation and its predicted value, where the predicted value is based on the estimated linear relation between the dependent and independent variables using sample data.

Resistance In technical analysis, a price range in which selling activity is sufficient to stop the rise in the price of a security.

Responsible investing An overall (umbrella) term for several investment strategies—ESG investing, SRI investing, thematic investing, and impact investing—that incorporate ESG analysis in their investment processes.

Restricted payments A bond covenant meant to protect creditors by limiting how much cash can be paid out to shareholders over time.

Retracement In technical analysis, a reversal in the movement of a security's price such that it is counter to the prevailing longer-term price trend.

Return-generating model A model that can provide an estimate of the expected return of a security given certain parameters and estimates of the values of the independent variables in the model.

Return on assets (ROA) A profitability ratio calculated as net income divided by average total assets; indicates a company's net profit generated per dollar invested in total assets.

Return on equity (ROE) A profitability ratio calculated as net income divided by average shareholders' equity.

Return on invested capital A measure of the profitability of a company relative to the amount of capital invested by the equity- and debtholders.

Return on sales An indicator of profitability, calculated as net income divided by revenue; indicates how much of each dollar of revenues is left after all costs and expenses. Also referred to as *net profit margin*.

Return on total capital A profitability ratio calculated as EBIT divided by the sum of short- and long-term debt and equity.

Revaluation model Under IFRS, the process of valuing long-lived assets at fair value, rather than at cost less accumulated depreciation. Any resulting profit or loss is either reported on the income statement and/or through equity under revaluation surplus.

Revenue The amount charged for the delivery of goods or services in the ordinary activities of a business over a stated period; the inflows of economic resources to a company over a stated period.

Reversal pattern A type of pattern used in technical analysis to predict the end of a trend and a change in the direction of a security's price.

Reverse repo A repurchase agreement viewed from the perspective of the cash lending counterparty.

Reverse repurchase agreement A repurchase agreement viewed from the perspective of the cash lending counterparty.

Reverse stock split A reduction in the number of shares outstanding with a corresponding increase in share price, but no change to the company's underlying fundamentals.

Revolving credit agreements (also known as revolvers) The most reliable form of short-term bank borrowing facilities; they are in effect for multiple years (e.g., three to five years) and can have optional medium-term loan features.

Rho The sensitivity of the option price to the risk-free rate.

Ricardian equivalence An economic theory that implies that it makes no difference whether a government finances a deficit by increasing taxes or issuing debt.

Risk Exposure to uncertainty. The chance of a loss or adverse outcome as a result of an action, inaction, or external event.

Risk averse The assumption that an investor will choose the least risky alternative.

Risk aversion The degree of an investor's inability and unwillingness to take risk.

Risk budgeting The establishment of objectives for individuals, groups, or divisions of an organization that takes into account the allocation of an acceptable level of risk.

Risk exposure The state of being exposed or vulnerable to a risk. The extent to which an organization is sensitive to underlying risks.

Risk governance The top-down process and guidance that directs risk management activities to align with and support the overall enterprise.

Risk management The process of identifying the level of risk an organization wants, measuring the level of risk the organization currently has, taking actions that bring the actual

level of risk to the desired level of risk, and monitoring the new actual level of risk so that it continues to be aligned with the desired level of risk.

Risk management framework The infrastructure, process, and analytics needed to support effective risk management in an organization.

Risk-neutral pricing Sometimes said of derivatives pricing, uses the fact that arbitrage opportunities guarantee that a risk-free portfolio consisting of the underlying and the derivative must earn the risk-free rate.

Risk-neutral probabilities Weights that are used to compute a binomial option price. They are the probabilities that would apply if a risk-neutral investor valued an option.

Risk premium An extra return expected by investors for bearing some specified risk.

Risk shifting Actions to change the distribution of risk outcomes.

Risk tolerance The amount of risk an investor is willing and able to bear to achieve an investment goal.

Risk transfer Actions to pass on a risk to another party, often, but not always, in the form of an insurance policy.

Robo-adviser A machine-based analytical tool or service that provides technology-driven investment solutions through online platforms.

Rule of 72 The principle that the approximate number of years necessary for an investment to double is 72 divided by the stated interest rate.

Running yield See *current yield.*

Safety-first rules Rules for portfolio selection that focus on the risk that portfolio value or portfolio return will fall below some minimum acceptable level over some time horizon.

Sales Generally, a synonym for revenue; “sales” is generally understood to refer to the sale of goods, whereas “revenue” is understood to include the sale of goods or services.

Sales risk Uncertainty with respect to the quantity of goods and services that a company is able to sell and the price it is able to achieve; the risk related to the uncertainty of revenues.

Sample A subset of a population.

Sample correlation coefficient A standardized measure of how two variables in a sample move together. It is the ratio of the sample covariance to the product of the two variables’ standard deviations.

Sample covariance A measure of how two variables in a sample move together.

Sample excess kurtosis A sample measure of the degree of a distribution’s kurtosis in excess of the normal distribution’s kurtosis.

Sample mean The sum of the sample observations divided by the sample size.

Sample selection bias Bias introduced by systematically excluding some members of the population according to a particular attribute—for example, the bias introduced when data availability leads to certain observations being excluded from the analysis.

Sample-size neglect A type of representativeness bias in which financial market participants incorrectly assume that small sample sizes are representative of populations (or “real” data).

Sample skewness A sample measure of the degree of asymmetry of a distribution.

Sample standard deviation The positive square root of the sample variance.

Sample statistic A quantity computed from or used to describe a sample.

Sample variance The sum of squared deviations around the mean divided by the degrees of freedom.

Sampling The process of obtaining a sample.

Sampling distribution The distribution of all distinct possible values that a statistic can assume when computed from samples of the same size randomly drawn from the same population.

Sampling error The difference between the observed value of a statistic and the estimate resulting from using subsets of the population.

Sampling plan The set of rules used to select a sample.

Say on pay A process whereby shareholders may vote on executive remuneration (compensation) matters.

Scatter plot A chart in which two variables are plotted along the axis and points on the chart represent pairs of the two variables. In regression, the dependent variable is plotted on the vertical axis and the independent variable is plotted along the horizontal axis. Also known as a scattergram and a *scatter diagram.*

Scatter plot matrix A tool for organizing scatter plots between pairs of variables, making it easy to inspect all pairwise relationships in one combined visual.

Scenario analysis Analysis that shows the changes in key financial quantities that result from given (economic) events, such as the loss of customers, the loss of a supply source, or a catastrophic event; a risk management technique involving examination of the performance of a portfolio under specified situations. Closely related to stress testing.

Screening The application of a set of criteria to reduce a set of potential investments to a smaller set having certain desired characteristics.

Seasoned offering An offering in which an issuer sells additional units of a previously issued security.

Second-degree price discrimination When the monopolist charges different per-unit prices using the quantity purchased as an indicator of how highly the customer values the product.

Second lien A secured interest in the pledged assets that ranks below first lien debt in both collateral protection and priority of payment.

Secondary bond markets Markets in which existing bonds are traded among investors.

Secondary market The market where securities are traded among investors.

Secondary precedence rules Rules that determine how to rank orders placed at the same time.

Sector A group of related industries (GICS definition).

Sector indexes Indexes that represent and track different economic sectors—such as consumer goods, energy, finance, health care, and technology—on either a national, regional, or global basis.

Secured (“asset-based”) loan A loan that is backed by specific, secured company assets.

Secured bonds Bonds secured by assets or financial guarantees pledged to ensure debt repayment in case of default.

Secured debt Debt in which the debtholder has a direct claim—a pledge from the issuer—on certain assets and their associated cash flows.

Securitization A process that involves moving assets into a special legal entity, which then uses the assets as guarantees to secure a bond issue.

Securitized assets Assets that are typically used to create asset-backed bonds; for example, when a bank securitizes a pool of loans, the loans are said to be securitized.

Security characteristic line A plot of the excess return of a security on the excess return of the market.

Security market index A portfolio of securities representing a given security market, market segment, or asset class.

Security market line (SML) The graph of the capital asset pricing model.

Security selection The process of selecting individual securities; typically, security selection has the objective of generating superior risk-adjusted returns relative to a portfolio's benchmark.

Self-attribution bias A bias in which people take too much credit for successes (*self-enhancing*) and assign responsibility to others for failures (*self-protecting*).

Self-control bias A bias in which people fail to act in pursuit of their long-term, overarching goals because of a lack of self-discipline.

Self-investment limits With respect to investment limitations applying to pension plans, restrictions on the percentage of assets that can be invested in securities issued by the pension plan sponsor.

Sell-side firm A broker/dealer that sells securities and provides independent investment research and recommendations to their clients (i.e., buy-side firms).

Semi-strong-form efficient market A market in which security prices reflect all publicly known and available information.

Semiannual bond basis yield An annual rate having a periodicity of two; also known as a *semiannual bond equivalent yield*.

Semiannual bond equivalent yield See *semiannual bond basis yield*.

Seniority ranking Priority of payment of various debt obligations.

Sensitivity analysis Analysis that shows the range of possible outcomes as specific assumptions are changed.

Separately managed account (SMA) An investment portfolio managed exclusively for the benefit of an individual or institution.

Serial maturity structure Structure for a bond issue in which the maturity dates are spread out during the bond's life; a stated number of bonds mature and are paid off each year before final maturity.

Settlement The process that occurs after a trade is completed, the securities are passed to the buyer, and payment is received by the seller.

Settlement date Date when the buyer makes cash payment and the seller delivers the security.

Settlement price The official price, designated by the clearinghouse, from which daily gains and losses will be determined and marked to market.

Share repurchase A transaction in which a company buys back its own shares. Unlike stock dividends and stock splits, share repurchases use corporate cash.

Shareholder activism Strategies used by shareholders to attempt to compel a company to act in a desired manner.

Shareholder engagement The process whereby companies engage with their shareholders.

Shareholders' equity Assets less liabilities; the residual interest in the assets after subtracting the liabilities.

Sharpe ratio The average return in excess of the risk-free rate divided by the standard deviation of return; a measure of the average excess return earned per unit of standard deviation of return.

Shelf registration A type of public offering that allows the issuer to file a single, all-encompassing offering circular that covers a series of bond issues.

Short The seller of an asset or derivative contract. Also refers to the position of being short an asset or derivative contract.

Short position A position in an asset or contract in which one has sold an asset one does not own, or in which a right under a contract can be exercised against oneself.

Short-run average total cost The curve describing average total cost when some costs are considered fixed.

Short selling A transaction in which borrowed securities are sold with the intention to repurchase them at a lower price at a later date and return them to the lender.

Shortfall risk The risk that portfolio value or portfolio return will fall below some minimum acceptable level over some time horizon.

Shutdown point The point at which average revenue is equal to the firm's average variable cost.

Side letters Side agreements created between the GP and specific LPs. These agreements exist *outside* the LPA. These agreements provide additional terms and conditions related to the investment agreement.

Simple interest The interest earned each period on the original investment; interest calculated on the principal only.

Simple linear regression (SLR) A regression that summarizes the relation between the dependent variable and a single independent variable.

Simple random sample A subset of a larger population created in such a way that each element of the population has an equal probability of being selected to the subset.

Simple random sampling The procedure of drawing a sample to satisfy the definition of a simple random sample.

Simple yield The sum of the coupon payments plus the straight-line amortized share of the gain or loss, divided by the flat price.

Simulation Computer-generated sensitivity or scenario analysis that is based on probability models for the factors that drive outcomes.

Simulation trial A complete pass through the steps of a simulation.

Single-step format With respect to the format of the income statement, a format that does not subtotal for gross profit (revenue minus cost of goods sold).

Sinking fund arrangement Provision that reduces the credit risk of a bond issue by requiring the issuer to retire a portion of the bond's principal outstanding each year.

Situational influences External factors, such as environmental or cultural elements, that shape our behavior.

Skewed Not symmetrical.

Skewness A quantitative measure of skew (lack of symmetry); a synonym of skew. It is computed as the average cubed deviation from the mean standardized by dividing by the standard deviation cubed.

Slope coefficient The coefficient of an independent variable that represents the average change in the dependent variable for a one-unit change in the independent variable.

Small country A country that is a price taker in the world market for a product and cannot influence the world market price.

Smart beta Involves the use of simple, transparent, rules-based strategies as a basis for investment decisions.

Smart contract A computer program that is designed to self-execute on the basis of pre-specified terms and conditions agreed to by parties to a contract.

Socially responsible investing An investment approach that excludes investments in companies or industries that deviate from an organization's beliefs and sometimes includes investments with favorable environmental or social profiles.

Soft-bullet covered bonds Covered bonds for which bond default and payment acceleration of bond cash flows may be delayed upon sponsor default until a new final maturity date is reached.

Solvency With respect to financial statement analysis, the ability of a company to fulfill its long-term obligations.

Solvency ratios Ratios that measure a company's ability to meet its long-term obligations.

Solvency risk The risk that an organization does not survive or succeed because it runs out of cash, even though it might otherwise be solvent.

Sovereign bond A bond issued by a national government. Also called "Sovereign."

Spearman rank correlation coefficient A measure of correlation applied to ranked data.

Special dividend A dividend paid by a company that does not pay dividends on a regular schedule, or a dividend that supplements regular cash dividends with an extra payment.

Special purpose entity A non-operating entity created to carry out a specified purpose, such as leasing assets or securitizing receivables; can be a corporation, partnership, trust, or limited liability partnership formed to facilitate a specific type of business activity. Also called *special purpose vehicle*, *special purpose company*, or *variable interest entity*.

Special purpose vehicle See *special purpose entity*.

Specific identification method An inventory accounting method that identifies which specific inventory items were sold and which remained in inventory to be carried over to later periods.

Speculative demand for money The demand to hold speculative money balances based on the potential opportunities or risks that are inherent in other financial instruments. Also called *portfolio demand for money*.

Speculative money balances Monies held in anticipation that other assets will decline in value.

Split coupon bond See *deferred coupon bond*.

Sponsored A type of depository receipt in which the foreign company whose shares are held by the depository has a direct involvement in the issuance of the receipts.

Spot curve A sequence of yields-to-maturity on zero-coupon bonds. Sometimes called *zero* or *strip curve* (because coupon payments are "stripped" off the bonds).

Spot markets Markets in which assets are traded for immediate delivery.

Spot prices The price of an asset for immediately delivery.

Spot rates A sequence of market discount rates that correspond to the cash flow dates; yields-to-maturity on zero-coupon bonds maturing at the date of each cash flow.

Spread In general, the difference in yield between different fixed-income securities. Often used to refer to the difference between the yield-to-maturity and the benchmark.

Spread over the benchmark See *required yield spread*.

Spread risk Bond price risk arising from changes in the yield spread on credit-risky bonds; reflects changes in the market's assessment and/or pricing of credit migration (or downgrade) risk and market liquidity risk.

Spurious correlation Refers to: 1) correlation between two variables that reflects chance relationships in a particular dataset; 2) correlation induced by a calculation that mixes each of two variables with a third variable; and 3) correlation between two variables arising not from a direct relation between them but from their relation to a third variable.

Stacked bar chart An alternative form for presenting the frequency distribution of two categorical variables, where bars representing the sub-groups are placed on top of each other to form a single bar. Each sub-section is shown in a different color to represent the contribution of each sub-group, and the overall height of the stacked bar represents the marginal frequency for the category.

Stackelberg model A prominent model of strategic decision making in which firms are assumed to make their decisions sequentially.

Stagflation The combination of a high inflation rate with a high level of unemployment and a slowdown of the economy.

Staggered boards Election process whereby directors are typically divided into multiple classes that are elected separately in consecutive years—that is, one class every year.

Stakeholder management The identification, prioritization, and understanding of the interests of stakeholder groups and managing the company's relationships with these groups.

Stakeholders Individuals or groups of individuals who may be affected either directly or indirectly by a decision and thus have an interest, or stake, in the decision.

Standard deviation The positive square root of the variance; a measure of dispersion in the same units as the original data.

Standard error of the estimate A measure of the fit of a regression line, calculated as the square root of the mean square error. Also known as the *standard error of the regression* and the *root mean square error*.

Standard error of the forecast A measure of the uncertainty associated with a forecasted value of the dependent variable that depends on the standard error of the estimate, the variability of the independent variable, the deviation of the forecasted independent variable from the mean in the regression, and the number of observations.

Standard error of the slope coefficient The standard error of the slope, which in a simple linear regression is the ratio of the model's standard error of the estimate (s_e) to the square root of the variation of the independent variable.

Standard normal distribution The normal density with mean (μ) equal to 0 and standard deviation (σ) equal to 1.

Standardizing A transformation that involves subtracting the mean and dividing the result by the standard deviation.

Standards of conduct Behaviors required by a group; established benchmarks that clarify or enhance a group's code of ethics.

Standing limit orders A limit order at a price below market and which therefore is waiting to trade.

Stated annual interest rate A quoted interest rate that does not account for compounding within the year. Also called *quoted interest rate*.

Statement of changes in equity (statement of owners' equity) A financial statement that reconciles the beginning-of-period and end-of-period balance sheet values of

shareholders' equity; provides information about all factors affecting shareholders' equity. Also called *statement of owners' equity*.

Statement of financial condition The financial statement that presents an entity's current financial position by disclosing resources the entity controls (its assets) and the claims on those resources (its liabilities and equity claims), as of a particular point in time (the date of the balance sheet).

Statement of financial position The financial statement that presents an entity's current financial position by disclosing resources the entity controls (its assets) and the claims on those resources (its liabilities and equity claims), as of a particular point in time (the date of the balance sheet).

Statement of operations A financial statement that provides information about a company's profitability over a stated period of time.

Static trade-off theory of capital structure A theory pertaining to a company's optimal capital structure. The optimal level of debt is found at the point where additional debt would cause the costs of financial distress to increase by a greater amount than the benefit of the additional tax shield.

Statistic A summary measure of a sample of observations.

Statistically significant A result indicating that the null hypothesis can be rejected; with reference to an estimated regression coefficient, frequently understood to mean a result indicating that the corresponding population regression coefficient is different from zero.

Status quo bias An emotional bias in which people do nothing (i.e., maintain the status quo) instead of making a change.

Statutory voting A common method of voting where each share represents one vote.

Step-up coupon bond Bond for which the coupon, fixed or floating, increases by specified margins at specified dates.

Stochastic oscillator A momentum indicator that compares a particular closing price of a security to a range of the security's prices over a certain period of time.

Stock dividend A type of dividend in which a company distributes additional shares of its common stock to shareholders instead of cash.

Stock split An increase in the number of shares outstanding with a consequent decrease in share price, but no change to the company's underlying fundamentals.

Stop-loss order See *stop order*.

Stop order An order in which a trader has specified a stop price condition. Also called *stop-loss order*.

Store of value The quality of tending to preserve value.

Store of wealth Goods that depend on the fact that they do not perish physically over time, and on the belief that others would always value the good.

Straight-line method A depreciation method that allocates evenly the cost of a long-lived asset less its estimated residual value over the estimated useful life of the asset.

Straight voting A shareholder voting process in which shareholders receive one vote for each share owned.

Strategic analysis Analysis of the competitive environment with an emphasis on the implications of the environment for corporate strategy.

Strategic asset allocation The set of exposures to IPS-permissible asset classes that is expected to achieve the client's long-term objectives given the client's investment constraints.

Stratified random sampling A procedure that first divides a population into subpopulations (strata) based on classification criteria and then randomly draws samples from each stratum in sizes proportional to that of each stratum in the population.

Street convention A yield measure that neglects weekends and holidays; the internal rate of return on cash flows assuming payments are made on the scheduled dates, even when the scheduled date falls on a weekend or holiday.

Stress testing A specific type of scenario analysis that estimates losses in rare and extremely unfavorable combinations of events or scenarios.

Strong-form efficient market A market in which security prices reflect all public and private information.

Structural (or cyclically adjusted) budget deficit The deficit that would exist if the economy was at full employment (or full potential output).

Structural subordination Arises in a holding company structure when the debt of operating subsidiaries is serviced by the cash flow and assets of the subsidiaries before funds can be passed to the holding company to service debt at the parent level.

Structured data Data that are highly organized in a predefined manner, usually with repeating patterns.

Structured financial instrument A financial instrument that shares the common attribute of repackaging risks. Structured financial instruments include asset-backed securities, collateralized debt obligations, and other structured financial instruments such as capital protected, yield enhancement, participation, and leveraged instruments.

Subjective probability A probability drawing on personal or subjective judgment.

Subordinated debt A class of unsecured debt that ranks below a firm's senior unsecured obligations.

Subordination Form of internal credit enhancement that relies on creating more than one bond tranche and ordering the claim priorities for ownership or interest in an asset between the tranches. The ordering of the claim priorities is called a senior/subordinated structure, where the tranches of highest seniority are called senior followed by subordinated or junior tranches. Also called *credit tranching*.

Substitutes Said of two goods or services such that if the price of one increases the demand for the other tends to increase, holding all other things equal (e.g., butter and margarine).

Sum of squares error (SSE) The sum of the squared deviations of (1) the value of the dependent variable and (2) the value of the dependent variable based on the estimated regression line. Also referred to as the *residual sum of squares*.

Sum of squares regression (SSR) The sum of the squared deviations of (1) the value of the dependent variable based on the estimated regression line and (2) the mean of the dependent variable.

Sum of squares total (SST) The sum of the squared deviations of the dependent variable from its mean; the variation of the dependent variable. Also referred to as the *total sum of squares*.

Sunk cost A cost that has already been incurred.

Supervised learning A machine learning approach that makes use of labeled training data.

Supply shock A typically unexpected disturbance to supply.

Support In technical analysis, a price range in which buying activity is sufficient to stop the decline in the price of a security.

Support tranches Classes or tranches in CMOs that protect PAC tranches from prepayment risk.

Supranational bond A bond issued by a supranational agency such as the World Bank.

Surety bond Form of external credit enhancement whereby a rated and regulated insurance company guarantees to reimburse bondholders for any losses incurred up to a maximum amount if the issuer defaults.

Survey approach An estimate of the equity risk premium that is based on estimates provided by a panel of finance experts.

Survivorship bias Relates to the inclusion of only current investment funds in a database. As such, the returns of funds that are no longer available in the marketplace (have been liquidated) are excluded from the database. In addition, *backfill bias* is another problem, whereby certain surviving hedge funds may be added to databases and various hedge fund indexes only after they are initially successful and start to report their returns.

Sustainability linked loans These are any types of loan instruments and/or contingent facilities (such as bonding lines, guarantee lines, or letters of credit) that incentivize the borrower's achievement of ambitious, pre-determined sustainability performance objectives.

Sustainable growth rate The rate of dividend (and earnings) growth that can be sustained over time for a given level of return on equity, keeping the capital structure constant and without issuing additional common stock.

Sustainable investing A term used in a similar context to responsible investing, but its key focus is on factoring in sustainability issues while investing.

Sustainable rate of economic growth The rate of increase in the economy's productive capacity or potential GDP.

Swap contract An agreement between two parties to exchange a series of future cash flows.

Syndicated loan A loan from a group of lenders to a single borrower.

Syndicated offering A bond issue underwritten by a group of investment banks.

Systematic risk Risk that affects the entire market or economy; it cannot be avoided and is inherent in the overall market. Systematic risk is also known as non-diversifiable or market risk.

Systematic sampling A procedure of selecting every *k*th member until reaching a sample of the desired size. The sample that results from this procedure should be approximately random.

Tactical asset allocation The decision to deliberately deviate from the strategic asset allocation in an attempt to add value based on forecasts of the near-term relative performance of asset classes.

Tactical asset allocation (TAA) A portfolio strategy that shifts the percentages of assets held in various asset classes (or categories) to take advantage of market opportunities. Allocation shifts can occur within an asset class or across asset classes.

Tag cloud see **word cloud**.

Target capital structure A company's chosen proportions of debt and equity.

Target independent A bank's ability to determine the definition of inflation that they target, the rate of inflation that they target, and the horizon over which the target is to be achieved.

Target semideviation A measure of downside risk, calculated as the square root of the average of the squared deviations of observations below the target (also called target downside deviation).

Tariffs Taxes that a government levies on imported goods.

Tax base The amount at which an asset or liability is valued for tax purposes.

Tax expense An aggregate of an entity's income tax payable (or recoverable in the case of a tax benefit) and any changes in deferred tax assets and liabilities. It is essentially the income tax payable or recoverable if these had been determined based on accounting profit rather than taxable income.

Tax loss carry forward A taxable loss in the current period that may be used to reduce future taxable income.

Taxable income The portion of an entity's income that is subject to income taxes under the tax laws of its jurisdiction.

Taxable temporary differences Temporary differences that result in a taxable amount in a future period when determining the taxable profit as the balance sheet item is recovered or settled.

Technical analysis A form of security analysis that uses price and volume data, often displayed graphically, in decision making.

Technology The process a company uses to transform inputs into outputs.

Tender offer Corporate takeover mechanism that involves shareholders selling their interests directly to the group seeking to gain control.

Tenor The time-to-maturity for a bond or derivative contract. Also called *term to maturity*.

Term maturity structure Structure for a bond issue in which the bond's notional principal is paid off in a lump sum at maturity.

Term structure See *maturity structure*.

Term structure of credit spreads The relationship between the spreads over the "risk-free" (or benchmark) rates and times-to-maturity.

Term structure of yield volatility The relationship between the volatility of bond yields-to-maturity and times-to-maturity.

Terminal stock value The expected value of a share at the end of the investment horizon—in effect, the expected selling price. Also called *terminal value*.

Terminal value The expected value of a share at the end of the investment horizon—in effect, the expected selling price.

Terms of trade The ratio of the price of exports to the price of imports, representing those prices by export and import price indexes, respectively.

Test of the mean of the differences A statistical test for differences based on paired observations drawn from samples that are dependent on each other.

Text analytics The use of computer programs to analyze and derive meaning from typically large, unstructured text- or voice-based datasets.

Thematic investing An ESG investment approach that focuses on investing in themes or assets specifically relating to ESG factors, such as clean energy, green technology, or sustainable agriculture.

Thin-Tailed Describes a distribution that has relatively less weight in the tails than the normal distribution (also called platykurtic).

Third-degree price discrimination When the monopolist segregates customers into groups based on demographic or other characteristics and offers different pricing to each group.

Time-period bias The possibility that when we use a time-series sample, our statistical conclusion may be sensitive to the starting and ending dates of the sample.

Time-series data A sequence of observations for a single observational unit of a specific variable collected over time and at discrete and typically equally spaced intervals of time (such as daily, weekly, monthly, annually, or quarterly).

Time tranching The creation of classes or tranches in an ABS/MBS that possess different (expected) maturities.

Time value The difference between the market price of the option and its intrinsic value.

Time value decay Said of an option when, at expiration, no time value remains and the option is worth only its exercise value.

Time value of money The principles governing equivalence relationships between cash flows with different dates.

Time-weighted rate of return The compound rate of growth of one unit of currency invested in a portfolio during a stated measurement period; a measure of investment performance that is not sensitive to the timing and amount of withdrawals or additions to the portfolio.

Tokenization The process of representing ownership rights to physical assets on a blockchain or distributed ledger.

Top-down analysis An investment selection approach that begins with consideration of macroeconomic conditions and then evaluates markets and industries based upon such conditions.

Total comprehensive income The change in equity during a period resulting from transaction and other events, other than those changes resulting from transactions with owners in their capacity as owners.

Total cost The summation of all costs, for which costs are classified as fixed or variable.

Total factor productivity A scale factor that reflects the portion of growth unaccounted for by explicit factor inputs (e.g., capital and labor).

Total fixed cost The summation of all expenses that do not change as the level of production varies.

Total invested capital The sum of market value of common equity, book value of preferred equity, and face value of debt.

Total probability rule A rule explaining the unconditional probability of an event in terms of probabilities of the event conditional on mutually exclusive and exhaustive scenarios.

Total probability rule for expected value A rule explaining the expected value of a random variable in terms of expected values of the random variable conditional on mutually exclusive and exhaustive scenarios.

Total return Measures the price appreciation, or percentage change in price of the securities in an index or portfolio, plus any income received over the period.

Total return index An index that reflects the price appreciation or percentage change in price of the constituent securities plus any income received since inception.

Total return swap A swap in which one party agrees to pay the total return on a security. Often used as a credit derivative, in which the underlying is a bond.

Total variable cost The summation of all variable expenses.

Tracking error The standard deviation of the differences between a portfolio's returns and its benchmark's returns; a synonym of active risk.

Tracking risk The standard deviation of the differences between a portfolio's returns and its benchmarks returns. Also called *tracking error*.

Trade creation When regional integration results in the replacement of higher cost domestic production by lower cost imports from other members.

Trade credit A spontaneous form of credit in which a purchaser of the goods or service is financing its purchase by delaying the date on which payment is made.

Trade diversion When regional integration results in lower-cost imports from non-member countries being replaced with higher-cost imports from members.

Trade payables Amounts that a business owes to its vendors for goods and services that were purchased from them but which have not yet been paid.

Trade protection Government policies that impose restrictions on trade, such as tariffs and quotas.

Trade surplus (deficit) When the value of exports is greater (less) than the value of imports.

Trading securities Under US GAAP, a category of debt securities held by a company with the intent to trade them. Also called *held-for-trading securities*.

Traditional investment markets Markets for traditional investments, which include all publicly traded debts and equities and shares in pooled investment vehicles that hold publicly traded debts and/or equities.

Transactions money balances Money balances that are held to finance transactions.

Transfer payments Welfare payments made through the social security system that exist to provide a basic minimum level of income for low-income households.

Transparency Said of something (e.g., a market) in which information is fully disclosed to the public and/or regulators.

Treasury stock method A method for accounting for the effect of options (and warrants) on earnings per share (EPS) that specifies what EPS would have been if the options and warrants had been exercised and the company had used the proceeds to repurchase common stock.

Tree-Map Another graphical tool for displaying categorical data. It consists of a set of colored rectangles to represent distinct groups, and the area of each rectangle is proportional to the value of the corresponding group.

Trend A long-term pattern of movement in a particular direction.

Treynor ratio A measure of risk-adjusted performance that relates a portfolio's excess returns to the portfolio's beta.

Triangle pattern In technical analysis, a continuation chart pattern that forms as the range between high and low prices narrows, visually forming a triangle.

Trimmed mean A mean computed after excluding a stated small percentage of the lowest and highest observations.

Trimodal A distribution that has the three most frequently occurring values.

Triple bottom In technical analysis, a reversal pattern that results when the price forms three troughs at roughly the same price level. A triple bottom is used to predict a change from a downtrend to an uptrend.

Triple top In technical analysis, a reversal pattern that results when the price forms three peaks at roughly the same price level. A triple top is used to predict a change from an uptrend to a downtrend.

True yield The internal rate of return on cash flows using the actual calendar, including weekends and bank holidays.

Trust deed The governing legal credit agreement, typically incorporated by reference in the prospectus. Also called *bond indenture*.

Turn-of-the-year effect Calendar anomaly that stock market returns in January are significantly higher compared to the rest of the months of the year, with most of the abnormal returns reported during the first five trading days in January.

Two-dimensional rectangular array A popular form for organizing data for processing by computers or for presenting data visually. It is comprised of columns and rows to hold multiple variables and multiple observations, respectively (also called a **data table**).

Two-fund separation theorem The theory that all investors regardless of taste, risk preferences, and initial wealth will hold a combination of two portfolios or funds: a risk-free asset and an optimal portfolio of risky assets.

Two-sided hypothesis test A test in which the null hypothesis is rejected in favor of the alternative hypothesis if the evidence indicates that the population parameter is either smaller or larger than a hypothesized value; occurs when the alternative hypothesis is stated as not equal to the hypothesized population parameters.

Two-way table See *contingency table*.

Two-week repo rate The interest rate on a two-week repurchase agreement; may be used as a policy rate by a central bank.

Type I error The error of rejecting a true null hypothesis; a false positive.

Type II error The error of not rejecting a false null hypothesis; false negative.

Unanticipated (unexpected) inflation The component of inflation that is a surprise.

Uncommitted lines of credit The least reliable form of bank borrowing in which a bank offers, without formal commitment, a line of credit for an extended period of time but reserves the right to refuse any request for its use.

Unconditional probability The probability of an event *not* conditioned on another event.

Underemployed A person who has a job but has the qualifications to work a significantly higher-paying job.

Underlying An asset that trades in a market in which buyers and sellers meet, decide on a price, and the seller then delivers the asset to the buyer and receives payment. The underlying is the asset or other derivative on which a particular derivative is based. The market for the underlying is also referred to as the *spot market*.

Underwriter A firm, usually an investment bank, that takes the risk of buying the newly issued securities from the issuer and then reselling them to investors or to dealers, thus guaranteeing the sale of the securities at the offering price negotiated with the issuer.

Underwritten offering A type of securities issue mechanism in which the investment bank guarantees the sale of the securities at an offering price that is negotiated with the issuer. Also known as *firm commitment offering*.

Unearned revenue A liability account for money that has been collected for goods or services that have not yet been delivered; payment received in advance of providing a good or service. Also called *deferred revenue* or *deferred income*.

Unemployed People who are actively seeking employment but are currently without a job.

Unemployment rate The ratio of unemployed to the labor force.

Unexpected inflation The component of inflation that is a surprise.

Unimodal A distribution with a single value that is most frequently occurring.

Unit elastic An elasticity with a magnitude of negative one. Also called *unitary elastic*.

Unit labor cost The average labor cost to produce one unit of output.

Unit normal distribution The normal density with mean (μ) equal to 0 and standard deviation (σ) equal to 1.

Unitranche debt Consists of a hybrid or blended loan structure that combines different tranches of secured and unsecured debt into a single loan with a single, blended interest rate.

Units-of-production method A depreciation method that allocates the cost of a long-lived asset based on actual usage during the period.

Univariate distribution A distribution that specifies the probabilities for a single random variable.

Universal owners Long-term investors, such as pension funds, that have significant assets invested in globally diversified portfolios.

Unlimited funds An unlimited funds environment assumes that the company can raise the funds it wants for all profitable investments simply by paying the required rate of return.

Unsecured debt Debt that gives the debtholder only a general claim on an issuer's assets and cash flow.

Unsponsored A type of depository receipt in which the foreign company whose shares are held by the depository has no involvement in the issuance of the receipts.

Unstructured data Data that do not follow any conventionally organized forms.

Unsupervised learning A machine learning approach that does not make use of labeled training data.

Up transition probability The probability that an asset's value moves up.

Uptrend A pattern that occurs when the price of an asset moves higher over a period of time.

Validity instructions Instructions which indicate when the order may be filled.

Valuation allowance A reserve created against deferred tax assets, based on the likelihood of realizing the deferred tax assets in future accounting periods.

Valuation ratios Ratios that measure the quantity of an asset or flow (e.g., earnings) in relation to the price associated with a specified claim (e.g., a share or ownership of the enterprise).

Value at risk A money measure of the minimum value of losses expected during a specified time period at a given level of probability.

Value investors With reference to equity investors, investors who are focused on paying a relatively low share price in relation to earnings or assets per share.

VaR See *value at risk*.

Variable A characteristic or quantity that can be measured, counted, or categorized and that is subject to change (also called a field, an attribute, or a feature).

Variable costs Costs that fluctuate with the level of production and sales.

Variance The expected value (the probability-weighted average) of squared deviations from a random variable's expected value.

Variation margin Additional margin that must be deposited in an amount sufficient to bring the balance up to the initial margin requirement.

Veblen goods Goods that increase in desirability with increasing price.

Vega A measure of the sensitivity of an option's price to changes in the underlying's volatility.

Venture capital Investments that provide "seed" or startup capital, early-stage financing, or later-stage financing (including mezzanine-stage financing) to companies that are in early development stages and require additional capital for expansion or preparation for an initial public offering.

Venture capital fund A hedge fund that seeks to buy, optimize, and ultimately sell portfolio companies to generate profits. See *private equity fund*.

Venture capital funds Funds that seek to invest in, optimize, and eventually exit portfolio companies to generate profits. See *private equity funds.*

Vertical analysis Common-size analysis using only one reporting period or one base financial statement; for example, an income statement in which all items are stated as percentages of sales.

Vertical demand schedule Implies that some fixed quantity is demanded, regardless of price.

Visual technique The most common and readily available method of initial data assessment. Experts in pattern recognition maintain that the visual (or "eyeball") technique is still the most effective way of searching for recognizable patterns.

Visualization The presentation of data in a pictorial or graphical format for the purpose of increasing understanding and for gaining insights into the data.

Volatility The standard deviation of the continuously compounded returns on the underlying asset.

Voluntarily unemployed A person voluntarily outside the labor force, such as a jobless worker refusing an available vacancy.

Voluntary export restraint A trade barrier under which the exporting country agrees to limit its exports of the good to its trading partners to a specific number of units.

Vote by proxy A mechanism that allows a designated party—such as another shareholder, a shareholder representative, or management—to vote on the shareholder's behalf.

Warrant Attached option that gives its holder the right to buy the underlying stock of the issuing company at a fixed exercise price until the expiration date.

Waterfall Represents the distribution method that defines the order in which allocations are made to LPs and GPs. There are two major types of waterfall: *deal by deal* (or *American*) and *whole of fund* (or *European*).

Weak-form efficient market hypothesis The belief that security prices fully reflect all past market data, which refers to all historical price and volume trading information.

Wealth effect An increase (decrease) in household wealth increases (decreases) consumer spending out of a given level of current income.

Web-based lender A lender that operates primarily on the internet, offering loans in relatively small amounts, typically to small businesses in need of cash.

Weighted average cost method An inventory accounting method that averages the total cost of available inventory items over the total units available for sale.

Weighted average cost of capital A weighted average of the after-tax required rates of return on a company's common stock, preferred stock, and long-term debt, where the weights are the fraction of each source of financing in the company's target capital structure.

Weighted average cost of capital (WACC) A weighted average of the after-tax required rates of return on a company's common stock, preferred stock, and long-term debt, where the weights are the fraction of each source of financing in the company's target capital structure.

Weighted average coupon rate Weighting the mortgage rate of each mortgage loan in the pool by the percentage of the mortgage outstanding relative to the outstanding amount of all the mortgages in the pool.

Weighted average life A measure that gives investors an indication of how long they can expect to hold the MBS before it is paid off; the convention-based average time to receipt of all principal repayments. Also called *average life*.

Weighted average maturity Weighting the remaining number of months to maturity for each mortgage loan in the pool by the amount of the outstanding mortgage balance.

Weighted mean An average in which each observation is weighted by an index of its relative importance.

Winsorized mean A mean computed after assigning a stated percentage of the lowest values equal to one specified low value and a stated percentage of the highest values equal to one specified high value.

Word cloud A visual device for representing textual data, which consists of words extracted from a source of textual data. The size of each distinct word is proportional to the frequency with which it appears in the given text (also known as **tag cloud**).

Working capital The difference between current assets and current liabilities.

Working capital management The management of a company's short-term assets (such as inventory) and short-term liabilities (such as money owed to suppliers).

World price The price prevailing in the world market.

Yield duration The sensitivity of the bond price with respect to the bond's own yield-to-maturity.

Yield to maturity Annual return that an investor earns on a bond if the investor purchases the bond today and holds it until maturity. It is the discount rate that equates the present value of the bond's expected cash flows until maturity with the bond's price. Also called *yield to redemption* or *redemption yield*.

Yield-to-maturity Annual return that an investor earns on a bond if the investor purchases the bond today and holds it until maturity. It is the discount rate that equates the present value of the bond's expected cash flows until maturity with the bond's price. Also called *yield-to-redemption* or *redemption yield*.

Yield-to-redemption See *yield-to-maturity*.

Yield-to-worst The lowest of the sequence of yields-to-call and the yield-to-maturity.

Zero-coupon bond A bond that does not pay interest during its life. It is issued at a discount to par value and redeemed at par. Also called *pure discount bond*.

Zero-volatility spread (Z-spread) Calculates a constant yield spread over a government (or interest rate swap) spot curve.

How to Use the CFA Program Curriculum

Congratulations on your decision to enter the Chartered Financial Analyst (CFA®) Program. This exciting and rewarding program of study reflects your desire to become a serious investment professional. You are embarking on a program noted for its high ethical standards and the breadth of knowledge, skills, and abilities (competencies) it develops. Your commitment should be educationally and professionally rewarding.

The credential you seek is respected around the world as a mark of accomplishment and dedication. Each level of the program represents a distinct achievement in professional development. Successful completion of the program is rewarded with membership in a prestigious global community of investment professionals. CFA charterholders are dedicated to life-long learning and maintaining currency with the ever-changing dynamics of a challenging profession. CFA Program enrollment represents the first step toward a career-long commitment to professional education.

The CFA exam measures your mastery of the core knowledge, skills, and abilities required to succeed as an investment professional. These core competencies are the basis for the Candidate Body of Knowledge (CBOK™). The CBOK consists of four components:

- A broad outline that lists the major CFA Program topic areas (www.cfainstitute.org/programs/cfa/curriculum/cbok);
- Topic area weights that indicate the relative exam weightings of the top-level topic areas (www.cfainstitute.org/programs/cfa/curriculum);
- Learning outcome statements (LOS) that advise candidates about the specific knowledge, skills, and abilities they should acquire from readings covering a topic area (LOS are provided in candidate study sessions and at the beginning of each reading); and
- CFA Program curriculum that candidates receive upon exam registration.

Therefore, the key to your success on the CFA exams is studying and understanding the CBOK. The following sections provide background on the CBOK, the organization of the curriculum, features of the curriculum, and tips for designing an effective personal study program.

BACKGROUND ON THE CBOK

CFA Program is grounded in the practice of the investment profession. CFA Institute performs a continuous practice analysis with investment professionals around the world to determine the competencies that are relevant to the profession, beginning with the Global Body of Investment Knowledge (GBIK®). Regional expert panels and targeted surveys are conducted annually to verify and reinforce the continuous feedback about the GBIK. The practice analysis process ultimately defines the CBOK. The CBOK reflects the competencies that are generally accepted and applied by investment professionals. These competencies are used in practice in a generalist context and are expected to be demonstrated by a recently qualified CFA charterholder.

© 2021 CFA Institute. All rights reserved.

The CFA Institute staff—in conjunction with the Education Advisory Committee and Curriculum Level Advisors, who consist of practicing CFA charterholders—designs the CFA Program curriculum in order to deliver the CBOK to candidates. The exams, also written by CFA charterholders, are designed to allow you to demonstrate your mastery of the CBOK as set forth in the CFA Program curriculum. As you structure your personal study program, you should emphasize mastery of the CBOK and the practical application of that knowledge. For more information on the practice analysis, CBOK, and development of the CFA Program curriculum, please visit www.cfainstitute.org.

ORGANIZATION OF THE CURRICULUM

The Level I CFA Program curriculum is organized into 10 topic areas. Each topic area begins with a brief statement of the material and the depth of knowledge expected. It is then divided into one or more study sessions. These study sessions should form the basic structure of your reading and preparation. Each study session includes a statement of its structure and objective and is further divided into assigned readings. An outline illustrating the organization of these study sessions can be found at the front of each volume of the curriculum.

The readings are commissioned by CFA Institute and written by content experts, including investment professionals and university professors. Each reading includes LOS and the core material to be studied, often a combination of text, exhibits, and in-text examples and questions. End of Reading Questions (EORQs) followed by solutions help you understand and master the material. The LOS indicate what you should be able to accomplish after studying the material. The LOS, the core material, and the EORQs are dependent on each other, with the core material and EORQs providing context for understanding the scope of the LOS and enabling you to apply a principle or concept in a variety of scenarios.

The entire readings, including the EORQs, are the basis for all exam questions and are selected or developed specifically to teach the knowledge, skills, and abilities reflected in the CBOK.

You should use the LOS to guide and focus your study because each exam question is based on one or more LOS and the core material and practice problems associated with the LOS. As a candidate, you are responsible for the entirety of the required material in a study session.

We encourage you to review the information about the LOS on our website (www.cfainstitute.org/programs/cfa/curriculum/study-sessions), including the descriptions of LOS “command words” on the candidate resources page at www.cfainstitute.org.

FEATURES OF THE CURRICULUM

End of Reading Questions/Solutions *All End of Reading Questions (EORQs) as well as their solutions are part of the curriculum and are required material for the exam.* In addition to the in-text examples and questions, these EORQs help demonstrate practical applications and reinforce your understanding of the concepts presented. Some of these EORQs are adapted from past CFA exams and/or may serve as a basis for exam questions.

Glossary For your convenience, each volume includes a comprehensive Glossary. Throughout the curriculum, a **bolded** word in a reading denotes a term defined in the Glossary.

Note that the digital curriculum that is included in your exam registration fee is searchable for key words, including Glossary terms.

LOS Self-Check We have inserted checkboxes next to each LOS that you can use to track your progress in mastering the concepts in each reading.

Source Material The CFA Institute curriculum cites textbooks, journal articles, and other publications that provide additional context or information about topics covered in the readings. As a candidate, you are not responsible for familiarity with the original source materials cited in the curriculum.

Note that some readings may contain a web address or URL. The referenced sites were live at the time the reading was written or updated but may have been deactivated since then.

Some readings in the curriculum cite articles published in the *Financial Analysts Journal®*, which is the flagship publication of CFA Institute. Since its launch in 1945, the *Financial Analysts Journal* has established itself as the leading practitioner-oriented journal in the investment management community. Over the years, it has advanced the knowledge and understanding of the practice of investment management through the publication of peer-reviewed practitioner-relevant research from leading academics and practitioners. It has also featured thought-provoking opinion pieces that advance the common level of discourse within the investment management profession. Some of the most influential research in the area of investment management has appeared in the pages of the *Financial Analysts Journal*, and several Nobel laureates have contributed articles.

Candidates are not responsible for familiarity with *Financial Analysts Journal* articles that are cited in the curriculum. But, as your time and studies allow, we strongly encourage you to begin supplementing your understanding of key investment management issues by reading this, and other, CFA Institute practice-oriented publications through the Research & Analysis webpage (www.cfainstitute.org/en/research).

Errata The curriculum development process is rigorous and includes multiple rounds of reviews by content experts. Despite our efforts to produce a curriculum that is free of errors, there are times when we must make corrections. Curriculum errata are periodically updated and posted by exam level and test date online (www.cfainstitute.org/en/programs/submit-errata). If you believe you have found an error in the curriculum, you can submit your concerns through our curriculum errata reporting process found at the bottom of the Curriculum Errata webpage.

DESIGNING YOUR PERSONAL STUDY PROGRAM

Create a Schedule An orderly, systematic approach to exam preparation is critical. You should dedicate a consistent block of time every week to reading and studying. Complete all assigned readings and the associated problems and solutions in each study session. Review the LOS both before and after you study each reading to ensure that

you have mastered the applicable content and can demonstrate the knowledge, skills, and abilities described by the LOS and the assigned reading. Use the LOS self-check to track your progress and highlight areas of weakness for later review.

Successful candidates report an average of more than 300 hours preparing for each exam. Your preparation time will vary based on your prior education and experience, and you will probably spend more time on some study sessions than on others.

You should allow ample time for both in-depth study of all topic areas and additional concentration on those topic areas for which you feel the least prepared.

CFA INSTITUTE LEARNING ECOSYSTEM (LES)

As you prepare for your exam, we will email you important exam updates, testing policies, and study tips. Be sure to read these carefully.

Your exam registration fee includes access to the CFA Program Learning Ecosystem (LES). This digital learning platform provides access, even offline, to all of the readings and End of Reading Questions found in the print curriculum organized as a series of shorter online lessons with associated EORQs. This tool is your one-stop location for all study materials, including practice questions and mock exams.

The LES provides the following supplemental study tools:

Structured and Adaptive Study Plans The LES offers two ways to plan your study through the curriculum. The first is a structured plan that allows you to move through the material in the way that you feel best suits your learning. The second is an adaptive study plan based on the results of an assessment test that uses actual practice questions.

Regardless of your chosen study path, the LES tracks your level of proficiency in each topic area and presents you with a dashboard of where you stand in terms of proficiency so that you can allocate your study time efficiently.

Flashcards and Game Center The LES offers all the Glossary terms as Flashcards and tracks correct and incorrect answers. Flashcards can be filtered both by curriculum topic area and by action taken—for example, answered correctly, unanswered, and so on. These Flashcards provide a flexible way to study Glossary item definitions.

The Game Center provides several engaging ways to interact with the Flashcards in a game context. Each game tests your knowledge of the Glossary terms a in different way. Your results are scored and presented, along with a summary of candidates with high scores on the game, on your Dashboard.

Discussion Board The Discussion Board within the LES provides a way for you to interact with other candidates as you pursue your study plan. Discussions can happen at the level of individual lessons to raise questions about material in those lessons that you or other candidates can clarify or comment on. Discussions can also be posted at the level of topics or in the initial Welcome section to connect with other candidates in your area.

Practice Question Bank The LES offers access to a question bank of hundreds of practice questions that are in addition to the End of Reading Questions. These practice questions, only available on the LES, are intended to help you assess your mastery of individual topic areas as you progress through your studies. After each practice question, you will receive immediate feedback noting the correct response and indicating the relevant assigned reading so you can identify areas of weakness for further study.

Mock Exams The LES also includes access to three-hour Mock Exams that simulate the morning and afternoon sessions of the actual CFA exam. These Mock Exams are intended to be taken after you complete your study of the full curriculum and take practice questions so you can test your understanding of the curriculum and your readiness for the exam. If you take these Mock Exams within the LES, you will receive feedback afterward that notes the correct responses and indicates the relevant assigned readings so you can assess areas of weakness for further study. We recommend that you take Mock Exams during the final stages of your preparation for the actual CFA exam. For more information on the Mock Exams, please visit www.cfainstitute.org.

PREP PROVIDERS

You may choose to seek study support outside CFA Institute in the form of exam prep providers. After your CFA Program enrollment, you may receive numerous solicitations for exam prep courses and review materials. When considering a prep course, make sure the provider is committed to following the CFA Institute guidelines and high standards in its offerings.

Remember, however, that there are no shortcuts to success on the CFA exams; reading and studying the CFA Program curriculum *is* the key to success on the exam. The CFA Program exams reference only the CFA Institute assigned curriculum; no prep course or review course materials are consulted or referenced.

SUMMARY

Every question on the CFA exam is based on the content contained in the required readings and on one or more LOS. Frequently, an exam question is based on a specific example highlighted within a reading or on a specific practice problem and its solution. To make effective use of the CFA Program curriculum, please remember these key points:

1. All pages of the curriculum are required reading for the exam.
2. All questions, problems, and their solutions are part of the curriculum and are required study material for the exam. These questions are found at the end of the readings in the print versions of the curriculum. In the LES, these questions appear directly after the lesson with which they are associated. The LES provides immediate feedback on your answers and tracks your performance on these questions throughout your study.
3. We strongly encourage you to use the CFA Program Learning Ecosystem. In addition to providing access to all the curriculum material, including EORQs, in the form of shorter, focused lessons, the LES offers structured and adaptive study planning, a Discussion Board to communicate with other candidates, Flashcards, a Game Center for study activities, a test bank of practice questions, and online Mock Exams. Other supplemental study tools, such as eBook and PDF versions of the print curriculum, and additional candidate resources are available at www.cfainstitute.org.
4. Using the study planner, create a schedule and commit sufficient study time to cover the study sessions. You should also plan to review the materials, answer practice questions, and take Mock Exams.
5. Some of the concepts in the study sessions may be superseded by updated rulings and/or pronouncements issued after a reading was published. Candidates are expected to be familiar with the overall analytical framework contained in the assigned readings. Candidates are not responsible for changes that occur after the material was written.

FEEDBACK

At CFA Institute, we are committed to delivering a comprehensive and rigorous curriculum for the development of competent, ethically grounded investment professionals. We rely on candidate and investment professional comments and feedback as we work to improve the curriculum, supplemental study tools, and candidate resources.

Please send any comments or feedback to info@cfainstitute.org. You can be assured that we will review your suggestions carefully. Ongoing improvements in the curriculum will help you prepare for success on the upcoming exams and for a lifetime of learning as a serious investment professional.

Economics

STUDY SESSIONS

Study Session 3	Economics (1)
Study Session 4	Economics (2)

TOPIC LEVEL LEARNING OUTCOME

The candidate should be able to demonstrate knowledge of microeconomic and macroeconomic principles.

The next study sessions introduce fundamental microeconomic and macroeconomic concepts relevant to financial analysis and investment management. Microeconomic factors such as a firm's competitive (or non-competitive) environment and its pricing strategy may be critical inputs for cash flow forecasting and bottom up security selection approaches. Economic output, global trade flows, monetary and fiscal policies, and the business cycle are key considerations for conducting top own investment analysis and economic forecasting.

Candidates should be familiar with the material covered in the following prerequisite economics readings available in Candidate Resources on the CFA Institute website:

- **Demand and Supply Analysis: Introduction**
- **Demand and Supply Analysis: Consumer Demand**
- **Demand and Supply Analysis: The Firm**

© 2021 CFA Institute. All rights reserved.

ECONOMICS
STUDY SESSION
3

Economics (1)

This study session begins by introducing fundamental concepts of demand and supply analysis for individual consumers and firms. Also covered are the various market structures (perfect competition, oligopoly, monopoly) in which firms operate. Key macroeconomic concepts and principles then follow, including aggregate output and income measurement, aggregate demand and supply analysis, and analysis of economic growth factors. The study session concludes with coverage of the business cycle and its effect on economic activity.

READING ASSIGNMENTS

Reading 8	Topics in Demand and Supply Analysis by Richard V. Eastin, PhD, and Gary L. Arbogast, PhD, CFA
Reading 9	The Firm and Market Structures by Richard Fritz, PhD, and Michele Gambera, PhD, CFA
Reading 10	Aggregate Output, Prices, and Economic Growth by Paul R. Kutasovic, PhD, CFA, and Richard Fritz, PhD
Reading 11	Understanding Business Cycles by Michele Gambera, PhD, CFA, Milton Ezrati, and Bolong Cao, PhD, CFA

READING

8

Topics in Demand and Supply Analysis

by Richard V. Eastin, PhD, and Gary L. Arbogast, PhD, CFA

Richard V. Eastin, PhD, is at the University of Southern California (USA). Gary L. Arbogast, PhD, CFA (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** calculate and interpret price, income, and cross-price elasticities of demand and describe factors that affect each measure;
☐	**b.** compare substitution and income effects;
☐	**c.** contrast normal goods with inferior goods;
☐	**d.** describe the phenomenon of diminishing marginal returns;
☐	**e.** determine and interpret breakeven and shutdown points of production;
☐	**f.** describe how economies of scale and diseconomies of scale affect costs.

INTRODUCTION

1

In a general sense, *economics* is the study of production, distribution, and consumption and can be divided into two broad areas of study: macroeconomics and microeconomics. **Macroeconomics** deals with aggregate economic quantities, such as national output and national income, and is rooted in **microeconomics**, which deals with markets and decision making of individual economic units, including consumers and businesses. Microeconomics is a logical starting point for the study of economics.

Microeconomics classifies private economic units into two groups: consumers (or households) and firms. These two groups give rise, respectively, to the theory of the consumer and the theory of the firm as two branches of study. The *theory of the consumer* deals with consumption (the demand for goods and services) by utility-maximizing individuals (i.e., individuals who make decisions that maximize the satisfaction received from present and future consumption). The *theory of the firm* deals with the supply of goods and services by profit-maximizing firms.

© 2019 CFA Institute. All rights reserved.

It is expected that candidates will be familiar with the basic concepts of demand and supply. This material is covered in detail in the recommended prerequisite readings. In this reading, we will explore how buyers and sellers interact to determine transaction prices and quantities. The reading is organized as follows: Sections 2–6 discuss the consumer or demand side of the market model, and Sections 7–12 discuss the supply side of the consumer goods market, paying particular attention to the firm's costs. Section 13 provides a summary of key points in the reading.

2 DEMAND CONCEPTS

a calculate and interpret price, income, and cross-price elasticities of demand and describe factors that affect each measure;

The fundamental model of the private-enterprise economy is the demand and supply model of the market. In this section, we examine three important topics concerning the demand side of the model: (1) elasticities, (2) substitution and income effects, and (3) normal and inferior goods. The candidate is assumed to have a basic understanding of the demand and supply model and to understand how a market discovers the equilibrium price at which the quantity willingly demanded by consumers at that price is just equal to the quantity willingly supplied by firms. Here, we explore more deeply some of the concepts underlying the demand side of the model.

2.1 Demand Concepts

The quantity of a good that consumers are willing to buy depends on a number of different variables. Perhaps the most important of those variables is the item's own price. In general, economists believe that as the price of a good rises, buyers will choose to buy less of it, and as its price falls, they buy more. This opinion is so nearly universal that it has come to be called the **law of demand**.

Although a good's own price is important in determining consumers' willingness to purchase it, other variables also influence that decision. Consumers' incomes, their tastes and preferences, and the prices of other goods that serve as substitutes or complements are just a few of the other variables that influence consumers' demand for a product or service. Economists attempt to capture all these influences in a relationship called the **demand function**. (A function is a relationship that assigns a unique value to a dependent variable for any given set of values of a group of independent variables.)

Equation 1 is an example of a demand function. In Equation 1, we are saying, "The quantity demanded of good *X* depends on (is a function of) the price of good *X*, consumers' income, and the price of good *Y*":

$$Q_x^d = f\left(P_x, I, P_y\right) \tag{1}$$

where

Q_x^d = the quantity demanded of some good X (such as per household demand for gasoline in liters per month)

P_x = the price per unit of good X (such as € per liter)

I = consumers' income (as in €1,000s per household annually)

P_y = the price of another good, Y. (There can be many other goods, not just one, and they can be complements or substitutes.)

Often, economists use simple linear equations to approximate real-world demand and supply functions in relevant ranges. Equation 2 illustrates a hypothetical example of our function for gasoline demand:

$$Q_x^d = 84.5 - 6.39P_x + 0.25I - 2P_y \tag{2}$$

where the quantity of gasoline demanded $\left(Q_x^d\right)$ is a function of the price of a liter of gasoline (P_x), consumers' income in €1,000s (I), and the average price of an automobile in €1,000s (P_y).

The signs of the coefficients on gasoline price (negative) and consumers' income (positive) reflect the relationship between those variables and the quantity of gasoline consumed. The negative sign on average automobile price indicates that if automobiles go up in price, fewer will likely be purchased and driven; hence, less gasoline will be consumed. (As discussed later, such a relationship would indicate that gasoline and automobiles have a negative cross-price elasticity of demand and are thus complements.)

To continue our example, suppose that the price of gasoline (P_x) is €1.48 per liter, per household income (I) is €50,000, and the price of the average automobile (P_y) is €20,000. In this case, this function would predict that the per-household monthly demand for gasoline would be 47.54 liters, calculated as follows:

$$Q_x^d = 84.5 - 6.39(1.48) + 0.25(50) - 2(20) = 47.54$$

recalling that income and automobile prices are measured in thousands. Note that the sign on the "own-price" variable (P_x) is negative; thus, as the price of gasoline rises, per household consumption would decrease by 6.39 liters per month for every €1 increase in gas price. **Own price** is used by economists to underscore that the reference is to the price of a good itself and not the price of some other good.

In our example, there are three independent variables in the demand function and one dependent variable. If any one of the independent variables changes, so does the quantity demanded. It is often desirable to concentrate on the relationship between the dependent variable and just one of the independent variables at a time. To accomplish this goal, we can hold the other independent variables constant and rewrite the equation.

For example, to concentrate on the relationship between the quantity demanded of the good and its own price, P_x, we hold constant the values of income and the price of good Y. In our example, those values are 50 and 20, respectively. The equation would then be rewritten as

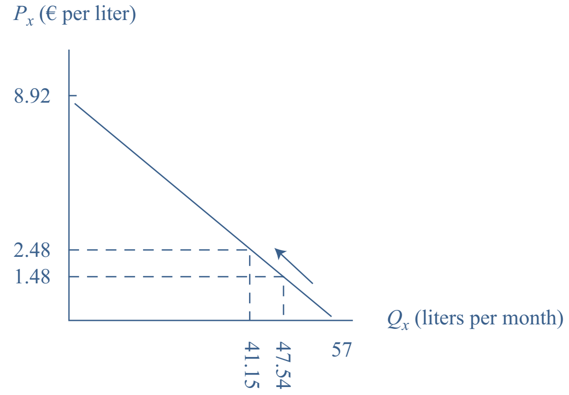
$$Q_x^d = 84.5 - 6.39P_x + 0.25(50) - 2(20) = 57 - 6.39P_x \tag{3}$$

The quantity of gasoline demanded is a function of the price of gasoline (6.39 per liter), per household income (€50,000), and the average price of an automobile (€20,000). Notice that income and the price of automobiles are not ignored; they are simply held constant, and they are "collected" in the new constant term, 57 [84.5 + (0.25)(50) – (2)(20)]. Notice also that we can solve for P_x in terms of Q_x^d by rearranging Equation 3, which gives us Equation 4:

$$P_x = 8.92 - 0.156Q_x^d \tag{4}$$

Equation 4 gives the price of gasoline as a function of the quantity of gasoline consumed per month and is referred to as the **inverse demand function**. Q_x in Equation 4 must be restricted to be less than or equal to 57 so that price is not negative. The graph of the inverse demand function is called the **demand curve** and is shown in Exhibit 1.[1]

Exhibit 1 Household Demand Curve for Gasoline



The demand curve represents the highest quantity willingly purchased at each price as well as the highest price willingly paid for each quantity. In this example, this household would be willing to purchase 47.54 liters of gasoline per month at a price of €1.48 per liter. If price were to rise to €2.48 per liter, the household would be willing to purchase only 41.15 liters per month.

This demand curve is drawn with price on the vertical axis and quantity on the horizontal axis. It can be correctly interpreted as specifying *either* the highest quantity a household would buy at a given price *or* the highest price it would be willing to pay for a given quantity. In our example, at a price of €1.48 per liter, households would each be willing to buy 47.54 liters per month. Alternatively, the highest price they would be willing to pay for 47.54 liters per month is €1.48 per liter. If the price were to rise by €1, households would reduce the quantity they each bought by 6.39 units, to 41.15 liters. The slope of the demand curve is measured as the change in price, P, divided by the change in quantity, Q ($\Delta P/\Delta Q$, where Δ stands for "the change in"). In this case, the slope of the demand curve is 1/–6.39, or –0.156.

The general model of demand and supply can be highly useful in understanding directional changes in prices and quantities that result from shifts in one curve or the other. Often, though, we need to measure how sensitive quantity demanded or supplied is to changes in the independent variables that affect them. This is the concept of **elasticity of demand** and **elasticity of supply**. Fundamentally, all elasticities are calculated in the same way: They are ratios of percentage changes. Let us begin with the sensitivity of quantity demanded to changes in the own price.

---

[1] Following usual practice, we show linear demand curves intersecting the quantity axis at a price of zero. Real-world demand functions may be non-linear in some or all parts of their domain. Thus, linear demand functions in practical cases are approximations of the true demand function that are useful for a relevant range of values.

PRICE ELASTICITY OF DEMAND

3

a calculate and interpret price, income, and cross-price elasticities of demand and describe factors that affect each measure;

In Equation 1, we expressed the quantity demanded of some good as a function of several variables, one of which was the price of the good itself (the good's "own-price").

In Equation 3, we introduced a hypothetical household demand function for gasoline, assuming that the household's income and the price of another good (automobiles) were held constant. That function was given by the simple linear expression $Q_x^d = 57 - 6.39P_x$. Using this expression, if we were asked how sensitive the quantity of gasoline demanded is to changes in price, we might say that whenever price changes by one unit, quantity changes by 6.39 units in the opposite direction; for example, if price were to rise by €1, quantity demanded would fall by 6.39 liters per month. The coefficient on the price variable (–6.39) could be the measure of sensitivity we are seeking.

There is a drawback associated with that measure, however. It is dependent on the units in which we measured Q and P. When we want to describe the sensitivity of demand, we need to recall the specific units in which Q and P were measured—liters per month and euros per liter—in our example. This relationship cannot readily be extrapolated to other units of measure—for example, gallons and dollars. Economists, therefore, prefer to use a gauge of sensitivity that does not depend on units of measure. That metric is called **elasticity**. Elasticity is a general measure of how sensitive one variable is to any other variable, and it is expressed as the ratio of percentage changes in each variable: $\%\Delta y/\%\Delta x$. In the case of **own-price elasticity of demand**, that measure is illustrated in Equation 5:

$$E_{p_x}^d = \frac{\%\Delta Q_x^d}{\%\Delta P_x} \tag{5}$$

This equation expresses the sensitivity of the quantity demanded to a change in price. $E_{p_x}^d$ is the good's own-price elasticity and is equal to the percentage change in quantity demanded divided by the percentage change in price. This measure is independent of the units in which quantity and price are measured. If quantity demanded falls by 8% when price rises by 10%, then the elasticity of demand is simply –0.8. It does not matter whether we are measuring quantity in gallons per week or liters per day, and it does not matter whether we measure price in dollars per gallon or euros per liter; 10% is 10%, and 8% is 8%. So the ratio of the first to the second is still –0.8.

We can expand Equation 5 algebraically by noting that the percentage change in any variable x is simply the change in x (Δx) divided by the level of x. So, we can rewrite Equation 5, using a few simple steps, as

$$E_{p_x}^d = \frac{\%\Delta Q_x^d}{\%\Delta P_x} = \frac{\dfrac{\Delta Q_x^d}{Q_x^d}}{\dfrac{\Delta P_x}{P_x}} = \left(\frac{\Delta Q_x^d}{\Delta P_x}\right)\left(\frac{P_x}{Q_x^d}\right) \tag{6}$$

To get a better idea of price elasticity, it might be helpful to illustrate using our hypothetical demand function: $Q_x^d = 57 - 6.39P_x$. When the relationship between two variables is linear, $\Delta Q_x^d / \Delta P_x$ is equal to the slope coefficient on P_x in the demand function. Thus, in our example, the elasticity of demand is –6.39 multiplied by the ratio of price to quantity. We need to choose a price at which to calculate the elasticity coefficient. Using our hypothetical original price of €1.48, we can find the quantity associated with that particular price by inserting 1.48 into the demand function as given in Equation 3:

$$Q = 57 - (6.39)(1.48) = 47.54$$

and we find that $Q = 47.54$ liters per month.

The result of our calculation is that at a price of 1.48, the elasticity of our market demand function is −6.39(1.48/47.54) = −0.2. How do we interpret that value? It means, simply, that when price equals 1.48, a 1% rise in price would result in a fall in quantity demanded of 0.2%.

In our example, when the price is €1.48 per liter, demand is not very sensitive to changes in price because a 1% rise in price would reduce quantity demanded by only 0.2%. In this case, we would say that demand is **inelastic**. To be precise, when the magnitude (ignoring algebraic sign) of the own-price elasticity coefficient has a value of less than one, demand is said to be inelastic. When that magnitude is greater than one, demand is said to be **elastic**. And when the elasticity coefficient is equal to negative one, demand is said to be **unit elastic**, or unitary elastic. Note that if the law of demand holds, own-price elasticity of demand will always be negative because a rise in price will be associated with a fall in quantity demanded, but it can be either elastic (very sensitive to a change in price) or inelastic (insensitive to a change in price). In our hypothetical example, suppose the price of gasoline was very high, say, €5 per liter. In this case, the elasticity coefficient would be −1.28:

$$Q = 57 - (6.39)(5) = 25.05$$

and

$$-6.39\ (5/25.05) = -1.28$$

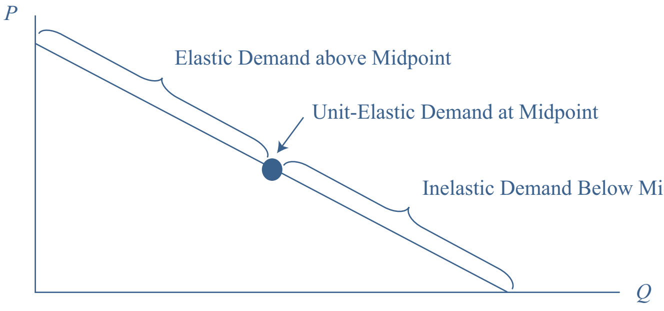
Because the magnitude of the elasticity coefficient is greater than one, we know that demand is elastic at that price.[2] In other words, at lower prices (€1.48 per liter), a slight change in the price of gasoline does not have much effect on the quantity demanded, but when gasoline is expensive (€5 per liter), consumer demand for gas is highly affected by changes in price.

By examining Equation 6 more closely, we can see that for a linear demand curve the elasticity depends on where on the curve we calculate it. The first term, $\Delta Q/\Delta P$, which is the inverse of the slope of the demand curve, remains constant along the entire demand curve. But the second term, P/Q, changes depending on where we are on the demand curve. At very low prices, P/Q is very small, so demand is inelastic. But at very high prices, Q is low and P is high, so the ratio P/Q is very high and demand is elastic. Exhibit 2 illustrates a characteristic of all negatively sloped linear demand curves. Above the midpoint of the curve, demand is elastic; below the midpoint, demand is inelastic; and at the midpoint, demand is unit elastic.

---

[2] If interested, evidence on price elasticities of demand for gasoline can be found in Molly Espey, "Explaining the Variation in Elasticity Estimates of Gasoline Demand in the United States: A Meta-analysis," *Energy Journal*, vol. 17, no. 3 (1996): 49–60. The robust estimates were about −0.26 for short-run elasticity—less than one year—and −0.58 for more than a year.

Exhibit 2 The Elasticity of a Linear Demand Curve

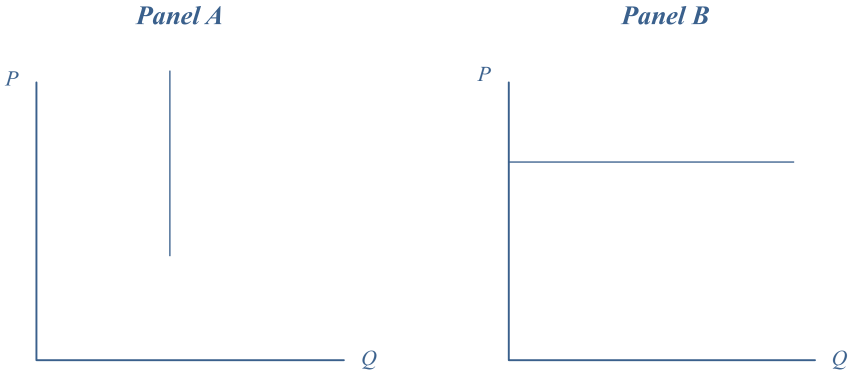


Note: For all negatively sloped, linear demand curves, elasticity varies depending on where it is calculated.

3.1 Extremes of Price Elasticity

There are two special cases in which linear demand curves have the same elasticity at all points: vertical demand curves and horizontal demand curves. Consider a vertical demand curve, as in Panel A of Exhibit 3, and a horizontal demand curve, as in Panel B. In the first case, the quantity demanded is the same, regardless of price. There is no demand curve that is perfectly vertical at all possible prices, but it is reasonable to assume that, over some range of prices, the same quantity would be purchased at a slightly higher price or a slightly lower price. Thus, in that price range, quantity demanded is not at all sensitive to price, and we would say that demand is **perfectly inelastic** in that range.

Exhibit 3 The Extremes of Price Elasticity



Note: A vertical demand has zero elasticity and is called perfectly inelastic.

Note: A horizontal demand has infinite elasticity and is called perfectly elastic.

In the second case, the demand curve is horizontal at some given price. It implies that even a minute price increase will reduce demand to zero, but at that given price, the consumer would buy some large, unknown amount. This situation is a reasonable description of the demand curve facing an individual seller in a perfectly competitive market, such as the wheat market. At the current market price of wheat, an individual farmer could sell all she has. If, however, she held out for a price above market price, it is reasonable to believe that she would not be able to sell any at all; other farmers' wheat is a perfect substitute for hers, so no one would be willing to buy any of hers at a higher price. In this case, we would say that the demand curve facing a seller under conditions of perfect competition is **perfectly elastic**.

4

PREDICTING DEMAND ELASTICITY, PRICE ELASTICITY AND TOTAL EXPENDITURE

a calculate and interpret price, income, and cross-price elasticities of demand and describe factors that affect each measure;

Own-price elasticity of demand is a measure of how sensitive the quantity demanded is to changes in the price of a good or service, but what characteristics of a good or its market might be informative in determining whether demand is highly elastic? Perhaps the most important characteristic is whether there are close substitutes for the good in question. If there are close substitutes for the good, then if its price rises even slightly, a consumer would tend to purchase much less of this good and switch to the less costly substitute. If there are no substitutes, however, then it is likely that the demand is much less elastic. Consider a consumer's demand for some broadly defined product, such as bread. There really are no close substitutes for the entire category of bread, which includes all types from French bread to pita bread to tortillas and so on. So, if the price of all bread were to rise, perhaps a consumer would purchase a little less of it each week, but probably not a significantly smaller amount. Now, consider that the consumer's demand is for a particular baker's specialty bread instead of the category "bread" as a whole. Surely, there are close substitutes for Baker Bob's Whole Wheat Bread with Sesame Seeds than for bread in general. We would expect, then, that the demand for Baker Bob's special loaf is much more elastic than for the entire category of bread.

In addition to the degree of substitutability, other characteristics tend to be generally predictive of a good's elasticity of demand. These include the portion of the typical budget that is spent on the good, the amount of time that is allowed to respond to the change in price, the extent to which the good is seen as necessary or optional, and so on. In general, if consumers tend to spend a very small portion of their budget on a good, their demand tends to be less elastic than if they spend a very large part of their income. Most people spend only a little on toothpaste each month, for example, so it really does not matter whether the price rises 10%. They would probably still buy about the same amount. If the price of housing were to rise significantly, however, most households would try to find a way to reduce the quantity they buy, at least in the long run.

This example leads to another characteristic regarding price elasticity. For most goods and services, the long-run demand is much more elastic than the short-run demand. For example, if the price of gasoline rises, we probably would not be able to respond quickly to reduce the quantity we consume. In the short run, we tend to be locked into modes of transportation, housing and employment location, and so on. With a longer adjustment period, however, we can adjust the quantity consumed in response to the change in price by adopting a new mode of transportation or reducing the distance of our commute. Hence, for most goods, long-run elasticity of demand is greater than short-run elasticity. Durable goods, however, tend to behave in the opposite way. If the price of washing machines were to fall, people might react quickly because they have an old machine that they know will need to be replaced fairly soon anyway. So when price falls, they might decide to go ahead and make a purchase. If the price of washing machines were to stay low forever, however, it is unlikely that a typical consumer would buy more machines over a lifetime.

Knowing whether the good or service is seen to be discretionary or non-discretionary helps to understand its sensitivity to a price change. Faced with the same percentage increase in prices, consumers are much more likely to give up their Friday night restaurant meal (discretionary) than they are to cut back significantly on staples in their pantry (non-discretionary). The more a good is seen as being necessary, the less elastic its demand is likely to be.

In summary, own-price elasticity of demand is likely to be greater (i.e., more sensitive) for items that have many close substitutes, occupy a large portion of the total budget, are seen to be optional instead of necessary, or have longer adjustment times. Obviously, not all these characteristics operate in the same direction for all goods, so elasticity is likely to be a complex result of these and other characteristics. In the end, the actual elasticity of demand for a particular good turns out to be an empirical fact that can be learned only from careful observation and, often, sophisticated statistical analysis.

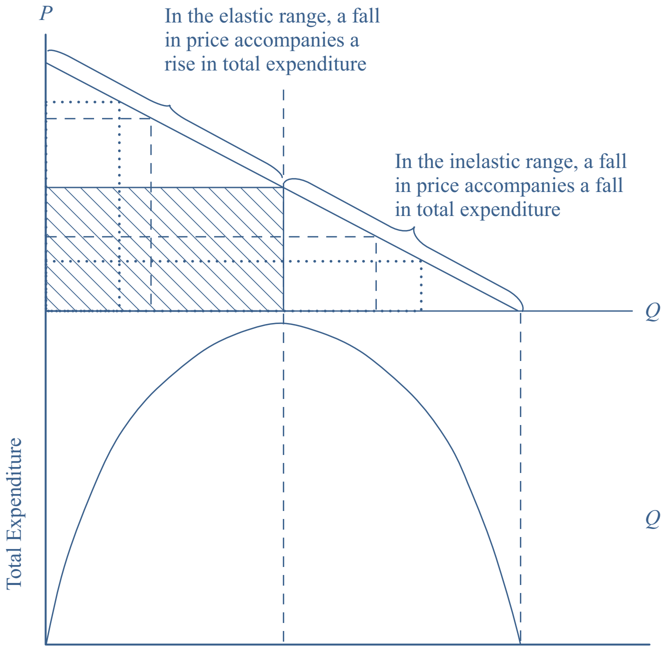
4.1 Elasticity and Total Expenditure

Because of the law of demand, an increase in price is associated with a decrease in the number of units demanded of some good or service. But what can we say about the total expenditure on that good? That is, what happens to price times quantity when price falls? Recall that elasticity is defined as the ratio of the percentage change in quantity demanded to the percentage change in price. So if demand is elastic, a decrease in price is associated with a larger percentage rise in quantity demanded. Although each unit of the good has a lower price, a sufficiently greater number of units are purchased so that total expenditure (price times quantity) would rise as price falls when demand is elastic.

If demand is inelastic, however, a given percentage decrease in price is associated with a smaller percentage rise in quantity demanded. Consequently, when demand is inelastic, a fall in price brings about a fall in total expenditure.

In summary, when demand is elastic, price and total expenditure move in *opposite* directions. When demand is inelastic, price and total expenditure move in the *same* direction. This relationship is easy to identify in the case of a linear demand curve. Recall that above the midpoint, demand is elastic, and below the midpoint, demand is inelastic. In the upper section of Exhibit 4, total expenditure ($P \times Q$) is measured as the area of a rectangle whose base is Q and height is P. Notice that as price falls, the areas of the inscribed rectangles (each outlined with their own dotted or dashed line) at first grow in size, become largest at the midpoint of the demand curve, and thereafter become smaller as price continues to fall and total expenditure declines toward zero. In the lower section of Exhibit 4, total expenditure is shown for each quantity purchased.

Exhibit 4 Elasticity and Total Expenditure



Note: Figure depicts the relationship among changes in price, changes in quantity, and changes in total expenditure. Maximum total expenditure occurs at the unit-elastic point on a linear demand curve (the cross-hatched rectangle).

The relationships just described hold for any demand curve, so it does not matter whether we are dealing with the demand curve of an individual consumer, the demand curve of the market, or the demand curve facing any given seller. For a market, the total expenditure by buyers becomes the total revenue to sellers in that market. It follows, then, that if market demand is elastic, a fall in price will result in an increase in total revenue to sellers as a whole, and if demand is inelastic, a fall in price will result in a decrease in total revenue to sellers. If the demand faced by any given seller were inelastic at the current price, that seller could increase revenue by increasing its price. But because demand is negatively sloped, the increase in price would decrease total units sold, which would almost certainly decrease total production cost. If raising price both increases revenue and decreases cost, such a move would always be profit enhancing. Faced with inelastic demand, a one-product seller would always be inclined to raise the price until the point at which demand becomes elastic.

5

INCOME ELASTICITY OF DEMAND, CROSS-PRICE ELASTICITY OF DEMAND

a calculate and interpret price, income, and cross-price elasticities of demand and describe factors that affect each measure;

Elasticity is a measure of how sensitive one variable is to change in the value of another variable. Up to this point, we have focused on price elasticity, but the quantity demanded of a good is also a function of consumer income.

Income elasticity of demand is defined as the percentage change in quantity demanded $\left(\%\Delta Q_x^d\right)$ divided by the percentage change in income ($\%\Delta I$), holding all other things constant, as shown in Equation 7:

$$E_I^d = \frac{\%\Delta Q_x^d}{\%\Delta I} \tag{7}$$

The structure of this expression is identical to the structure of own-price elasticity given in Equation 5. (All elasticity measures that we will examine have the same general structure; the only thing that changes is the independent variable of interest.) For example, if the income elasticity of demand for some good has a value of 0.8, we would interpret that to mean that whenever income rises by 1%, the quantity demanded at each price would rise by 0.8%.

Although own-price elasticity of demand will almost always be negative, *income* elasticity of demand can be negative, positive, or zero. Positive income elasticity means that as income rises, quantity demanded also rises. Negative income elasticity of demand means that when people experience a rise in income, they buy less of these goods, and when their income falls, they buy more of the same good.

Goods with positive income elasticity are called "normal" goods. Goods with negative income elasticity are called "inferior" goods. Typical examples of inferior goods are rice, potatoes, or less expensive cuts of meat. We will discuss the concepts of normal and inferior goods in a later section.

In our discussion of the demand curve, we held all other things constant, including consumer income, to plot the relationship between price and quantity demanded. If income were to change, the entire demand curve would shift one way or the other. For normal goods, a rise in income would shift the entire demand curve upward and to the right. For inferior goods, however, a rise in income would result in a downward and leftward shift in the entire demand curve.

5.1 Cross-Price Elasticity of Demand

We previously discussed a good's own-price elasticity. However, the price of another good might also have an impact on the demand for that good or service, and we should be able to define an elasticity with respect to the other price (P_y) as well. That elasticity is called the **cross-price elasticity of demand** and takes on the same structure as own-price elasticity and income elasticity of demand, as represented in Equation 8:

$$E_{p_y}^d = \frac{\%\Delta Q_x^d}{\%\Delta P_y} \tag{8}$$

Note how similar this equation is to the equation for own-price elasticity. The only difference is that the subscript on P is now y, where y indicates some other good. This cross-price elasticity of demand measures how sensitive the demand for good X is to changes in the price of some other good, Y, holding all other things constant. For some pairs of goods, X and Y, when the price of Y rises, more of good X is demanded; the cross-price elasticity of demand is positive. Those goods are referred to as **substitutes**. In economics, if the cross-price elasticity of two goods is positive, they are substitutes, irrespective of whether someone would consider them "similar."

This concept is intuitive if you think about two goods that are seen to be close substitutes, perhaps like two brands of beer. When the price of one of your favorite brands of beer rises, you would probably buy less of that brand and more of a cheaper brand, so the cross-price elasticity of demand would be positive. For substitute goods, an increase in the price of one good would shift the demand curve for the other good upward and to the right.

Alternatively, two goods whose cross-price elasticity of demand is negative are said to be **complements**. Typically, these goods tend to be consumed together as a pair, such as gasoline and automobiles or houses and furniture. When automobile prices fall, we might expect the quantity of autos demanded to rise, and thus we might expect to see a rise in the demand for gasoline.

Whether two goods are substitutes or complements might not be immediately intuitive. For example, grocery stores often put things like coffee on sale in the hope that customers will come in for coffee and end up doing their weekly shopping there as well. In that case, coffee and, say, cabbage could very well empirically turn out to be complements even though we would not think that the price of coffee has any relation to sales of cabbage. Regardless of whether someone would see two goods as related in some fashion, if the cross-price elasticity of two goods is negative, they are complements.

Although a conceptual understanding of demand elasticities is helpful in sorting out the qualitative and directional effects among variables, using an empirically estimated demand function can yield insights into the behavior of a market. For illustration, let us return to our hypothetical individual demand function for gasoline in Equation 2, duplicated here for convenience:

$$Q_x^d = 84.5 - 6.39P_x + 0.25I - 2P_y$$

The quantity demanded of a given good $\left(Q_x^d\right)$ is a function of its own price (P_x), consumer income (I), and the price of another good (P_y).

To derive the market demand function, the individual consumers' demand functions are simply added together. If there were 1,000 individuals who represented a market and they all had identical demand functions, the market demand function would be the individual consumer's demand function multiplied by the number of consumers. Using the individual demand function given by Equation 2, the market demand function would be as shown in Equation 9:

$$Q_x^d = 84{,}500 - 6{,}390P_x + 250I - 2{,}000P_y \tag{9}$$

Earlier, when we calculated own-price elasticity of demand, we needed to choose a price at which to calculate the elasticity coefficient. Similarly, we need to choose actual values for the independent variables—P_x, I, and P_y—and insert these values into the "estimated" market demand function to find the quantity demanded. Choosing €1.48 for P_x, €50 (in thousands) for I, and €20 (in thousands) for P_y, we find that the quantity of gasoline demanded is 47,543 liters per month. We now have everything we need to calculate own-price, income, and cross-price elasticities of demand for our market. Those elasticities are expressed in Equations 10, 11, and 12. Each of those expressions has a term denoting the change in quantity divided by the change in each respective variable: own price, $\Delta Q_x/\Delta P_x$; income, $\Delta Q_x/\Delta I$, and cross price, $\Delta Q_x/\Delta P_y$.

As we stated in the discussion of own-price elasticity, when the relationship between two variables is linear, the change in quantity $\left(\Delta Q_x^d\right)$ divided by the change in own price (ΔP_x), income (ΔI), or cross price (ΔP_y) is equal to the slope coefficient on that other variable. The elasticities are calculated by inserting the slope coefficients from Equation 9 into the elasticity formulas.

Own-price elasticity:

$$E_{p_x}^d = \left(\frac{\Delta Q_x^d}{\Delta P_x}\right)\left(\frac{P_x}{Q_x^d}\right) = \left(-6{,}390\right)\left(\frac{1.48}{47{,}542.8}\right) = -0.20 \tag{10}$$

Income elasticity:

$$E_I^d = \left(\frac{\Delta Q_x^d}{\Delta I}\right)\left(\frac{I}{Q_x^d}\right) = (250)\left(\frac{50}{47{,}542.8}\right) = 0.26 \tag{11}$$

Cross-price elasticity:

$$E_{P_y}^d = \left(\frac{\Delta Q_x^d}{\Delta P_y}\right)\left(\frac{P_y}{Q_x^d}\right) = (-2000)\left(\frac{20}{47{,}542.8}\right) = -0.84 \tag{12}$$

In our example, at a price of €1.48, the own-price elasticity of demand is –0.20; a 1% increase in the price of gasoline leads to a decrease in quantity demanded of about 0.20% (Equation 10). Because the absolute value of the own-price elasticity is less than one, we characterize demand as being *inelastic* at that price; for example, an increase in price would result in an increase in total expenditure on gasoline by consumers in that market. The income elasticity of demand is 0.26 (Equation 11): A 1% increase in income would result in an increase of 0.26% in the quantity demanded of gasoline. Because that elasticity is positive (but small), we would characterize gasoline as a normal good. The cross-price elasticity of demand between gasoline and automobiles is –0.84 (Equation 12): If the price of automobiles rose by 1%, the demand for gasoline would fall by 0.84%. We would, therefore, characterize gasoline and automobiles as complements because the cross-price elasticity is negative. The magnitude is quite small, however, so we would conclude that the complementary relationship is weak.

EXAMPLE 1

Calculating Elasticities from a Given Demand Function

An individual consumer's monthly demand for downloadable e-books is given by the equation $Q_{eb}^d = 2 - 0.4P_{eb} + 0.0005I + 0.15P_{hb}$, where Q_{eb}^d equals the number of e-books demanded each month, I equals the household monthly income, P_{eb} equals the price of e-books, and P_{hb} equals the price of hardbound books. Assume that the price of e-books is €10.68, household income is €2,300, and the price of hardbound books is €21.40.

1. Determine the value of own-price elasticity of demand for e-books.
2. Determine the income elasticity of demand for e-books.
3. Determine the cross-price elasticity of demand for e-books with respect to the price of hardbound books.

Solution to 1:

The own-price elasticity of demand is given by $\left(\Delta Q_{eb}^d / \Delta P_{eb}\right)\left(P_{eb} / Q_{eb}^d\right)$. Notice from the demand function that $\Delta Q_{eb}^d / \Delta P_{eb} = -0.4$. Inserting the given variable values into the demand function yields $Q_{eb}^d = 2 - (0.4)(10.68) + (.0005)(2300) + (0.15)(21.4) = 2.088$. So at a price of €10.68, the own-price elasticity of demand equals (–0.4)(10.68/2.088) = –2.046, which is elastic because in absolute value the elasticity coefficient is greater than 1.

Solution to 2:

Recall that income elasticity of demand is given by $\left(\Delta Q_{eb}^{d}/\Delta I\right)\left(I/Q_{eb}^{d}\right)$. Notice from the demand function that $\Delta Q_{eb}^{d}/\Delta I = 0.0005$. Inserting the values for I and Q_{eb}^{d} yields income elasticity of (0.0005)(2,300/2.088) = 0.551, which is positive, so e-books are a normal good.

Solution to 3:

Recall that cross-price elasticity of demand is given by $(\Delta Q_{eb}/\Delta P_{hb})(P_{hb}/Q_{eb})$, and notice from the demand function that $\Delta Q_{eb}/\Delta P_{hb} = 0.15$. Inserting the values for P_{hb} and Q_{eb} yields a cross-price elasticity of demand for e-books of (0.15)(21.40/2.088) = 1.537, which is positive, implying that e-books and hardbound books are substitutes.

6

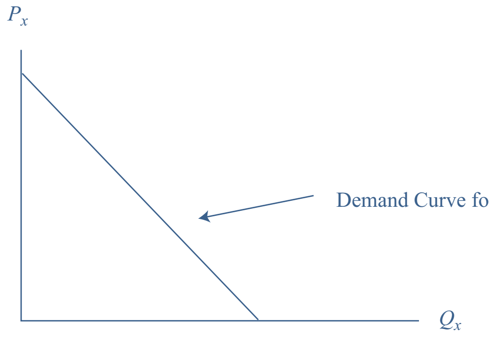
SUBSTITUTION AND INCOME EFFECTS; NORMAL GOODS, INFERIOR GOODS AND SPECIAL CASES

b compare substitution and income effects;

c contrast normal goods with inferior goods;

The law of demand states that if nothing changes other than the price of a particular good or service itself, a decrease in that good's price will tend to result in a greater quantity of that good being purchased. Simply stated, it is the assumption that a demand curve has negative slope; that is, where price per unit is measured on the vertical axis and quantity demanded per time period is measured on the horizontal axis, the demand curve is falling from left to right, as shown in Exhibit 5.

Exhibit 5 A Negatively Sloped Demand Curve—The Law of Demand



There are two reasons why a consumer would be expected to purchase more of a good when its price falls and less of a good when its price rises. These two reasons are known as the substitution effect and the income effect of a change in price. We address these two effects separately and then examine the combination of the two.

When the price of something—say, gasoline—falls, that good becomes relatively less costly compared with other goods or services a consumer might purchase. For example, gasoline is used in driving to work, so when its price falls, it is relatively cheaper to drive to work than to take public transportation. Hence, the consumer is likely to substitute a little more driving to work for a little less public transportation. When the price of beef falls, it becomes relatively cheaper than chicken. The typical consumer is, therefore, likely to purchase a little more beef and a little less chicken.

On its own, the substitution effect suggests that when the price of something falls, consumers tend to purchase more of that good. But another influence is often at work as well—the income effect. Consider a consumer spending all of her "money income" on a given combination of goods and services. (Her money income is simply the quantity of dollars or euros, or other relevant currency, that is available to her to spend in any given time period.) Now suppose the price of something she was regularly purchasing falls while her money income and the prices of all other goods remain unchanged. Economists refer to this as an increase in purchasing power or **real income**. For most goods and services, consumers tend to buy more of them when their income rises. So when the price of a good—say, beef—falls, most consumers would tend to buy more beef because of the increase in their real income. Although the consumer's money income (the number on her paycheck) is assumed not to have changed, her real income has risen because she can now buy more beef—and other goods, too—as a result of the fall in the price of that one good. So, quite apart from the substitution effect of a fall in a good's price, the income effect tends to cause consumers to purchase more of that good as well.

Substitution and income effects work the other way, too. If the price of beef were to rise, the substitution effect would cause the consumer to buy less of it and substitute more chicken for the now relatively more expensive beef. Additionally, the rise in the price of beef results in a decrease in the consumer's real income because now she can buy less goods with the same amount of money income. If beef is a good that consumers tend to buy more of when their income rises and less of when their income falls, then the rise in beef price would have an income effect that causes the consumer to buy less of it.

6.1 Normal and Inferior Goods

Economists classify goods on various dimensions, one of which relates to how consumers' purchases of a good respond to changes in consumer income. Earlier, when discussing income elasticity of demand, we introduced the concept of normal goods and inferior goods. For most goods and services, an increase in income would cause consumers to buy more; these are called **normal goods**. But that does not hold true for all goods: There are goods that consumers buy less of when their income rises and goods that they buy more of when their incomes fall. These are called **inferior goods**. This section will contrast normal goods with inferior goods.

We previously discussed income and substitution effects of a change in price. If a good is normal, a decrease in price will result in the consumer buying more of that good. Both the substitution effect and the income effect are at play here:

- A decrease in price tends to cause consumers to buy more of this good in place of other goods—the substitution effect.
- The increase in real income resulting from the decline in this good's price causes people to buy even more of this good when its price falls—the income effect.

So, we can say that for normal goods (restaurant meals, for example, as most people tend to eat out more often when their incomes rise), the substitution and the income effects reinforce one another to cause the demand curve to be negatively sloped.

For inferior goods (cheaper cuts of meat or generic beverages, for example, which most people buy less of as their incomes rise), an increase in income causes consumers to buy less, not more, and if their incomes fall, they buy more, not less. “Inferior” does not imply anything at all about the quality of the good; it is simply used to refer to a good for which an increase in income causes some people to buy less of it.

The same good could be normal for some consumers while it is inferior for others. Consider a very low-income segment of the population. For those consumers, an increase in their income might very well result in their buying more fast-food meals. They might take some of that added income and enjoy eating out at a fast-food restaurant a little more often. Now consider a high-income group. If their income rises, they might be much less inclined to eat at fast-food restaurants and instead do their dining out at a fashionable French bistro, for example. So, fast-food meals might be a normal good for some people and an inferior good for others.

Let us now consider the substitution and income effects of a change in the price of normal and inferior goods. The substitution effect says that if the price of a good falls, the consumer will substitute more of this good in the consumption bundle and buy less of some other good. The substitution effect is true for both normal and inferior goods. Next, we provide an example.

We begin with a hypothetical consumer with a certain money income (R$200,000). Given the prices for all goods, he makes a decision to buy a given amount of Good *X*, coffee. If the price of coffee falls, the consumer is better off than when the price was higher. We can assume that this consumer would have been willing to pay some amount of money each month to be able to buy coffee at the lower price. We now have two states of the world: In State 1, he spends his income on all the various goods, including his desired quantity of coffee at the original price. In State 2, he is able to buy coffee at the new lower price, but because he has paid a portion of his income to buy coffee at the lower price, he now has less money income to spend on all goods combined. If we adjusted the amount of money he would have to pay to lock in the lower price of coffee until he is just indifferent between the two states of the world, we would have exactly offset the “good” thing of the lower price with the “bad” thing of less income. This removes the income effect of the price decrease and allows us to isolate the pure substitution effect. We find that in State 2, he would buy more coffee than in State 1. The pure substitution effect is always in the direction of buying more at the lower relative price.

Continuing our example, assume that we give back to the consumer the amount of money he is willing to pay for the privilege of buying coffee at the lower price. Clearly, he is better off because now he can buy coffee at the lower price without having to pay for the privilege. We want to know whether, with this higher money income, he will now buy more or less coffee at the lower price. The answer depends on whether coffee is a normal or an inferior good for this consumer. Recall that for normal goods, an increase in income causes consumers to buy more, but for inferior goods, an increase in income causes consumers to buy less.

In conclusion, the substitution effect of a change in the price of a good will always be in the direction of buying more at a lower price or less at a higher price. The income effect of that same price change, however, depends on whether the good is normal or inferior. If the good is normal, the income effect reinforces the substitution effect, both leading to a negatively sloped demand curve. But if the good is inferior, the income effect and the substitution effect work in opposite directions; the income effect tends to mitigate the substitution effect.

Exhibit 6 summarizes the substitution and income effects for normal and inferior goods.

Exhibit 6 The Substitution and Income Effects of a Price Decrease on Normal and Inferior Goods

	Substitution Effect	Income Effect
Normal good	Buy more because the good is relatively cheaper than its substitutes.	Buy more because the increase in purchasing power raises the total consumption level.
Inferior good	Buy more because the good is relatively cheaper than its substitutes.	Buy less because the increase in real income prompts the consumer to buy less of the inferior good in favor of its preferred substitutes.

Exceptions to the Law of Demand

In virtually every case in the real world, the law of demand holds: A decrease in price results in an increase in quantity demanded, resulting in a negatively sloped demand curve. In a few unusual cases, however, we may find a positively sloped demand curve—a decrease (increase) in price may result in a decrease (increase) in the quantity demanded. These unusual cases are called Giffen goods and Veblen goods.

In theory, it is possible for the income effect to be so strong and so negative as to overpower the substitution effect. In such a case, more of a good would be consumed as the price rises and less would be consumed as the price falls. These goods are called **Giffen goods**, named for Robert Giffen based on his observations of the purchasing habits of the Victorian era poor. For many decades, no one really believed that a Giffen good actually existed anywhere other than in textbooks. But in recent years, studies have documented a few rare cases. One study was conducted in a poor rural community where individuals spend a very large portion of their incomes on rice. For these individuals, rice was an inferior good. Under the law of demand, the quantity of rice purchased would rise with the decline in price, but the rise in quantity would be partially offset by the income effect (a decrease in the amount of rice purchased as a result of rising incomes). What the experimenters discovered, however, was that for a certain subset of consumers, the quantity of rice purchased declined in absolute terms—the income effect actually overwhelmed the substitution effect. For consumers living at subsistence levels—incomes just barely sufficient to enable them to meet their caloric intake needs—a decline in the price of the staple enabled them to shift more of their consumption from rice to the alternate sources of calories in their diet (e.g., meat).

With some goods, the item's price tag itself might drive the consumer's preferences for it. Thorstein Veblen posited just such a circumstance in his concept of conspicuous consumption. According to this way of thinking, a consumer might derive utility out of being known by others to consume a so-called high-status good, such as a luxury automobile or a very expensive piece of jewelry. Importantly, it is the high price itself that partly imparts value to such a good. These are called **Veblen goods**, and they derive their value from the consumption of them as symbols of the purchaser's high status in society; they are certainly not inferior goods. It is argued that by increasing the price of a Veblen good, the consumer would be more inclined to purchase it, not less.

EXAMPLE 2

Income and Substitution Effects of a Decrease in Price

Monica has a monthly entertainment budget that she spends on (a) movies and (b) an assortment of other entertainment items. When the price of each movie is \$8, she spends a quarter of her budget on six movies a month and the rest of her budget on other entertainment. Monica was offered an opportunity to join a movie club at her local theater that allows her to purchase movies at half the regular price, and she can choose each month whether to join the movie club or not. There is a membership fee she must pay for each month she belongs to the club. Monica is exactly indifferent between (a) not buying the membership and, therefore, paying \$8 for movies and (b) buying the membership and paying \$4 per movie. So, she flips a coin each month to determine whether to join the club that month. In months that she does join the club, she sees eight movies. For her birthday, a friend gave her a one-month club membership as a gift, and that month she saw 12 movies.

1 If there were no club and the price of movies were to simply fall from \$8 to \$4, how many more movies would Monica buy each month?

2 Of the increased number of movies Monica would purchase if the price were to fall from \$8 to \$4, determine how much of the increase would be attributable to the substitution effect and how much to the income effect of that price decrease.

3 For Monica, are movies a normal, inferior, or Giffen good?

Solution to 1:

Six movies. When her friend gave her a club membership, she bought 12 movies instead of her usual 6. With the gift of the club membership, Monica could buy movies at a price of \$4 without paying for that privilege. This is the same as if the price of each movie fell from \$8 to \$4.

Solution to 2:

When Monica pays the club membership herself, she buys eight movies, two more than usual. Because Monica is equally well off whether she joins the club for a monthly fee and thereby pays half price or whether she does not join the club and pays full price, we can say that the income effect of the price decrease has been removed by charging her the monthly fee. So the increase from six movies to eight is the result of the substitution effect. When Monica's friend gave her the gift of a club membership, allowing her to pay half price without paying for the privilege, Monica bought 12 movies, 6 more than usual and 4 more than she would have had she paid the membership fee. The increase from 8 movies to 12 is the result of the income effect.

Solution to 3:

When the price fell from \$8 to \$4, Monica bought more movies, so clearly movies are not a Giffen good for her. Additionally, because the substitution effect and the income effect are in the same direction of buying more movies, they are a normal good for Monica. The substitution effect caused her to buy two more movies, and the income effect caused her to buy an additional four movies.

SUPPLY ANALYSIS: COST, MARGINAL RETURN, AND PRODUCTIVITY

7

d describe the phenomenon of diminishing marginal returns;

To fully comprehend the supply side of a consumer goods market, an analyst must understand the firm's costs. (As a reminder, this reading builds on the basics of the market model as covered in the recommended prerequisite reading material.)

The firm's marginal cost is the foundation of the firm's ability and willingness to offer a given quantity for sale, and its costs depend on both the productivity of its inputs and their prices. In this section, we will describe the firm's cost curves—total, average, and marginal costs in both the short run and in the long run—paying special attention to what economists call the **law of diminishing marginal returns**. We will then use this information to explore the conditions under which a firm would find it beneficial to continue operation, even if its economic profits are negative, and at what levels of production its shutdown and breakeven points occur. Long-run costs will be examined in the context of economies and diseconomies of scale.

7.1 Marginal Returns and Productivity

There is an economic phenomenon known as **increasing marginal returns**, in which **marginal product**—the productivity of each additional unit of a resource—increases as additional units of that input are employed.

Initially, a firm can experience increasing returns from adding labor to the production process because of the concepts of specialization and division of labor. At first, by having too few workers relative to total physical capital, the understaffing situation requires employees to multi-task and share duties. As more workers are added, employees can specialize, become more adept at their individual functions, and realize an increase in marginal productivity. But after a certain output level, the law of diminishing marginal returns becomes evident.

When more and more workers are added to a fixed capital base, the marginal return of the labor factor eventually decreases because the fixed input restricts the output potential of additional workers. As an illustration, consider automobile production. When an auto manufacturing plant is operating at full capacity, adding additional labor will not increase production because the physical plant is already 100% employed. More labor hours will merely add to costs without adding to output. Assuming all workers are of equal quality and motivation, the decline in marginal product occurs in the short run, where all other resources (typically, plant size, physical capital, and technology) are fixed.

Marginal returns are directly related to **input productivity**, a measure of the output per unit of input.

7.1.1 *Productivity: The Relationship between Production and Cost*

The cost of producing anything depends on the amount of *inputs*, or *factors of production* (these terms are synonymous), and the input prices. Examples of factors of production are employee hours, machine hours, raw materials, and so on. For simplicity, economists typically concentrate on only two inputs, labor and capital, although obviously there can be many inputs to a particular production process. The labor input is simply employee time, and it is measured as labor hours per time period, such as per week or per month. We denote labor hours as L. If a firm is using two laborers per week and each laborer works 35 hours per week, then L equals 70 labor hours per week. We denote hours of capital as K. If the firm is using three machines and each one is used for 12 hours per week, then K equals 36 machine hours per week. That is, the capital input is measured as machine hours used per time period. In this way, capital and labor are stated in similar terms. They represent flows of services—labor hours and machine hours—that are used to produce a flow of output per time period.

Accordingly, the respective input prices would be the wage rate per labor hour (we use w to denote wage rate) and the rental rate per machine hour (we use r to denote the rental rate per machine hour). It is helpful to think of a firm as renting the services of labor and of machines. Although the firm might own its own machines, it could in theory rent its machines out to another user, so it is forgoing the rate it could earn elsewhere when it is using its machines internally instead of renting them out. So, a firm is not using its own machines "for free." It is incurring the **opportunity cost** of not being able to rent those machines to another user.

The **total cost** of production (TC) is the number of hours of labor multiplied by the wage rate plus the number of machine hours multiplied by the rental rate of machines:

$$\text{TC} = (w)(L) + (r)(K)$$

This formula illustrates that the total cost is just the cost of all the firm's inputs. It is not a cost function, however, which is a relationship between the cost of production and the flow of output. The cost function $C = f(Q)$, where (Q) denotes the flow of output in units of production per time period, relates the production cost per time period to the number of units of output produced per time period.

Two things could cause the cost of producing any given level of output to fall: Either the price of one or both inputs could fall or the inputs themselves could become more productive and less of them would be needed (e.g., a worker is more productive when fewer hours of labor are needed to produce the same output). The reverse is true also: A rise in cost could result from either a rise in input prices or a fall in input productivity, or both.

Why is productivity important? Cost-minimization and profit-maximization behavior dictate that the firm strives to maximize productivity—for example, produce the most output per unit of input or produce any given level of output with the least amount of inputs. A firm that lags behind the industry in productivity is at a competitive disadvantage and is likely to face decreases in future earnings and shareholders' wealth. An increase in productivity lowers production costs, which leads to greater profitability and investment value. These productivity benefits can be fully or partially distributed to other stakeholders of the business, such as to consumers in the form of lower prices and to employees in the form of enhanced compensation. Transferring some or all of the productivity rewards to non-equity holders creates synergies that benefit shareholders over time.

The benefits from increased productivity are as follows:

- lower business costs, which translate into increased profitability;
- an increase in the market value of equity and shareholders' wealth resulting from an increase in profit; and
- an increase in worker rewards, which motivates further productivity increases from labor.

Undoubtedly, increases in productivity reinforce and strengthen the competitive position of the firm over the long run. A fundamental analysis of a company should examine the firm's commitment to productivity enhancements and the degree to which productivity is integrated into the competitive nature of the industry or market. In some cases, productivity is not only an important promoter of growth in firm value over the long term but is also the key factor for economic survival. A business that lags the market in terms of productivity often finds itself less competitive, while at the same time confronting profit erosion and deterioration in shareholders' wealth. Typical productivity measures for a firm are based on the concepts of total product, average product, and marginal product of labor.

7.1.2 *Total, Average, and Marginal Product of Labor*

When measuring a firm's operating efficiency, it is easier and more practical to use a single resource factor as the input variable rather than a bundle of the different resources that the firm uses in producing units of output. As discussed in the previous section, labor is typically the input that is the most identifiable and calculable for measuring productivity. However, any input that is not difficult to quantify can be used. As an example, a business that manually assembles widgets has 50 workers, one production facility, and an assortment of equipment and hand tools. The firm would like to assess its productivity when using these three input factors to produce widgets. In this example, it is most appropriate to use labor as the input factor for determining productivity because the firm uses only one (fixed) plant building and a variety of other physical capital.

We will use labor as the input variable to illustrate the concepts of total product, average product, and marginal product. Exhibit 7 provides a summary of these three concepts.

Exhibit 7 Definitions and Calculations for Total, Marginal, and Average Product of Labor

Term	Calculation
Total product	Sum of the output from all inputs during a time period; usually illustrated as the total output (Q) using labor quantity (L)
Average product	Total product divided by the quantity of a given input; measured as total product divided by the number of worker hours used at that output level (Q/L)
Marginal product	The amount of additional output resulting from using one more unit of input assuming other inputs are fixed; measured by taking the difference in total product and dividing by the change in the quantity of labor ($\Delta Q/\Delta L$)

Total product (Q) is defined as the aggregate sum of production for a firm during a time period. As a measure of productivity, total product provides superficial information about how effective and efficient a firm is in terms of producing output. For instance, three firms—Company A, Company B, and Company C—that make up an entire industry have total output levels of 100,000 units, 180,000 units, and 200,000 units, respectively. Obviously, Company C dominates the market with a 41.7% share, followed by Company B's 37.5% share and Company A's 20.8% portion of the market. However, this information says little about how efficient each firm is in generating its total output level. Total product only provides insight into a firm's production volume relative to the industry; it does not show how efficient a firm is in producing its output.

Average product of labor (AP_L) measures the productivity of an input (in this case, labor) on average and is calculated by dividing total product by the total number of units for the given input that is used to generate that output. Average product is usually measured on the basis of the labor input. It is a representative or overall measure of labor's productivity: Some workers are more productive than average, and others are less productive than average.

Exhibit 8 compares the productivity of the three firms introduced earlier. Company A employs 100 worker hours and produces 100,000 widgets per hour. Company B employs 200 worker hours and produces 180,000 widgets per hour. Company C employs 250 worker hours and produces 200,000 widgets per hour.

Exhibit 8 Comparing Productivity

	Output (Q)	Number of Worker Hours (L)	Average Product of Labor (AP_L)
Company A	100,000	100	1,000
Company B	180,000	200	900
Company C	200,000	250	800

Using this metric, it is apparent that Company A, with AP_L equal to 1,000, is the most efficient firm, despite having the lowest market share. Company C has the largest market share, but it is the least efficient of the three, with AP_L equal to 800. Assuming that Company A can maintain its productivity advantage over the long run, it will be positioned to generate the greatest return on investment through lower costs and higher profit outcomes relative to the other firms in the market.

Marginal product of labor (MP_L), also known as *marginal return*, measures the productivity of each additional unit of input and is calculated by observing the difference in total product when adding another unit of input (assuming other resource quantities are held constant). It is a gauge of the productivity of the individual additional worker hour rather than an average across all workers.

Exhibit 9 provides a numerical illustration for total, average, and marginal products of labor.

Exhibit 9 Total, Average, and Marginal Product of Labor

Labor (L)	Total Product (Q_L)	Average Product (AP_L)	Marginal Product (MP_L)
0	0	—	—
1	100	100	100
2	210	105	110
3	300	100	90
4	360	90	60
5	400	80	40
6	420	70	20
7	350	50	–70

Total product increases as the firm adds each additional hour of labor—until the seventh labor hour, at which point total production declines by 70 units. Obviously, the firm would want to avoid negative worker productivity.

At an employment level of five labor hours, AP_L is 80 units (400/5) and MP_L is 40 units [(400 – 360)/(5 – 4)]. The average productivity for all five labor hours is 80 units, but the productivity of the fifth labor hour is only 40 units.

EXAMPLE 3

Calculation and Interpretation of Total, Average, and Marginal Product

Exhibit 10 illustrates the production relationship between the number of machine hours and total product.

1. Interpret the results for total, average, and marginal product.
2. Indicate at what point increasing marginal returns change to diminishing marginal returns.

Exhibit 10

Machine Hours (K)	Total Product (Q_K)	Average Product (AP_K)	Marginal Product (MP_K)
0	0	—	—
1	1,000	1,000	1,000
2	2,500	1,250	1,500
3	4,500	1,500	2,000
4	6,400	1,600	1,900
5	7,400	1,480	1,000
6	7,500	1,250	100
7	7,000	1,000	–500

Solution to 1:

Total product increases up to six machine hours, where it tops out at 7,500. Because total product declines from Hour 6 to Hour 7, the marginal product for Machine Hour 7 is negative 500 units. Average product peaks at 1,600 units with four machine hours. Average product increases at a steady pace with the addition of Machine Hours 2 and 3. The addition of Machine Hour 4 continues to increase average product but at a decreasing rate. Beyond four machine hours, average product decreases—at an increasing rate. Marginal product peaks with Machine Hour 3 and decreases thereafter.

Solution to 2:

The marginal product, MP_K, of Machine Hour 3 is 2,000. The marginal product of each additional machine hour beyond Machine Hour 3 declines. Diminishing marginal returns are evident beyond Machine Hour 3.

A firm has a choice of using total product, average product, marginal product, or some combination of the three to measure productivity. Because total product is simply an indication of a firm's output volume and potential market share, average product and marginal product are better gauges of a firm's productivity. Both can reveal competitive advantage through production efficiency. However, individual worker productivity is not easily measurable when workers perform tasks collectively. In this case, average product is the preferred measure of productivity performance.

Referring to the total product column in Exhibit 9, output is more than twice as great (210 widgets) when two hours of labor are used as opposed to only one hour (100 widgets.) In this range of production, there is an increase in return when employee hours are added to the production process. This is the phenomenon of increasing marginal returns.

8 ECONOMC PROFIT VERSUS ACCOUNTING PROFIT

e determine and interpret breakeven and shutdown points of production;

Two important considerations of any firm are its level of profitability and whether to continue to operate in the current environment. Economists define profit differently than do accountants. **Economic profit** is defined as the difference between total revenue (TR) and total **economic costs**. **Accounting profit** is the difference between TR and total **accounting cost**. TR is the same from both an accounting standpoint and an economic standpoint; it is derived by multiplying the selling price per unit of output by the number of units: TR = $(P)(Q)$. The difference between the two measures of profit, therefore, lies in an understanding of economic cost (also called "opportunity cost," which is defined in detail in the next section).

8.1 Economic Cost vs. Accounting Cost

The opportunity cost of any particular decision, such as to produce a given level of output, can be determined by measuring the benefit forgone by not implementing the next best alternative. Suppose that a firm is currently operating with hired labor and its own plant and equipment to produce output at some level. The firm must continuously decide either to keep the level of output the same or to change it. The decision to maintain the same output requires that the firm hire the same amount of labor input and use the same level of its capital inputs as before. The labor expense is both an economic cost and an accounting cost because the money spent on labor hours could have been used for something else (opportunity cost), and it is also a current expense for the firm (accounting cost.)

Accountants typically attempt to recognize the cost of plant and equipment in the form of accounting depreciation, which is a means of distributing the historical cost of the fixed capital among the units of production for financial reporting purposes. The money spent in the past on the firm's plant and equipment is what economists call a "sunk cost." Because sunk costs cannot be altered, they cannot affect an optimal decision, which is forward looking. Sunk costs are therefore ignored, and the key management question is, Going forward, what are the opportunity costs and benefits of maintaining a given level of output?

Here is where economic depreciation comes into play. To understand the opportunity costs of using our plant and equipment—already bought and paid for—for one more period of time to produce output, we have to ask the question, What else could be done with that fixed capital if it were not used to produce our output? The answer might be that because there is no external market for our machines and buildings, we are forgoing nothing by using it to produce output. Or it might be that there is a market where we could rent out or sell our capital equipment elsewhere instead of using it to produce output. That rental rate is the economic depreciation associated with using our own equipment to produce output instead of renting or selling it elsewhere.

Economic depreciation is forward looking. It asks, What am I giving up if I use my resources to produce output in the coming period? Accounting depreciation is backward looking. It asks, How should I distribute the historical cost—that I have already paid—across units of output that I intend to produce this period? Both concepts are useful—one for making managerial decisions about output and the other as a way spreading historical costs for reporting or tax purposes—but there is not necessarily a direct relationship between the two.

MARGINAL REVENUE, MARGINAL COST AND PROFIT MAXIMIZATION; SHORT-RUN COST CURVES: TOTAL, VARIABLE, FIXED, AND MARGINAL COSTS

9

e determine and interpret breakeven and shutdown points of production;

It is assumed that any for-profit firm's management is tasked with achieving the goal of shareholder wealth maximization. Put most simply, that translates into the goal of economic profit maximization. Hereafter, when the word *profit* is used, it will be economic profit that we have in mind. Because profit is defined as TR minus TC, anything that increases revenue more than cost or decreases cost more than revenue will increase profit. Before we address profit maximization, we must introduce two important concepts: marginal revenue and marginal cost.

Marginal revenue (MR) is the additional revenue the firm realizes from the decision to increase output by one unit per time period. That is, MR = ΔTR/ΔQ. If the firm is operating in what economists call a perfectly competitive market, it is one of many sellers of identical products in an environment characterized by low or non-existent barriers to entry. Under perfect competition, the firm has no pricing power because there are many perfect substitutes for the product it sells. If it were to attempt to raise the price even by a very small amount, it would lose all of its sales to competitors. On the other hand, it can sell essentially any amount of product it wants without lowering the price below the market price.

Take the wheat market as an example of a perfectly competitive market. A seller of wheat would have no control over the market price of wheat; thus, because TR = (P)(Q), MR for this firm is simply price per unit of output. This firm is said to face a perfectly horizontal (zero-sloped), or infinitely elastic, demand curve for its product. For example, if the firm is selling 1,000 bushels of wheat per week at a price of £3 per bushel, TR is £3,000. If the firm were to increase its output by one unit, then TR would rise by exactly £3 because the firm would not have to lower its price to sell that added unit. So, for sellers in a market with perfect competition, MR = P.

In contrast, if a firm sells a product that is differentiated from other firms' products and that has a large market share, the firm is said to be operating in an environment of imperfect competition. In the extreme case of imperfect competition, there might be only one firm selling a product with no close substitutes. That firm holds a monopoly, and it is subject to the market demand curve for its product. Whether a monopoly or simply operating under imperfect competition, the firm faces a negatively sloped demand curve and must lower its price to sell another unit. Thus, MR will be lower than price.

To illustrate this concept, we will decompose MR. Recall from earlier in the reading that

TR = (P)(Q)

and

$$\text{MR} = \Delta\text{TR}/\Delta Q$$

Change in total revenue (ΔTR), the numerator of the ratio, can be written as $(P)(\Delta Q) + (Q)(\Delta P)$.

There are two competing forces affecting revenue: (1) Additional units are sold at the new price, and (2) all units must now be sold at the lower price. The firm is selling more units, but it is selling all units at a lower price than before.

To find MR, we divide the change in TR by the change in quantity:

$$\text{MR} = \frac{(P)(\Delta Q)}{\Delta Q} + \frac{(Q)(\Delta P)}{\Delta Q} = P + Q\frac{(\Delta P)}{\Delta Q}$$

In other words, MR is equal to price but with an "adjustment" equal to $(Q)(\Delta P/\Delta Q)$.

Taking this one step further, recall that earlier we said $(\Delta P/\Delta Q)$ is the slope of the demand curve. From our expression just given, $\text{MR} = P + Q(\Delta P/\Delta Q)$; so, MR is equal to price with an adjustment equal to quantity times the slope of the demand curve.

A perfectly competitive firm faces a demand curve with a slope of zero. Substituting 0 for $\Delta P/\Delta Q$ into the expression given, it becomes clear that MR is equal to price for the perfectly competitive firm—it need not lower its price to sell an additional unit. For a firm in an imperfectly competitive market, however, the demand curve is negatively sloped ($\Delta P/\Delta Q < 0$). Substituting this negative number into the expression for MR, $P + Q(\Delta P/\Delta Q)$, it becomes clear that MR for an imperfectly competitive firm is less than price.

Marginal cost (MC) is the increase to total cost resulting from the firm's decision to increase output by one additional unit per time period: $\text{MC} = \Delta\text{TC}/\Delta Q$. Economists distinguish between short-run marginal cost (SMC) and long-run marginal cost (LMC). Labor is variable over the short run, but the quantity of capital cannot be changed in the short run because there is a lead time required to build or buy new plant equipment and put it in place. In the long run, all inputs are variable.

SMC is essentially the additional cost of the variable input, labor, that must be incurred to increase the level of output by one unit. LMC is the additional cost of all inputs necessary to increase the level of output, allowing the firm the flexibility of changing both labor and capital inputs in a way that maximizes efficiency.

Understanding MC is aided by recalling that cost is *directly* related to input prices and *inversely* related to productivity. For example, if the wage rate were to rise, cost would also rise. If labor were to become more productive, cost would fall. This relationship can be captured in an expression that relates SMC to wage rate (w) and MP_L: $\text{SMC} = w/\text{MP}_L$.

This relationship between cost and productivity also holds with average variable cost. **Variable costs** are all costs that fluctuate with the level of production and sales. **Average variable cost** (AVC) is the ratio of total variable cost to total output: $\text{AVC} = \text{TVC}/Q$. Again, if labor's wage rises, AVC also rises; but if labor were to become more productive, AVC falls. This relationship is captured by the expression $\text{AVC} = w/\text{AP}_L$.

Earlier, we noted that over some range of low output, the firm might benefit from increasing marginal productivity of its labor input as workers begin to specialize. As the MP_L increases, SMCs decline. Eventually, as more and more labor is added to a fixed amount of capital, the MP_L must fall, causing SMCs to rise.

We began this section by stating that the goal of management is to maximize profit. We now address the conditions necessary for reaching that goal. Consider a firm currently producing 1,000 widgets each week and whose management is contemplating increasing that output incrementally. Would that additional unit increase profit? Clearly, profit would be increased (or losses reduced) if the additional revenue from that next unit were greater than the additional cost. So, a profit-seeking firm should increase Q if MR > MC. Conversely, if the additional unit added more to cost than to revenue, the firm should reduce output because it would save more in cost than it would lose in revenue. Only if the additional cost were exactly equal to the additional revenue would the firm be maximizing its profit.

There is another condition (called a second-order condition) necessary for profit maximization: At the level of output at which MR = MC, MC cannot be falling. This condition is fairly intuitive. If MC is falling with additional output, MP_L would be rising. (Recall that SMC = w/MP_L) If one additional hour of labor input causes MC to fall, the firm would want to add that hour and continue adding labor until SMC becomes positively sloped. We can sum up the profit-maximization decision for an operating firm as follows: Produce the level of output such that (1) MR = MC and (2) MC is not falling.

9.1 Understanding the Interaction between Total, Variable, Fixed, and Marginal Cost and Output

Exhibit 11 shows the graphical relationships between total cost, total fixed cost, and total variable cost. TC is the summation of all costs, where costs are classified on the basis of whether they are fixed or variable. **Total fixed cost** (TFC) is the summation of all expenses that do not change as the level of production varies. **Total variable cost** (TVC) is the summation of all variable expenses; TVC rises with increased production and falls with decreased production. At zero production, TC is equal to TFC because TVC at this output level is zero. The curve for TC always lies parallel to and above the TVC curve by the amount of TFC.

Exhibit 11 Total Cost, Total Variable Cost, and Total Fixed Cost

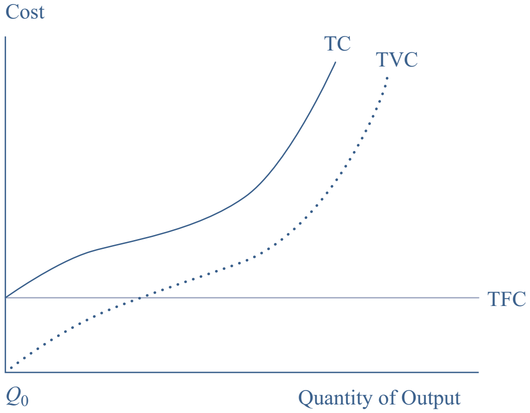


Exhibit 12 shows the relationships between the **average total cost** (ATC), average variable cost (AVC), **average fixed cost** (AFC), and marginal cost (MC) curves in the short run. As output quantity increases, AFC declines because TFCs are spread over a larger number of units. Both ATC and AVC take on a bowl-shaped pattern in which each curve initially declines, reaches a minimum average cost output level, and then increases after that point. The MC curve intersects both the ATC and the AVC at their minimum points—points *S* and *T*. When MC is less than AVC, AVC will be decreasing. When MC is greater than AVC, AVC will be increasing.

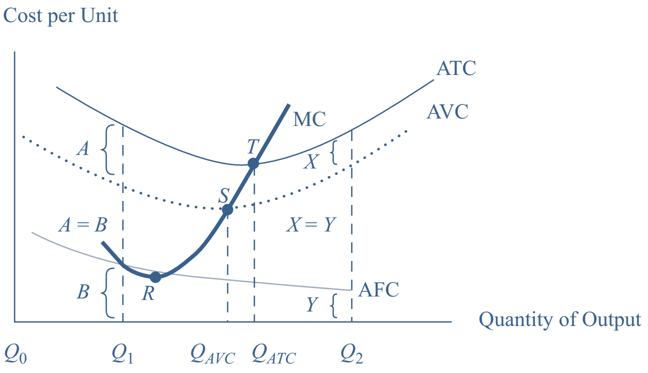
Exhibit 12 Average Total Cost, Average Variable Cost, Average Fixed Cost, and Marginal Cost



S, the lowest point on the AVC curve, is where MC equals AVC. Beyond quantity Q_{AVC}, MC is greater than AVC; thus, the AVC curve begins to rise. Note that it occurs at a quantity lower than the minimum point on the ATC curve.

T, the lowest point on the ATC curve, is where MC equals ATC. Beyond quantity Q_{ATC}, MC is greater than ATC; thus, the ATC curve is rising.

A, the difference between ATC and AVC at output quantity Q_1, is the amount of AFC.

R indicates the lowest point on the MC curve. Beyond this point of production, fixed input constraints reduce the productivity of labor.

X indicates the difference between ATC and AVC at quantity Q_2. It is less than *A* because AFC (*Y*) falls with output.

Exhibit 13 shows an example of how total, average, and marginal costs are derived. TC is calculated by summing TFC and TVC. MC is derived by observing the change in TC as the quantity variable changes. There is a relationship that always holds for average and marginal costs: If MC is less than average cost, average cost must fall, and if MC is greater than average cost, average cost must rise. For example, in Exhibit 13, AVC begins to increase as output rises from 2 to 3 units because MC (50) is greater than AVC (41.7). Also from Exhibit 13, ATC declines up to 3 units because MC is less than ATC. After 3 units, ATC increases because the MC of Unit 4 (85) exceeds the ATC of all prior units (75). Initially, the MC curve declines because of increasing marginal returns to labor, but at some point, it begins to increase because of the law of diminishing marginal returns.

Exhibit 13 Total, Average, Marginal, Fixed, and Variable Costs

Quantity (*Q*)	TFC[a]	AFC	TVC	AVC	TC	ATC	MC
0	100	—	0	—	100	—	—
1	100	100.0	50	50.0	150	150.0	50
2	100	50.0	75	37.5	175	87.5	25
3	100	33.3	125	41.7	225	75.0	50
4	100	25.0	210	52.5	310	77.5	85
5	100	20.0	300	60.0	400	80.0	90
6	100	16.7	450	75.0	550	91.7	150
7	100	14.3	650	92.9	750	107.1	200
8	100	12.5	900	112.5	1,000	125.0	250

Exhibit 13 (Continued)

Quantity (*Q*)	TFC[a]	AFC	TVC	AVC	TC	ATC	MC
9	100	11.1	1,200	133.3	1,300	144.4	300
10	100	10.0	1,550	155.0	1,650	165.0	350

[a] Includes all opportunity costs.

As stated earlier, TC increases as the firm expands output and decreases when production is cut. TC increases at a decreasing rate up to a certain output level. Thereafter, the rate of increase accelerates as the firm gets closer to full utilization of capacity. The rate of change in TC mirrors the rate of change in TVC. In Exhibit 13, TC at 5 units is 400—of which 300 is variable cost and 100 is fixed cost. At 10 units, TC is 1,650—of which 1,550 is variable cost and 100 is fixed cost.

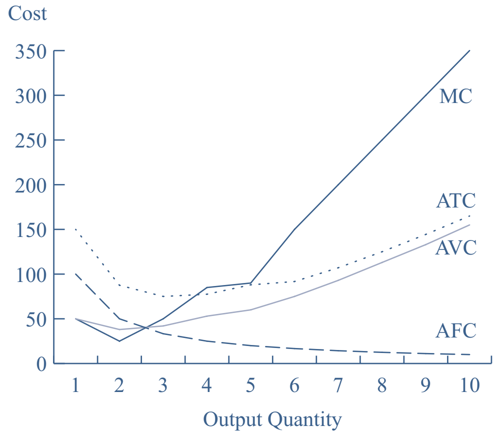
Fixed costs typically are incurred whether the firm produces anything or not. Fixed costs may stay the same over a given range of production but can change to another constant level when production moves outside of that range. The latter is referred to as a **quasi-fixed cost**, although it remains categorized as part of TFC. Examples of fixed costs are debt service, real estate lease agreements, and rental contracts. **Normal profit** is also considered to be a fixed cost because it is a return required by investors on their equity capital regardless of output level. Quasi-fixed cost examples would be certain utilities and administrative salaries that could be lower or avoided altogether when output is zero but would rise to higher constant levels over different production ranges.

Other fixed costs evolve primarily from investments in such fixed assets as real estate, production facilities, and equipment. These fixed costs cannot be arbitrarily cut when production declines. When a firm downsizes, the last expense to be cut is usually fixed cost.

TVC has a direct relationship with quantity. When quantity increases, TVC increases; when quantity decreases, TVC declines. At zero production, TVC is always zero. Variable cost examples are payments for labor, raw materials, and supplies. The change in TVC declines up to a certain output point and then increases as production approaches capacity limits. In Exhibit 13, TVC increases with an increase in quantity. However, the change from 1 to 2 units is 25 (75 – 50), and the change from 9 to 10 units is 350.

Exhibit 14 illustrates the relationships between MC, ATC, AVC, and AFC for the data presented in Exhibit 13.

Exhibit 14 Average Total Cost, Average Variable Cost, Average Fixed Cost, and Marginal Cost for Exhibit 13 Data



Dividing TFC by quantity yields AFC. AFC decreases throughout the production span, reflecting the spreading of a constant cost over more and more production units. At high production volumes, AFC may be so low that it is a small proportion of ATC. In Exhibit 13, AFC declines from 100 at 1 unit to 20 at 5 units, and then to 10 at an output level of 10 units.

In Exhibit 13, AVC at 5 units is 60 (300/5). Over an initial range of production, AVC declines and then reaches a minimum point. Thereafter, AVC increases as the firm uses more of its production capacity. This higher cost results primarily from production constraints imposed by the fixed assets at higher volume levels. The lowest AVC quantity does not correspond to the least-cost quantity for ATC because AFC is still declining. In Exhibit 13, AVC is minimized at 2 units, whereas ATC is minimized at 3 units.

ATC is calculated by dividing TC by quantity (or by summing AFC and AVC). In Exhibit 13, at 3 units, ATC is 75 (TC of 225/3 units of production or AFC of 33.3 + AVC of 41.7). This is the least average cost point of production and the minimum point on the ATC curve. Although cost-minimizing behavior on the part of the firm would dictate operating at the minimum point on its ATC curve, the profit-maximizing quantity may not correspond to this minimum ATC point. Profit per unit, but not necessarily total profit, is maximized at this point.

EXAMPLE 4

Calculation and Interpretation of Total, Average, Marginal, Fixed, and Variable Costs

The first three columns of Exhibit 15 display data on quantity, TFC, and TVC, which are used to calculate TC, AFC, AVC, ATC, and MC. Examine the results for total, average, marginal, fixed, and variable costs. Identify the quantity levels at which the ATC, AVC, and MC values reach their minimum points. Explain the relationship between TFC and TC at a quantity of zero output.

Exhibit 15

Q	TFC[a]	TVC	AFC	AVC	TC	ATC	MC
0	5,000	0	—	—	5,000	—	—
1	5,000	2,000	5,000.0	2,000	7,000	7,000.0	2,000
2	5,000	3,800	2,500.0	1,900	8,800	4,400.0	1,800
3	5,000	5,400	1,666.7	1,800	10,400	3,466.7	1,600
4	5,000	8,000	1,250.0	2,000	13,000	3,250.0	2,600
5	5,000	11,000	1,000.0	2,200	16,000	3,200.0	3,000
6	5,000	15,000	833.3	2,500	20,000	3,333.3	4,000
7	5,000	21,000	714.3	3,000	26,000	3,714.3	6,000
8	5,000	28,800	625.0	3,600	33,800	4,225.0	7,800
9	5,000	38,700	555.6	4,300	43,700	4,855.6	9,900
10	5,000	51,000	500.0	5,100	56,000	5,600.0	12,300

[a] Includes all opportunity costs

Solution:

TFC remains unchanged at 5,000 throughout the entire production range, whereas AFC continuously declines from 5,000 at 1 unit to 500 at 10 units. Both AVC and MC initially decline and then reach their lowest level at 3 units, with costs of 1,800 and 1,600, respectively. Beyond 3 units, both AVC and MC increase, indicating that the cost of production rises with greater output. The least-cost point for ATC is 3,200 at 5 units. At zero output, TC is 5,000, which equals the amount of TFC (at zero output, the firm will need no variable inputs, but it is committed to its fixed plant and equipment in the short run).

PERFECT AND IMPERFECT COMPETITION, PROFIT MAXIMIZATION

10

e determine and interpret breakeven and shutdown points of production;

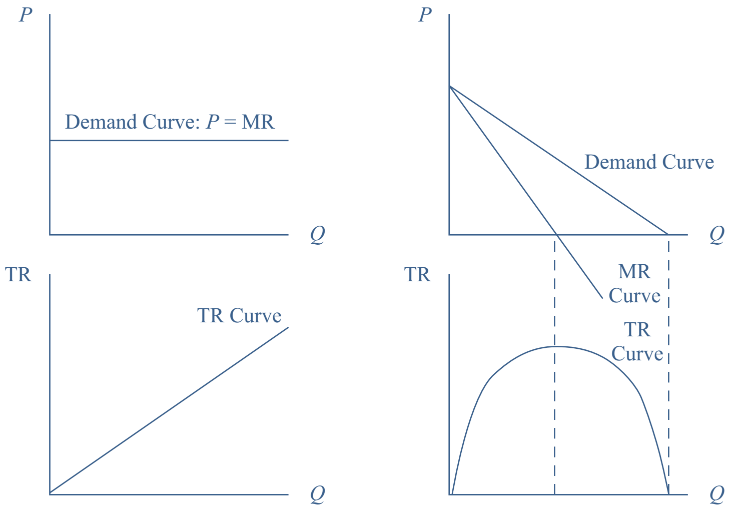
Recall from our earlier discussion of profit-maximizing conditions that a firm can generally be classified as operating in either a perfectly competitive or an imperfectly competitive environment. The difference between the two manifests itself in the slope of the demand curve facing the firm. If the environment of the firm is perfectly competitive, it must take the market price of its output as given, so it faces a perfectly elastic, horizontal demand curve. In this case, as we saw previously, the firm's MR and the price of its product are identical. Additionally, the firm's **average revenue** (AR), or revenue per unit, is also equal to price per unit. However, a firm that faces a negatively sloped demand curve must lower its price to sell an additional unit, so its MR is less than price (*P*).

These characteristics of MR are also applicable to the TR functions. Under conditions of perfect competition, TR (as always) is equal to price times quantity: TR = (*P*)(*Q*). But under conditions of perfect competition, price is dictated by the market; the firm has no control over price. As the firm sells one more unit, its TR rises by the exact amount of price per unit.

Under conditions of imperfect competition, price is a variable under the firm's control, and therefore price is a function of quantity: P = f(Q), and TR = f(Q) × Q. For simplicity, suppose the firm is monopolistic and faces the market demand curve, which we will assume is linear and negatively sloped. Because the monopolist is the only seller, its TR is identical to the total expenditure of all buyers in the market. Earlier, we noted what happens as price is reduced and quantity sold increases in this environment: At first, a decrease in price increases total expenditure by buyers and TR to the firm because the decrease in price is outweighed by the increase in units sold. But as price continues to fall, the decrease in price overshadows the increase in quantity, and total expenditure (revenue) falls. We can now depict the demand and TR functions for firms under conditions of perfect and imperfect competition, as shown in Exhibit 16.

Exhibit 16 Demand and Total Revenue Functions for Firms under Conditions of Perfect and Imperfect Competition

A. Perfectly Competitive Firm *B. Imperfectly Competitive Firm*

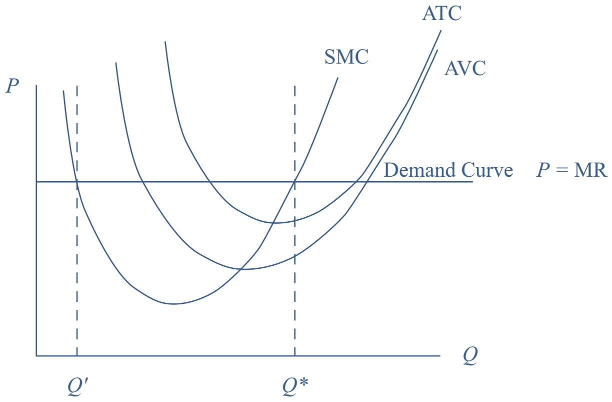


Panel A of Exhibit 16 depicts the demand curve (upper graph) and total revenue curve (lower graph) for the firm under conditions of perfect competition. Notice that the vertical axis in the upper graph is price per unit (e.g., £/bushel), whereas TR is measured on the vertical axis in the lower graph (e.g., £/week.) The same is true for the respective axes in Panel B, which depicts the demand and total revenue curves for the monopolist. The TR curve for the firm under conditions of perfect competition is linear, with a slope equal to price per unit. The TR curve for the monopolist first rises (in the range where MR is positive and demand is elastic) and then falls (in the range where MR is negative and demand is inelastic) with output.

10.1 Profit-Maximization, Breakeven, and Shutdown Points of Production

We can now combine the firm's short-run TC curves with its TR curves to represent profit maximization in the cases of perfect competition and imperfect competition. Exhibit 17 shows both the AR and average cost curves in one graph for the firm under conditions of perfect competition.

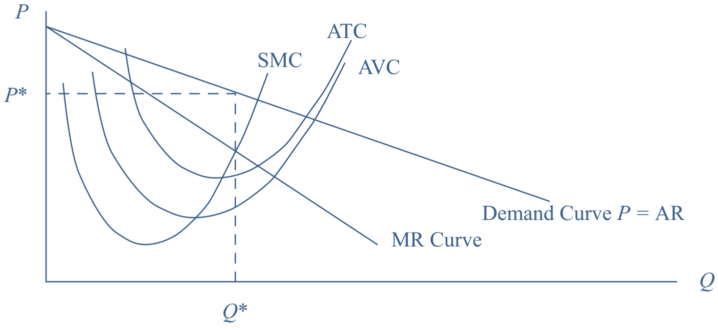
Exhibit 17 Demand and Average and Marginal Cost Curves for the Firm under Conditions of Perfect Competition



The firm is maximizing profit by producing Q^*, where price is equal to SMC and SMC is rising. (Note that there is another output level, Q', where P = SMC, but at that point, SMC is still falling, so this cannot be a profit-maximizing solution.) If market price were to rise, the firm's demand and MR curve would simply shift upward, and the firm would reach a new profit-maximizing output level to the right of Q^*. If, on the other hand, market price were to fall, the firm's demand and MR curve would shift downward, resulting in a new and lower level of profit-maximizing output. As depicted, this firm is currently earning a positive economic profit because market price exceeds ATC at output level Q^*. This profit is possible in the short run, but in the long run, competitors would enter the market to capture some of those profits and would drive the market price down to a level equal to each firm's ATC.

Exhibit 18 depicts the cost and revenue curves for the monopolist that is facing a negatively sloped market demand curve. The MR and demand curves are not identical for this firm. But the profit-maximizing rule is still the same: Find the level of Q that equates SMC to MR—in this case, Q^*. Once that level of output is determined, the optimal price to charge is given by the firm's demand curve at P^*. This monopolist is earning positive economic profit because its price exceeds its ATC. The barriers to entry that give this firm its monopolistic power mean that outside competitors would be unable to compete away this firm's profits.

Exhibit 18 Demand and Average and Marginal Cost Curves for the Monopolistic Firm



11

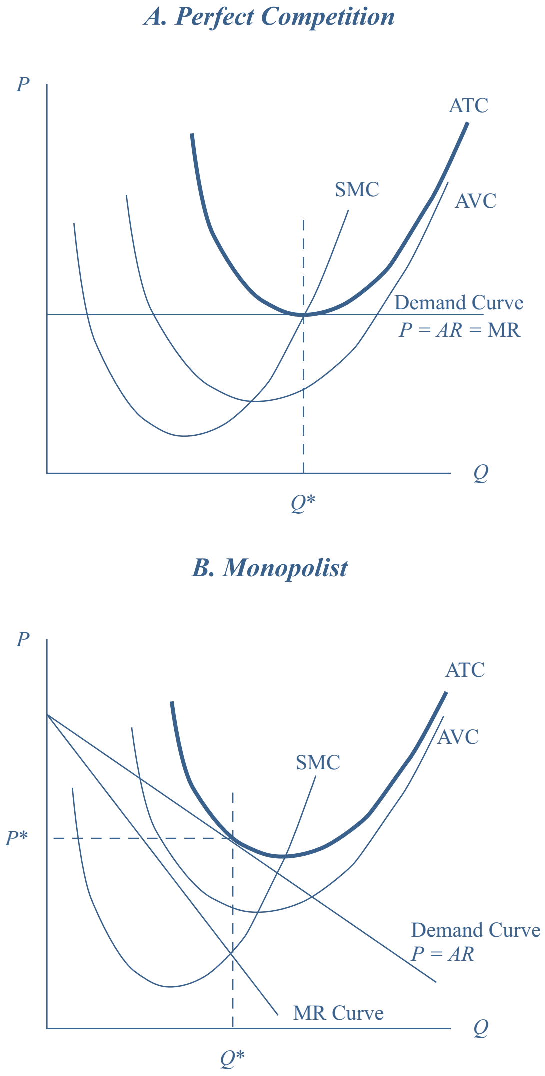
BREAKEVEN ANALYSIS AND SHUTDOWN DECISION

e determine and interpret breakeven and shutdown points of production;

A firm is said to break even if its TR is equal to its TC. It can also be said that a firm breaks even if its price (AR) is exactly equal to its ATC, which is true under conditions of perfect and imperfect competition. Of course, the goal of management is not just to break even but to maximize profit. However, perhaps the best the firm can do is cover all of its economic costs. Economic costs are the sum of total accounting costs and implicit opportunity costs. A firm whose revenue is equal to its economic costs is covering the opportunity cost of all of its factors of production, including capital. Economists would say that such a firm is earning normal profit, but not positive economic profit. It is earning a rate of return on capital just equal to the rate of return that an investor could expect to earn in an equivalently risky alternative investment (opportunity cost). Firms that are operating in a very competitive environment with no barriers to entry from other competitors can expect, in the long run, to be unable to earn a positive economic profit; the excess rate of return would attract entrants who would produce more output and ultimately drive the market price down to the level at which each firm is at best just earning a normal profit. This situation, of course, does not imply that the firm is earning zero accounting profit.

Exhibit 19 depicts the condition for both a firm under conditions of perfect competition (Panel A) and a monopolist (Panel B) in which the best each firm can do is to break even. Note that at the level of output at which SMC is equal to MR, price is just equal to ATC. Hence, economic profit is zero, and the firms are breaking even.

Exhibit 19 Examples of Firms under Perfect Competition and Monopolistic Firms That Can, at Best, Break Even



11.1 The Shutdown Decision

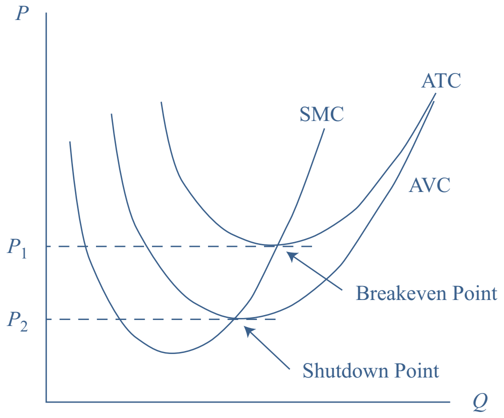
In the long run, if a firm cannot earn at least a zero economic profit, it will not operate because it is not covering the opportunity cost of all of its factors of production, labor, and capital. In the short run, however, a firm might find it advantageous to continue to operate even if it is not earning at least a zero economic profit. The discussion that follows addresses the decision to continue to operate and earn negative profit or shut down operations.

Recall that typically some or all of a firm's fixed costs are incurred regardless of whether the firm operates. The firm might have a lease on its building that it cannot avoid paying until the lease expires. In that case, the lease payment is a sunk cost: It cannot be avoided, no matter what the firm does. Sunk costs must be ignored in the decision to continue to operate in the short run. As long as the firm's revenues cover at least its variable cost, the firm is better off continuing to operate. If price is greater than AVC, the firm is not only covering all of its variable cost but also a portion of fixed cost.

For example, suppose a firm is producing 100 widgets and selling them at a price of €4 each. Obviously, its TR is €400 per time period. Suppose, also, that at that level of output, its ATC is €7, made up of AVC of €3.75 plus AFC of €3.25 per period. This firm is said to be earning negative economic profit (also referred to as **economic loss**, a condition in which revenues fall short of total opportunity cost) of €300 because its TC is €700 and its TR is only €400. Should this firm shut down immediately? If the fixed cost is unavoidable, then the firm is obligated to pay it whether it operates or not. The TFC is €325 (€3.25 per unit on 100 units). If it shuts down and earns zero revenue, then its variable cost would be zero but its losses would still equal the €325 of unavoidable fixed cost. If, however, it continued to operate, it could earn revenue of €400 that would cover its variable cost of €375 and contribute €25 toward the fixed costs. In other words, this firm would lose less by continuing to operate (€300) than by shutting down (€325).

In the long run, unless market price increases, this firm would exit the industry. But in the short run, it will continue to operate at a loss. Exhibit 20 depicts a firm under conditions of perfect competition facing three alternative market price ranges for its output. At any price above P_1, the firm can earn a positive profit and clearly should continue to operate. At a price below P_2, the minimum AVC, the firm could not even cover its variable cost and should shut down. At prices between P_2 and P_1, the firm should continue to operate in the short run because it is able to cover all of its variable cost and contribute something toward unavoidable fixed costs. Economists refer to the minimum AVC point as the **shutdown point** and the minimum ATC point as the **breakeven point**.

Exhibit 20 **A Firm under Conditions of Perfect Competition Will Choose to Shut Down If Market Price Is Less Than Minimum AVC**



EXAMPLE 5

Breakeven Analysis and Profit Maximization When the Firm Faces a Negatively Sloped Demand Curve under Imperfect Competition

Revenue and cost information for a future period is presented in Exhibit 21 for WR International, a newly formed corporation that engages in the manufacturing of low-cost, pre-fabricated dwelling units for urban housing markets in emerging economies. (Note that quantity increments are in blocks of 10 for a 250 change in price.) The firm has few competitors in a market setting of imperfect competition.

1. How many units must WR International sell to initially break even?
2. Where is the region of profitability?
3. At what point will the firm maximize profit? At what points are there economic losses?

Exhibit 21

Quantity (Q)	Price (P)	Total Revenue (TR)	Total Cost (TC)[a]	Profit
0	10,000	0	100,000	–100,000
10	9,750	97,500	170,000	–72,500
20	9,500	190,000	240,000	–50,000
30	9,250	277,500	300,000	–22,500
40	9,000	360,000	360,000	0
50	8,750	437,500	420,000	17,500
60	8,500	510,000	480,000	30,000
70	8,250	577,500	550,000	27,500
80	8,000	640,000	640,000	0
90	7,750	697,500	710,000	–12,500
100	7,500	750,000	800,000	–50,000

[a] Includes all opportunity costs

Solution to 1:

WR International will initially break even at 40 units of production, where TR and TC equal 360,000.

Solution to 2:

The region of profitability will range from greater than 40 units to less than 80 units. Any production quantity of less than 40 units and any quantity greater than 80 units will result in an economic loss.

Solution to 3:

Maximum profit of 30,000 will occur at 60 units. Lower profit will occur at any output level that is higher or lower than 60 units. From 0 units to less than 40 units and for quantities greater than 80 units, economic losses occur.

Given the relationships between TR, TVC, and TFC, Exhibit 22 summarizes the decisions to operate, shut down production, or exit the market in both the short run and the long run. The firm must cover its variable cost to remain in business in the short run; if TR cannot cover TVC, the firm shuts down production to minimize loss. The loss would be equal to the amount of fixed cost. If TVC exceeds TR in the long run, the firm will exit the market to avoid the loss associated with fixed cost at zero production. By exiting the market, the firm's investors do not suffer the erosion of their equity capital from economic losses. When TR is enough to cover TVC but not all of TFC, the firm can continue to produce in the short run but will be unable to maintain financial solvency in the long run.

Exhibit 22 Short Run and Long Run Decisions to Operate or Not

Revenue–Cost Relationship	Short-Run Decision	Long-Term Decision
TR = TC	Stay in market	Stay in market
TR = TVC but < TC	Stay in market	Exit market
TR < TVC	Shut down production	Exit market

EXAMPLE 6

Shutdown Analysis

For the most recent financial reporting period, a business domiciled in Ecuador (which recognizes the US dollar as an official currency) has revenue of $2 million and TC of $2.5 million, which are or can be broken down into TFC of $1 million and TVC of $1.5 million. The net loss on the firm's income statement is reported as $500,000 (ignoring tax implications). In prior periods, the firm had reported profits on its operations.

1 What decision should the firm make regarding operations over the short term?

2 What decision should the firm make regarding operations over the long term?

3 Assume the same business scenario except that revenue is now $1.3 million, which creates a net loss of $1.2 million. What decision should the firm make regarding operations in this case?

Solution to 1:

In the short run, the firm is able to cover all of its TVC but only half of its $1 million in TFC. If the business ceases to operate, its loss would be $1 million, the amount of TFC, whereas the net loss by operating would be minimized at $500,000. The firm should attempt to operate by negotiating special arrangements with creditors to buy time to return operations back to profitability.

Solution to 2:

If the revenue shortfall is expected to persist over time, the firm should cease operations, liquidate assets, and pay debts to the extent possible. Any residual for shareholders would decrease the longer the firm is allowed to operate unprofitably.

Solution to 3:

The firm would minimize loss at $1 million of TFC by shutting down. If the firm decided to continue to do business, the loss would increase to $1.2 million. Shareholders would save $200,000 in equity value by pursuing this option. Unquestionably, the business would have a rather short life expectancy if this loss situation were to continue.

When evaluating profitability, particularly of start-up firms and businesses using turnaround strategies, analysts should consider highlighting breakeven and shutdown points in their financial research. Identifying the unit sales levels at which the firm enters or leaves the production range for profitability and at which the firm can no longer function as a viable business entity provides invaluable insight for investment decisions.

ECONOMIES AND DISECONOMIES OF SCALE WITH SHORT-RUN AND LONG-RUN COST ANALYSIS

12

f describe how economies of scale and diseconomies of scale affect costs.

Rational behavior dictates that the firm select an operating size or scale that maximizes profit over any time frame. The time frame that defines the short run and long run for any firm is based on the ability of the firm to adjust the quantities of the fixed resources it uses. The short run is the time period during which at least one of the factors of production, such as technology, physical capital, and plant size, is fixed. The long run is defined as the time period during which all factors of production are variable. Additionally, in the long run, firms can enter or exit the market based on decisions regarding profitability. The long run is often referred to as the "planning horizon" in which the firm can choose the short-run position or optimal operating size that maximizes profit over time. The firm is always operating in the short run but planning in the long run.

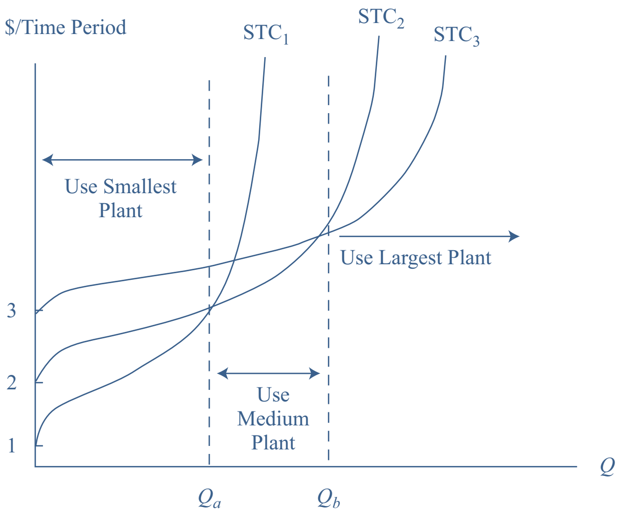
The time required for long-run adjustments varies by industry. For example, the long run for a small business using very little technology and physical capital may be less than a year, whereas for a capital-intensive firm, the long run may be more than a decade. Given enough time, however, all production factors are variable, which allows the firm to choose an operating size or plant capacity based on different technologies and physical capital. In this regard, costs and profits will differ between the short run and the long run.

12.1 Short- and Long-Run Cost Curves

Recall that when we addressed the short-run cost curves of the firm, we assumed that the capital input was held constant. That meant that the only way to vary output in the short run is to change the level of the variable input—in our case, labor. If the capital input—namely, plant and equipment—were to change, however, we would have an entirely new set of short-run cost curves, one for each level of capital input.

The short-run total cost includes all the inputs—labor and capital—the firm is using to produce output. For reasons discussed earlier, the typical short-run total cost (STC) curve might rise with output, first at a decreasing rate because of specialization economies and then at an increasing rate, reflecting the law of diminishing marginal returns to labor. Total fixed cost (the quantity of capital input multiplied by the rental rate on capital) determines the vertical intercept of the STC curve. At higher levels of fixed input, TFC is greater but the production capacity of the firm is also greater. Exhibit 23 shows three different STC curves for the same technology but using three distinct levels of capital input—Points 1, 2, and 3 on the vertical axis.

Exhibit 23 Short-Run Total Cost Curves for Various Plant Sizes



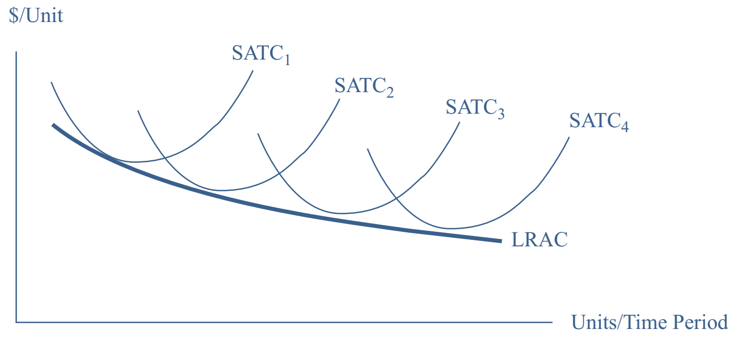
Plant Size 1 is the smallest and, of course, has the lowest fixed cost; hence, its STC_1 curve has the lowest vertical intercept. But note that STC_1 begins to rise more steeply with output, reflecting the lower plant capacity. Plant Size 3 is the largest of the three and reflects that size with both a higher fixed cost and a lower slope at any level of output. If a firm decided to produce an output between zero and Q_a, it would plan on building Plant Size 1 because for any output level in that range, its cost is less than it would be for Plant Size 2 or 3. Accordingly, if the firm were planning to produce output greater than Q_b, it would choose Plant Size 3 because its cost for any of those levels of output would be lower than for Plant Size 1 or 2. And of course, Plant Size 2 would be chosen for output levels between Q_a and Q_b. The long-run total cost curve is derived from the lowest level of STC for each level of output because in the long run, the firm is free to choose which plant size it will operate. This curve is called an "envelope curve." In essence, this curve envelopes—encompasses—all possible combinations of technology, plant size, and physical capital.

For each STC curve, there is also a corresponding **short-run average total cost** (SATC) curve and a corresponding **long-run average total cost** (LRAC) curve, the envelope curve of all possible short-run average total cost curves. The shape of the LRAC curve reflects an important concept called **economies of scale** and **diseconomies of scale**.

12.2 Defining Economies of Scale and Diseconomies of Scale

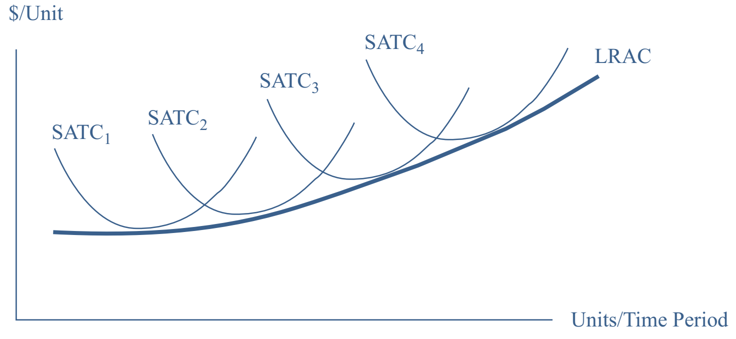
When a firm increases all of its inputs in order to increase its level of output (obviously, a long-run concept), it is said to *scale up* its production. *Scaling down* is the reverse—decreasing all of its inputs in order to produce less in the long run. Economies of scale occur if, as the firm increases its output, cost per unit of production falls. Graphically, this definition translates into a LRAC curve with a negative slope. Exhibit 24 depicts several SATC curves, one for each plant size, and the LRAC curve representing economies of scale.

Exhibit 24 Short-run Average Total Cost Curves for Various Plant Sizes and Their Envelope Curve, LRAC: Economies of Scale



Diseconomies of scale occur if cost per unit rises as output increases. Graphically, diseconomies of scale translate into an LRAC curve with a positive slope. Exhibit 25 depicts several SATC curves, one for each plant size, and their envelope curve, the LRAC curve, representing diseconomies of scale.

Exhibit 25 Short-run Average Total Cost Curves for Various Plant Sizes and Their Envelope Curve, LRAC: Diseconomies of Scale



As the firm grows in size, economies of scale and a lower ATC can result from the following factors:

- **Increasing returns to scale**, which is when a production process allows for increases in output that are proportionately larger than the increase in inputs.
- Having a division of labor and management in a large firm with numerous workers, which allows each worker to specialize in one task rather than perform many duties, as in the case of a small business (as such, workers in a large firm become more proficient at their jobs).
- Being able to afford more expensive, yet more efficient equipment and to adapt the latest in technology that increases productivity.
- Effectively reducing waste and lowering costs through marketable byproducts, less energy consumption, and enhanced quality control.
- Making better use of market information and knowledge for more effective managerial decision making.
- Obtaining discounted prices on resources when buying in larger quantities.

A classic example of a business that realizes economies of scale through greater physical capital investment is an electric utility. By expanding output capacity to accommodate a larger customer base, the utility company's per-unit cost will decline. Economies of scale help explain why electric utilities have naturally evolved from localized entities to regional and multi-region enterprises. Wal-Mart is an example of a business that uses bulk purchasing power to obtain deep discounts from suppliers to keep costs and prices low. Wal-Mart also uses the latest technology to monitor point-of-sale transactions to gather timely market information to respond to changes in customer buying behavior, which leads to economies of scale through lower distribution and inventory costs.

The factors that can lead to diseconomies of scale, inefficiencies, and rising costs when a firm increases in size include the following:

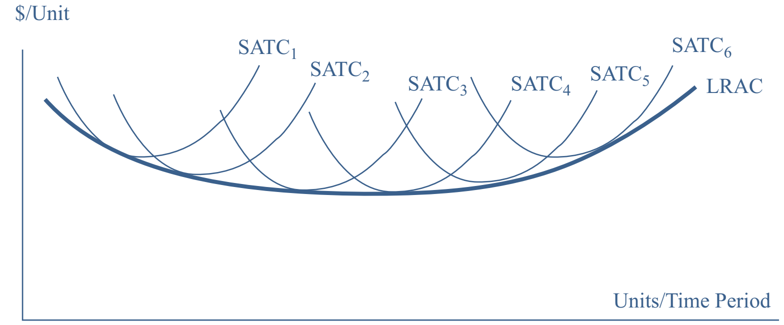
- **Decreasing returns to scale**, which is when a production process leads to increases in output that are proportionately smaller than the increase in inputs.
- Being so large that it cannot be properly managed.
- Overlapping and duplication of business functions and product lines.
- Higher resource prices because of supply constraints when buying inputs in large quantities.

Before its restructuring, General Motors (GM) was an example of a business that had realized diseconomies of scale by becoming too large. Scale diseconomies occurred through product overlap and duplication (i.e., similar or identical automobile models), and the fixed cost for these models was not spread over a large volume of output. In 2009, GM decided to discontinue three brands (Saturn, Pontiac, and Hummer), and in 2018 it was considering dropping various low-volume product models that overlapped with other models by 2020. GM had numerous manufacturing plants throughout the world and sold vehicles in more than a hundred countries. Given this geographical dispersion in production and sales, the company had communication and management coordination problems, which resulted in higher costs. In 2017, GM sold its European arm, Opel, to Groupe PSA, the maker of Peugeot and Citroën. GM also had significantly higher labor costs than its competitors. As the largest producer in the market, it had been a target of labor unions for higher compensation and benefits packages relative to other firms.

Economies and diseconomies of scale can occur at the same time; the impact on long-run average total cost (LRAC) depends on which dominates. If economies of scale dominate, LRAC decreases with increases in output. The reverse holds true when diseconomies of scale prevail. There may be a range of output over which LRAC falls (economies of scale) and then a range over which LRAC might be constant, followed by a range over which diseconomies of scale prevail, as depicted in Exhibit 26.

The minimum point on the LRAC curve is referred to as the **minimum efficient scale**. The minimum efficient scale is the optimal firm size under perfect competition over the long run. Theoretically, perfect competition forces the firm to operate at the minimum point on the LRAC curve because the market price will be established at this level over the long run. If the firm is not operating at this least-cost point, its long-term viability will be threatened.

Exhibit 26 LRAC Can Exhibit Economies and Diseconomies of Scale



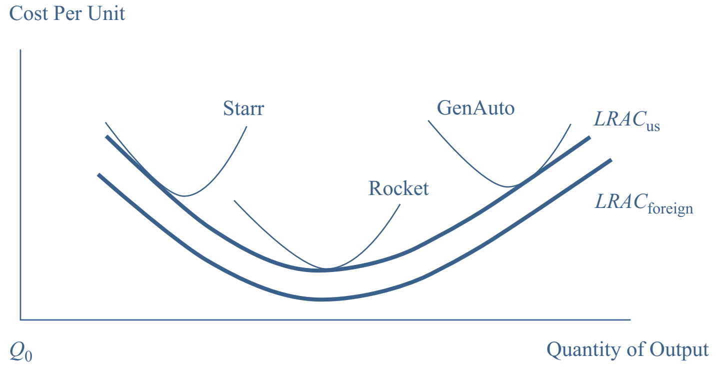
EXAMPLE 7

Long-Run Average Total Cost Curve

Exhibit 27 displays the long-run average total cost curve (LRAC$_{US}$) and the short-run average total cost curves for three hypothetical US-based automobile manufacturers—Starr Vehicles (Starr), Rocket Sports Cars (Rocket), and General Auto (GenAuto). The LRAC curve for foreign-owned automobile companies that compete in the US auto market (LRAC$_{foreign}$) is also indicated in the graph. (The market structure implicit in the exhibit is imperfect competition.)

To what extent are the cost relationships depicted in Exhibit 27 useful for an economic and financial analysis of the three US-based auto firms?

Exhibit 27



Solution:

First, it is observable that the foreign auto companies have a lower LRAC compared with that of the US automobile manufacturers. This competitive position places the US firms at a cost—and possibly, pricing—disadvantage in the market, with the potential to lose market share to the lower-cost foreign competitors. Second, only Rocket operates at the minimum point of the LRAC$_{US}$, whereas GenAuto is situated in the region of diseconomies of scale and Starr is positioned in the economies of scale portion of the curve. To become more efficient and competitive, GenAuto needs to downsize and restructure, which means moving down the LRAC_{US} curve to a smaller, yet lower-cost production volume. In Contrast, Starr has to grow in size to become more efficient and competitive by lowering per-unit costs.

From a long-term investment prospective and given its cost advantage, Rocket has the potential to create more investment value relative to GenAuto and Starr. Over the long run, if GenAuto and Starr can lower their ATC, they will become more attractive to investors. But if any of the three US auto companies cannot match the cost competitiveness of the foreign firms, they may be driven from the market. In the long run, the lower-cost foreign automakers pose a severe competitive challenge to the survival of the US manufacturers and their ability to maintain and grow shareholders' wealth.

SUMMARY

This reading addressed several important concepts that extend the basic market model of demand and supply to assist the analyst in assessing a firm's breakeven and shutdown points of production. Demand concepts covered include own-price elasticity of demand, cross-price elasticity of demand, and income elasticity of demand. Supply concepts covered include total, average, and marginal product of labor; total, variable, and marginal cost of labor; and total and marginal revenue. These concepts are used to calculate the breakeven and shutdown points of production.

- Elasticity of demand is a measure of how sensitive quantity demanded is to changes in various variables.
- Own-price elasticity of demand is the ratio of percentage change in quantity demanded to percentage change in a good or service's own price.
- If own-price elasticity of demand is greater than one in absolute terms, demand is elastic and a decline in price will result in higher total expenditure on that good.
- If own-price elasticity of demand is less than one in absolute terms, demand is inelastic and a decline in price will result in a lower total expenditure on that good.
- If own-price elasticity of demand is equal to negative one, demand is unit, or unitary, elastic and total expenditure on that good is independent of price.
- Own-price elasticity of demand will almost always be negative.
- Income elasticity of demand is the ratio of the percentage change in quantity demanded to the percentage change in consumer income.
- Demand is negatively sloped because of either the substitution effect or the income effect.
- The substitution effect is the phenomenon in which, as a good's price falls, more of this good is substituted for other, more expensive goods.
- The income effect is the phenomenon in which, as a good's price falls, real income rises and, if this good is normal, more of it will be purchased.
- If the good is inferior, the income effect will partially or fully offset the substitution effect.
- There are two exceptions to the law of demand: Giffen goods and Veblen goods.

- Giffen goods are highly inferior and make up a large portion of the consumer budget. As price falls, the substitution effect tends to cause more of the good to be consumed, but the highly negative income effect overwhelms the substitution effect. Demand curves for Giffen goods are positively sloped.
- Veblen goods are highly valued high-priced "status" goods; consumers may tend to buy more of a good if its price rises.
- If income elasticity of demand is positive, the good is a normal good. If income elasticity of demand is negative, the good is an inferior good.
- Cross-price elasticity of demand is the ratio of the percentage change in quantity demanded of one good to the percentage change in the price of a related good.
- If cross-price elasticity between two goods is positive, they are substitutes, and if cross-price elasticity between two goods is negative, they are complements.
- The law of demand states that a decrease in price will cause an increase in quantity demanded.
- Total product of labor is a short-run concept that is the total quantity that is able to be produced for each level of labor input, holding all other inputs constant.
- Average product of labor (APL) is the total product of labor divided by number of labor hours.
- Marginal product of labor (MP_L) is the change in total product divided by the change in labor hours. MP_L might rise as more labor is added to a fixed amount of capital.
- The law of diminishing returns dictates that additional output must fall as more and more labor is added to a fixed amount of capital.
- Production costs increase as input prices rise and fall as inputs become more productive.
- Short-run total cost (STC) is the total expenditure on fixed capital plus the total expenditure on labor.
- Short-run marginal cost (SMC) equals the ratio of wage to marginal product of labor (MP_L).
- Average variable cost (AVC) is the ratio of wage to average product of labor (APL).
- Average total cost (ATC) is total cost (TC) divided by the number of units produced.
- Revenue is price times quantity sold.
- Marginal revenue (MR) is the ratio of change in revenue to change in output.
- Firms under conditions of perfect competition have no pricing power and, therefore, face a perfectly horizontal demand curve at the market price. For firms under conditions of perfect competition, price is identical to marginal revenue (MR).
- Firms under conditions of imperfect competition face a negatively sloped demand curve and have pricing power. For firms under conditions of imperfect competition, marginal revenue (MR) is less than price.
- Economic profit equals total revenue (TR) minus total economic cost, whereas accounting profit equals TR minus total accounting cost.
- Economic cost takes into account the total opportunity cost of all factors of production.
- Opportunity cost is the next best alternative forgone in making a decision.

- Maximum economic profit requires that (1) marginal revenue (MR) equals marginal cost (MC) and (2) MC not be falling with output.
- The breakeven point occurs when total revenue (TR) equals total cost (TC), otherwise stated as the output quantity at which average total cost (ATC) equals price.
- Shutdown occurs when a firm is better off not operating than continuing to operate.
- If all fixed costs are sunk costs, then shutdown occurs when the market price falls below minimum average variable cost. After shutdown, the firm incurs only fixed costs and loses less money than it would operating at a price that does not cover variable costs.
- In the short run, it may be rational for a firm to continue to operate while earning negative economic profit if some unavoidable fixed costs are covered.
- Economies of scale is defined as decreasing long-run cost per unit as output increases. Diseconomies of scale is defined as increasing long-run cost per unit as output increases.
- Long-run average total cost is the cost of production per unit of output under conditions in which all inputs are variable.
- Specialization efficiencies and bargaining power in input price can lead to economies of scale.
- Bureaucratic and communication breakdowns and bottlenecks that raise input prices can lead to diseconomies of scale.
- The minimum point on the long-run average total cost curve defines the minimum efficient scale for the firm.

PRACTICE PROBLEMS

1 If the price elasticity coefficient of the demand curve for paper clips is equal to −1, demand is:

A elastic.

B inelastic.

C unit elastic.

2 The demand for membership at a local health club is determined by the following equation:

$$Q_{hm}^{d} = 400 - 5P_{hm}$$

where Q_{hm}^{d} is the number of health club members and P_{hm} is the price of membership. If the price of health club membership is $35, the price elasticity of demand is *closest* to:

A −0.778.

B −0.500.

C −0.438.

3 Price elasticity of demand for a good will *most likely* be greater if:

A there are no substitutes for the good.

B consumers consider the good as discretionary.

C consumers spend a small portion of their budget on the good.

4 If the income elasticity of demand for a product is −0.6, a:

A 1% increase in income will result in a 0.6% increase in demand.

B 1% increase in income will result in a 0.6% decrease in demand.

C 0.6% increase in income will result in a 1% decrease in demand.

5 An individual's demand for onions is given by the following equation:

$$Q_{o}^{d} = 3 - 0.05P_{o} + 0.009I - 0.16P_{t}$$

where Q_{o}^{d} is the number of onions demanded, P_{o} is the price per pound of onions, I is the household income, and P_{t} is the price per pound of tomatoes. If the price of onions is $1.25, household income is $2,500, and the price of tomatoes is $3.75, the cross-price elasticity of demand for onions with respect to the price of tomatoes is *closest* to:

A −1.0597.

B −0.0242.

C −0.0081.

6 Movement along the demand curve for good X occurs due to a change in:

A income.

B the price of good X.

C the price of a substitute for good X.

© 2017 CFA Institute. All rights reserved.

7 A wireless phone manufacturer introduced a next-generation phone that received a high level of positive publicity. Despite running several high-speed production assembly lines, the manufacturer is still falling short in meeting demand for the phone nine months after introduction. Which of the following statements is the *most* plausible explanation for the demand/supply imbalance?

A The phone price is low relative to the equilibrium price.

B Competitors introduced next-generation phones at a similar price.

C Consumer incomes grew faster than the manufacturer anticipated.

The following information relates to Questions 8–11

The market demand function for four-year private universities is given by the equation

$$Q_{pr}^{d} = 84 - 3.1P_{pr} + 0.8I + 0.9P_{pu}$$

where Q_{pr}^{d} is the number of applicants to private universities per year in thousands, P_{pr} is the average price of private universities (in thousands of USD), I is the household monthly income (in thousands of USD), and P_{pu} is the average price of public (government-supported) universities (in thousands of USD). Assume that P_{pr} is equal to 38, I is equal to 100, and P_{pu} is equal to 18.

8 The price elasticity of demand for private universities is *closest* to:

A –3.1.

B –1.9.

C 0.6.

9 The income elasticity of demand for private universities is *closest* to:

A 0.5.

B 0.8.

C 1.3.

10 The cross-price elasticity of demand for private universities with respect to the price of public universities is *closest* to:

A 0.3.

B 3.1.

C 3.9.

11 If the cross-price elasticity between two goods is negative, the two goods are classified as:

A normal.

B substitutes.

C complements.

---

12 In the case of a normal good with a decrease in own price, which of the following statements is *most likely* true?

A Both the substitution and income effects lead to an increase in the quantity purchased.

B The substitution effect leads to an increase in the quantity purchased, while the income effect has no impact.

C The substitution effect leads to an increase in the quantity purchased, while the income effect leads to a decrease.

13 For a Giffen good, the:

A demand curve is positively sloped.

B substitution effect overwhelms the income effect.

C income and substitution effects are in the same direction.

14 Normal profit is best described as:

A zero economic profit.

B total revenue minus all explicit costs.

C the sum of accounting profit plus economic profit.

15 A company plans to hire additional factory employees. In the short run, marginal returns are most likely to decrease if:

A the factory is operating at full capacity.

B the factory is experiencing a labor shortage.

C workers are required to multitask and share duties.

16 The production relationship between the number of machine hours and total product for a company is presented below.

Machine Hours	Total Product	Average Product
1	3	3.00
2	8	4.00
3	14	4.67
4	19	4.75
5	21	4.20

Diminishing marginal returns first occur beyond machine hour:

A 3.

B 4.

C 5.

17 The marketing director for a Swiss specialty equipment manufacturer estimates the firm can sell 200 units and earn total revenue of CHF500,000. However, if 250 units are sold, revenue will total CHF600,000. The marginal revenue per unit associated with marketing 250 units instead of 200 units is *closest* to:

A CHF 2,000.

B CHF 2,400.

C CHF 2,500.

18 An agricultural firm operating in a perfectly competitive market supplies wheat to manufacturers of consumer food products and animal feeds. If the firm were able to expand its production and unit sales by 10% the *most likely* result would be:

A a 10% increase in total revenue.

B a 10% increase in average revenue.

C an increase in total revenue of less than 10%.

19 An operator of a ski resort is considering offering price reductions on weekday ski passes. At the normal price of €50 per day, 300 customers are expected to buy passes each weekday. At a discounted price of €40 per day 450 customers are expected to buy passes each weekday. The marginal revenue per customer earned from offering the discounted price is *closest* to:

A €20.

B €40.

C €50.

20 The marginal revenue per unit sold for a firm doing business under conditions of perfect competition will *most likely* be:

A equal to average revenue.

B less than average revenue.

C greater than average revenue.

The following information relates to Questions 21–23

A firm's director of operations gathers the following information about the firm's cost structure at different levels of output:

Exhibit 1

Quantity (*Q*)	Total Fixed Cost (*TFC*)	Total Variable Cost (*TVC*)
0	200	0
1	200	100
2	200	150
3	200	200
4	200	240
5	200	320

21 Refer to the data in Exhibit 1. When quantity produced is equal to 4 units, the average fixed cost (*AFC*) is *closest* to:

A 50.

B 60.

C 110.

22 Refer to the data in Exhibit 1. When the firm increases production from 4 to 5 units, the marginal cost (*MC*) is *closest* to:

A 40.

B 64.

C 80.

23 Refer to the data in Exhibit 1. The level of unit production resulting in the lowest average total cost (*ATC*) is *closest* to:

A 3.

B 4.

C 5.

---

24 The short-term breakeven point of production for a firm operating under perfect competition will *most likely* occur when:

A price is equal to average total cost.

B marginal revenue is equal to marginal cost.

C marginal revenue is equal to average variable costs.

25 The short-term shutdown point of production for a firm operating under perfect competition will *most likely* occur when:

A price is equal to average total cost.

B marginal revenue is equal to marginal cost.

C marginal revenue is equal to average variable costs.

26 Under conditions of perfect competition, a company will break even when market price is equal to the minimum point of the:

A average total cost curve.

B average variable cost curve.

C short-run marginal cost curve.

27 A company will shut down production in the short run if total revenue is less than total:

A fixed costs.

B variable costs.

C opportunity costs.

28 A company has total variable costs of $4 million and fixed costs of $3 million. Based on this information, the company will stay in the market in the long term if total revenue is at least:

A $3.0 million.

B $4.5 million.

C $7.0 million.

29 When total revenue is greater than total variable costs but less than total costs, in the short term a firm will *most likely*:

A exit the market.

B stay in the market.

C shut down production.

30 A profit maximum is *least likely* to occur when:

A average total cost is minimized.

B marginal revenue equals marginal cost.

C the difference between total revenue and total cost is maximized.

31 A firm that increases its quantity produced without any change in per-unit cost is experiencing:

A economies of scale.

B diseconomies of scale.

C constant returns to scale.

32 A company is experiencing economies of scale when:

- **A** cost per unit increases as output increases.
- **B** it is operating at a point on the LRAC curve where the slope is negative.
- **C** It is operating beyond the minimum point on the long-run average total cost curve.

33 Diseconomies of scale *most likely* result from:

- **A** specialization in the labor force.
- **B** overlap of business functions and product lines.
- **C** discounted prices on resources when buying in larger quantities.

34 A firm is operating beyond minimum efficient scale in a perfectly competitive industry. To maintain long-term viability the *most likely* course of action for the firm is to:

- **A** operate at the current level of production.
- **B** increase its level of production to gain economies of scale.
- **C** decrease its level of production to the minimum point on the long-run average total cost curve.

35 Under conditions of perfect competition, in the long run firms will *most likely* earn:

- **A** normal profits.
- **B** positive economic profits.
- **C** negative economic profits.

The following information relates to Questions 36 and 37

The manager of a small manufacturing firm gathers the following information about the firm's labor utilization and production:

Exhibit 2

Labor (*L*)	Total Product (*TP*)
0	0
1	150
2	320
3	510
4	660
5	800

36 Refer to the data in Exhibit 2. The number of workers resulting in the highest level of average product of labor is *closest* to:

- **A** 3.
- **B** 4.
- **C** 5.

37 Refer to the data in Exhibit 2. The marginal product of labor demonstrates increasing returns for the firm if the number of workers is *closest* to but not more than:

A 2.

B 3.

C 4.

SOLUTIONS

1. C is correct. When the price elasticity of demand coefficient is –1, demand is said to be unit elastic, or unitary elastic.
2. A is correct. Inserting the price of \$35 into the demand function, quantity demanded is calculated as

   $$Q_{hm}^{d} = 400 - 5(35) = 225$$

   At a price of \$35 per health club membership, the elasticity of demand is

   $$\text{Price elasticity of demand} = \left(\Delta Q_{hm}^{d} / \Delta P_{hm}\right) \times \left(P_{hm} / Q_{hm}^{d}\right)$$

   $$\text{Price elasticity of demand} = -5 \times (35/225) = -0.778$$

3. B is correct. Price elasticity of demand is likely to be greater for items that are seen as optional or discretionary.
4. B is correct. Income elasticity is a measure of how sensitive quantity demanded is to a change in income. If the income elasticity of demand for the product is –0.6, whenever income increases by 1%, the quantity demanded of the product at each price decreases by 0.6%. Consequently, as income rises, consumers will purchase less of the product.
5. B is correct. The cross-price elasticity of demand measures the responsiveness of the demand for onions in response to a change in the price of tomatoes. From the demand function equation:

   $$Q_{o}^{d} = 3 - 0.05P_{o} + 0.009I - 0.16P_{t}$$

   $$Q_{o}^{d} = 3 - 0.05(1.25) + 0.009(2{,}500) - 0.16(3.75) = 24.8375$$

   At a price of onions of \$1.25 and a price of tomatoes of \$3.75, the cross-price elasticity of demand is calculated as follows:

   $$\text{Cross-price elasticity of demand} = \left(\Delta Q_{o}^{d} / \Delta P_{t}\right) \times \left(P_{t} / Q_{o}^{d}\right)$$

   $$\text{Cross-price elasticity of demand} = -0.16 \times (3.75/24.8375) = -0.0242$$

6. B is correct. The demand curve shows quantity demanded as a function of own price only.
7. A is correct. The situation described is one of excess demand because, in order for markets to clear at the given level of quantity supplied, the company would need to raise prices.
8. B is correct. From the demand function:

   Solve for Q_{pr}^{d}:

   $$\Delta Q_{pr}^{d} / \Delta P_{pr} = -3.1 \text{ (the coefficient in front of own price)}$$

   $$\begin{aligned} Q_{pr}^{d} &= 84 - 3.1P_{pr} + 0.8I + 0.9P_{pu} \\ &= 84 - 3.1(38) + 0.8(100) + 0.9(18) \\ &= 62.4 \end{aligned}$$

At $P_{pr} = 38$,

$$\text{price elasticity of demand} = \left(\Delta Q^d_{pr} / \Delta P_{pr}\right)\left(P_{pr} / Q^d_{pr}\right)$$
$$= (-3.1)(38/62.4)$$
$$= -1.9$$

9 C is correct. From the demand function:

Solve for Q^d_{pr}:

$$\Delta Q^d_{pr} / \Delta I = 0.8 \text{ (coefficient in front of the income variable)}$$

$$Q^d_{pr} = 84 - 3.1P_{pr} + 0.8I + 0.9P_{pu}$$
$$= 84 - 3.1(38) + 0.8(100) + 0.9(18)$$
$$= 62.4$$

At $I = 100$,

$$\text{the income elasticity of demand} = \left(\Delta Q^d_{pr} / \Delta I\right)\left(I / Q^d_{pr}\right)$$
$$= (0.8)(100/62.4)$$
$$= 1.3$$

10 A is correct. From the demand function:

Solve for Q^d_{pr}:

$$\Delta Q^d_{pr} / \Delta P_{pu} = 0.9 \text{ (the coefficient in front of } P_{pu}\text{)}$$

$$Q^d_{pr} = 84 - 3.1P_{pr} + 0.8I + 0.9P_{pu}$$
$$= 84 - 3.1(38) + 0.8(100) + 0.9(18)$$
$$= 62.4$$

At $P = 38$, and $P_{pu} = 18$,

$$\text{the cross-price elasticity of demand} = \left(\Delta Q^d_{pr} / \Delta P_{pu}\right)\left(P_{pu} / Q^d_{pr}\right)$$
$$= (0.9)(18/62.4)$$
$$= 0.3$$

11 C is correct. With complements, consumption goes up or down together. With a negative cross-price elasticity, as the price of one good goes up, the demand for both falls.

12 A is correct. In the case of normal goods, the income and substitution effects are reinforcing, leading to an increase in the amount purchased after a drop in price.

13 A is correct. The income effect overwhelms the substitution effect such that an increase in the price of the good results in greater demand for the good, resulting in a positively sloped demand curve.

14 A is correct. Normal profit is the level of accounting profit such that implicit opportunity costs are just covered; thus, it is equal to a level of accounting profit such that economic profit is zero.

15 A is correct. The law of diminishing returns occurs in the short run when additional output falls as more and more labor is added to a fixed amount of capital. When a factory is operating at full capacity, adding additional employees will not increase production because the physical plant is already 100% employed. More labor hours will add to costs without adding to output, thus resulting in diminishing marginal returns.

16 A is correct. Diminishing marginal returns occur when the marginal product of a resource decreases as additional units of that input are employed. Marginal product, which is the additional output resulting from using one more unit of input, is presented below.

Machine Hours	Total Product	Average Product	Marginal Product
1	3	3.00	3
2	8	4.00	5
3	14	4.67	6
4	19	4.75	5
5	21	4.20	2

The marginal product of the third machine hour is 6 and declines thereafter. Consequently, diminishing marginal returns are first evident beyond three machine hours.

17 A is correct. Marginal revenue per unit is defined as the change in total revenue divided by the change in quantity sold. MR = ΔTR ÷ ΔQ. In this case, change in total revenue equals CHF100,000, and change in total units sold equals 50. CHF100,000 ÷ 50 = CHF2,000.

18 A is correct. In a perfectly competitive market, an increase in supply by a single firm will not affect price. Therefore, an increase in units sold by the firm will be matched proportionately by an increase in revenue.

19 A is correct. Marginal revenue per unit is defined as the change in total revenues divided by the change in quantity sold. MR = ΔTR ÷ ΔQ. In this case, change in total revenue per day equals €3,000 [(450 × €40) – (300 × €50)], and change in units sold equals 150 (450 – 300). €3,000 ÷ 150 = €20.

20 A is correct. Under perfect competition, a firm is a price taker at any quantity supplied to the market, and AR = MR = Price.

21 A is correct. Average fixed cost is equal to total fixed cost divided by quantity produced: AFC = TFC/Q = 200/4 = 50.

22 C is correct. Marginal cost is equal to the change in total cost divided by the change in quantity produced. MC = ΔTC/ΔQ = 80/1 = 80.

23 C is correct. Average total cost is equal to total cost divided by quantity produced. At 5 units produced the average total cost is 104. ATC = TC/Q = 520/5 = 104.

24 A is correct. Under perfect competition, price equals marginal revenue. A firm breaks even when marginal revenue equals average total cost.

25 C is correct. The firm should shut down production when marginal revenue is less than or equal to average variable cost.

26 A is correct. A company is said to break even if its total revenue is equal to its total cost. Under conditions of perfect competition, a company will break even when market price is equal to the minimum point of the average total cost curve.

27 B is correct. A company will shut down production in the short run when total revenue is below total variable costs.

28 C is correct. A company will stay in the market in the long term if total revenue is equal to or greater than total cost. Because total costs are \$7 million (\$4 million variable costs and \$3 million fixed costs), the company will stay in the market in the long term if total revenue equals at least \$7 million.

29 B is correct. When total revenue is enough to cover variable costs but not total fixed costs in full, the firm can survive in the short run but would be unable to maintain financial solvency in the long run.

30 A is correct. The quantity at which average total cost is minimized does not necessarily correspond to a profit maximum.

31 C is correct. Output increases in the same proportion as input increases occur at constant returns to scale.

32 B is correct. Economies of scale occur if, as the firm increases output, cost per unit of production falls. Graphically, this definition translates into a long-run average cost curve (LRAC) with a negative slope.

33 B is correct. As the firm increases output, diseconomies of scale and higher average total costs can result when there is overlap and duplication of business functions and product lines.

34 C is correct. The firm operating at greater than long-run efficient scale is subject to diseconomies of scale. It should plan to decrease its level of production.

35 A is correct. Competition should drive prices down to long-run marginal cost, resulting in only normal profits being earned.

36 A is correct. Three workers produce the highest average product equal to 170. AP = 510/3 = 170.

37 B is correct. Marginal product is equal to the change in total product divided by the change in labor. The increase in MP from 2 to 3 workers is 190: $\text{MP} = \Delta\text{TP}/\Delta L = (510 - 320)/(3 - 2) = 190/1 = 190$.

The Firm and Market Structures

by Richard Fritz, PhD, and Michele Gambera, PhD, CFA

Richard Fritz, PhD, is at the School of Economics at Georgia Institute of Technology (USA). Michele Gambera, PhD, CFA, is at UBS Asset Management and the University of Illinois at Urbana-Champaign (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;
☐	**b.** explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;
☐	**c.** describe a firm's supply function under each market structure;
☐	**d.** describe and determine the optimal price and output for firms under each market structure;
☐	**e.** explain factors affecting long-run equilibrium under each market structure;
☐	**f.** describe pricing strategy under each market structure;
☐	**g.** describe the use and limitations of concentration measures in identifying market structure;
☐	**h.** identify the type of market structure within which a firm operates.

1

INTRODUCTION & ANALYSIS OF MARKET STRUCTURES

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

The purpose of this reading is to build an understanding of the importance of market structure. As different market structures result in different sets of choices facing a firm's decision makers, an understanding of market structure is a powerful tool in

© 2019 CFA Institute. All rights reserved.

analyzing issues such as a firm's pricing of its products and, more broadly, its potential to increase profitability. In the long run, a firm's profitability will be determined by the forces associated with the market structure within which it operates. In a highly competitive market, long-run profits will be driven down by the forces of competition. In less competitive markets, large profits are possible even in the long run; in the short run, any outcome is possible. Therefore, understanding the forces behind the market structure will aid the financial analyst in determining firms' short- and long-term prospects.

Section 1.1 introduces the analysis of market structures. The section addresses questions such as: What determines the degree of competition associated with each market structure? Given the degree of competition associated with each market structure, what decisions are left to the management team developing corporate strategy? How does a chosen pricing and output strategy evolve into specific decisions that affect the profitability of the firm? The answers to these questions are related to the forces of the market structure within which the firm operates.

Sections 2–16 analyze demand, supply, optimal price and output, and factors affecting long-run equilibrium for perfect competition, monopolistic competition, oligopoly, and pure monopoly, respectively.

Section 17 reviews techniques for identifying the various forms of market structure. For example, there are accepted measures of market concentration that are used by regulators of financial institutions to judge whether or not a planned merger or acquisition will harm the competitive nature of regional banking markets. Financial analysts should be able to identify the type of market structure a firm is operating within. Each different structure implies a different long-run sustainability of profits. A summary and practice problems conclude the reading.

1.1 Analysis of Market Structures

Traditionally, economists classify a market into one of four structures: perfect competition, monopolistic competition, oligopoly, and monopoly. Section 1.1.1 explains that four-way classification in more detail. Section 1.1.2 completes the introduction by providing and explaining the major points to evaluate in determining the structure to which a market belongs.

1.1.1 *Economists' Four Types of Structure*

Economists define a market as a group of buyers and sellers that are aware of each other and can agree on a price for the exchange of goods and services. While the internet has extended a number of markets worldwide, certain markets are limited by geographic boundaries. For example, the internet search engine Google operates in a worldwide market. In contrast, the market for premixed cement is limited to the area within which a truck can deliver the mushy mix from the plant to a construction site before the compound becomes useless. Thomas L. Friedman's international best seller *The World Is Flat*[1] challenges the concept of the geographic limitations of the market. If the service being provided by the seller can be digitized, its market expands worldwide. For example, a technician can scan your injury in a clinic in Switzerland. That radiographic image can be digitized and sent to a radiologist in India to be read. As a customer (i.e., patient), you may never know that part of the medical service provided to you was the result of a worldwide market.

Some markets are highly concentrated, with the majority of total sales coming from a small number of firms. For example, in the market for internet search, three firms controlled 98.9 percent of the US market (Google 63.5 percent, Microsoft 24 percent, and Oath (formerly Yahoo) 11.4 percent) as of January 2018.[2] Other markets are very fragmented, such as automobile repairs, where small independent shops often dominate and large chains may or may not exist. New products can lead to market concentration: It is estimated that the Apple iPod had a world market share of over 70 percent among MP3 players in 2009.

[1] Friedman (2006).

THE IMPORTANCE OF MARKET STRUCTURE

Consider the evolution of television broadcasting. As the market environment for television broadcasting evolved, the market structure changed, resulting in a new set of challenges and choices. In the early days, there was only one choice: the "free" analog channels that were broadcast over the airwaves. In most countries, there was only one channel, owned and run by the government. In the United States, some of the more populated markets were able to receive more channels because local channels were set up to cover a market with more potential viewers. By the 1970s, new technologies made it possible to broadcast by way of cable connectivity and the choices offered to consumers began to expand rapidly. Cable television challenged the "free" broadcast channels by offering more choice and a better-quality picture. The innovation was expensive for consumers and profitable for the cable companies. By the 1990s, a new alternative began to challenge the existing broadcast and cable systems: satellite television. Satellite providers offered a further expanded set of choices, albeit at a higher price than the free broadcast and cable alternatives. In the early 2000s, satellite television providers lowered their pricing to compete directly with the cable providers.

Today, cable program providers, satellite television providers, and terrestrial digital broadcasters that offer premium and pay-per-view channels compete for customers who are increasingly finding content on the internet and on their mobile devices. Companies like Netflix, Apple, and Amazon offered alternative ways for consumers to access content. By 2018, these companies had moved beyond the repackaging of existing shows to developing their own content, mirroring the evolution of cable channels such as HBO and ESPN a decade earlier.

This is a simple illustration of the importance of market structure. As the market for television broadcasting became increasingly competitive, managers have had to make decisions regarding product packaging, pricing, advertising, and marketing in order to survive in the changing environment. In addition, mergers and acquisitions as a response to these competitive pressures have changed the essential structure of the industry.

Market structure can be broken down into four distinct categories: perfect competition, monopolistic competition, oligopoly, and monopoly.

We start with the most competitive environment, **perfect competition**. Unlike some economic concepts, perfect competition is not merely an ideal based on assumptions. Perfect competition is a reality—for example, in several commodities markets, where sellers and buyers have a strictly homogeneous product and no single producer is large enough to influence market prices. Perfect competition's characteristics are well recognized and its long-run outcome unavoidable. Profits under the conditions of perfect competition are driven to the required rate of return paid by the entrepreneur to borrow capital from investors (so-called normal profit or rental cost of capital). This does not mean that all perfectly competitive industries are doomed to extinction by a lack of profits. On the contrary, millions of businesses that do very well are living under the pressures of perfect competition.

Monopolistic competition is also highly competitive; however, it is considered a form of imperfect competition. Two economists, Edward H. Chamberlin (US) and Joan Robinson (UK), identified this hybrid market and came up with the term because there are not only strong elements of competition in this market structure but also some monopoly-like conditions. The competitive characteristic is a notably large number of firms, while the monopoly aspect is the result of product differentiation. That is, if the seller can convince consumers that its product is uniquely different from other, similar products, then the seller can exercise some degree of pricing power over the market. A good example is the brand loyalty associated with soft drinks such as Coca-Cola. Many of Coca-Cola's customers believe that their beverages are truly different from and better than all other soft drinks. The same is true for fashion creations and cosmetics.

---

[2] Source: www.statista.com/statistics/267161/market-share-of-search-engines-in-the-united-states/.

The **oligopoly** market structure is based on a relatively small number of firms supplying the market. The small number of firms in the market means that each firm must consider what retaliatory strategies the other firms will pursue when prices and production levels change. Consider the pricing behavior of commercial airline companies. Pricing strategies and route scheduling are based on the expected reaction of the other carriers in similar markets. For any given route—say, from Paris, France, to Chennai, India—only a few carriers are in competition. If one of the carriers changes its pricing package, others will likely retaliate. Understanding the market structure of oligopoly markets can help in identifying a logical pattern of strategic price changes for the competing firms.

Finally, the least competitive market structure is **monopoly**. In pure monopoly markets, there are no other good substitutes for the given product or service. There is a single seller, which, if allowed to operate without constraint, exercises considerable power over pricing and output decisions. In most market-based economies around the globe, pure monopolies are regulated by a governmental authority. The most common example of a regulated monopoly is the local electrical power provider. In most cases, the monopoly power provider is allowed to earn a normal return on its investment and prices are set by the regulatory authority to allow that return.

1.1.2 *Factors That Determine Market Structure*

Five factors determine market structure:

1. The number and relative size of firms supplying the product;
2. The degree of product differentiation;
3. The power of the seller over pricing decisions;
4. The relative strength of the barriers to market entry and exit; and
5. The degree of non-price competition.

The number and relative size of firms in a market influence market structure. If there are many firms, the degree of competition increases. With fewer firms supplying a good or service, consumers are limited in their market choices. One extreme case is the monopoly market structure, with only one firm supplying a unique good or service. Another extreme is perfect competition, with many firms supplying a similar product. Finally, an example of relative size is the automobile industry, in which a small number of large international producers (e.g., Volkswagen and Toyota) are the leaders in the global market, and a number of small companies either have market power because they are niche players (e.g., Ferrari or McLaren) or have little market power because of their narrow range of models or limited geographical presence (e.g., Mazda or Fiat-Chrysler).

In the case of monopolistic competition, there are many firms providing products to the market, as with perfect competition. However, one firm's product is differentiated in some way that makes it appear better than similar products from other firms. If a firm is successful in differentiating its product, the differentiation will provide pricing leverage. The more dissimilar the product appears, the more the market will resemble the monopoly market structure. A firm can differentiate its product through aggressive advertising campaigns; frequent styling changes; the linking of its product with other, complementary products; or a host of other methods.

When the market dictates the price based on aggregate supply and demand conditions, the individual firm has no control over pricing. The typical hog farmer in Nebraska and the milk producer in Bavaria are **price takers**. That is, they must accept whatever price the market dictates. This is the case under the market structure of perfect competition. In the case of monopolistic competition, the success of product differentiation determines the degree with which the firm can influence price. In the case of oligopoly, there are so few firms in the market that price control becomes possible. However, the small number of firms in an oligopoly market invites complex pricing strategies. Collusion, price leadership by dominant firms, and other pricing strategies can result.

The degree to which one market structure can evolve into another and the difference between potential short-run outcomes and long-run equilibrium conditions depend on the strength of the barriers to entry and the possibility that firms fail to recoup their original costs or lose money for an extended period of time and are therefore forced to exit the market. Barriers to entry can result from very large capital investment requirements, as in the case of petroleum refining. Barriers may also result from patents, as in the case of some electronic products and drug formulas. Another entry consideration is the possibility of high exit costs. For example, plants that are specific to a special line of products, such as aluminum smelting plants, are non-redeployable, and exit costs would be high without a liquid market for the firm's assets. High exit costs deter entry and are therefore also considered barriers to entry. In the case of farming, the barriers to entry are low. Production of corn, soybeans, wheat, tomatoes, and other produce is an easy process to replicate; therefore, those are highly competitive markets.

Non-price competition dominates those market structures where product differentiation is critical. Therefore, monopolistic competition relies on competitive strategies that may not include pricing changes. An example of non-price competition is product differentiation through marketing. In other circumstances, non-price competition may occur because the few firms in the market feel dependent on each other. Each firm fears retaliatory price changes that would reduce total revenue for all of the firms in the market. Because oligopoly industries have so few firms, each firm feels dependent on the pricing strategies of the others. Therefore, non-price competition becomes a dominant strategy.

Exhibit 1 Characteristics of Market Structure

Market Structure	Number of Sellers	Degree of Product Differentiation	Barriers to Entry	Pricing Power of Firm	Non-price Competition
Perfect competition	Many	Homogeneous/ Standardized	Very Low	None	None
Monopolistic competition	Many	Differentiated	Low	Some	Advertising and Product Differentiation
Oligopoly	Few	Homogeneous/ Standardized	High	Some or Considerable	Advertising and Product Differentiation
Monopoly	One	Unique Product	Very High	Considerable	Advertising

From the perspective of the owners of the firm, the most desirable market structure is that with the most control over price, because this control can lead to large profits. Monopoly and oligopoly markets offer the greatest potential control over price; monopolistic competition offers less control. Firms operating under perfectly competitive market conditions have no control over price. From the consumers' perspective, the most desirable market structure is that with the greatest degree of competition because prices are generally lower. Thus, consumers would prefer as many goods and services as possible to be offered in competitive markets.

As often happens in economics, there is a trade-off. While perfect competition gives the largest quantity of a good at the lowest price, other market forms may spur more innovation. Specifically, there may be high costs in researching a new product, and firms will incur such costs only if they expect to earn an attractive return on their research investment. This is the case often made for medical innovations, for example—the cost of clinical trials and experiments to create new medicines would bankrupt perfectly competitive firms but may be acceptable in an oligopoly market structure. Therefore, consumers can benefit from less-than-perfectly-competitive markets.

PORTER'S FIVE FORCES AND MARKET STRUCTURE

A financial analyst aiming to establish market conditions and consequent profitability of incumbent firms should start with the questions framed by Exhibit 1: How many sellers are there? Is the product differentiated? and so on. Moreover, in the case of monopolies and quasi monopolies, the analyst should evaluate the legislative and regulatory framework: Can the company set prices freely, or are there governmental controls? Finally, the analyst should consider the threat of competition from potential entrants.

This analysis is often summarized by students of corporate strategy as "Porter's five forces," named after Harvard Business School professor Michael E. Porter. His book, *Competitive Strategy*, presented a systematic analysis of the practice of market strategy. Porter (2008) identified the five forces as:

- Threat of entry;
- Power of suppliers;
- Power of buyers (customers);
- Threat of substitutes; and
- Rivalry among existing competitors.

It is easy to note the parallels between four of these five forces and the columns in Exhibit 1. The only "orphan" is the power of suppliers, which is not at the core of the theoretical economic analysis of competition, but which has substantial weight in the practical analysis of competition and profitability.

Some stock analysts (e.g., Dorsey 2004) use the term "economic moat" to suggest that there are factors protecting the profitability of a firm that are similar to the moats (ditches full of water) that were used to protect some medieval castles. A deep moat means that there is little or no threat of entry by invaders, i.e. competitors. It also means that customers are locked in because of high switching costs.

PERFECT COMPETITION & DEMAND ANALYSIS IN PERFECTLY COMPETITIVE MARKETS

2

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

Perfect competition is characterized by the five conditions presented in Exhibit 1, above:

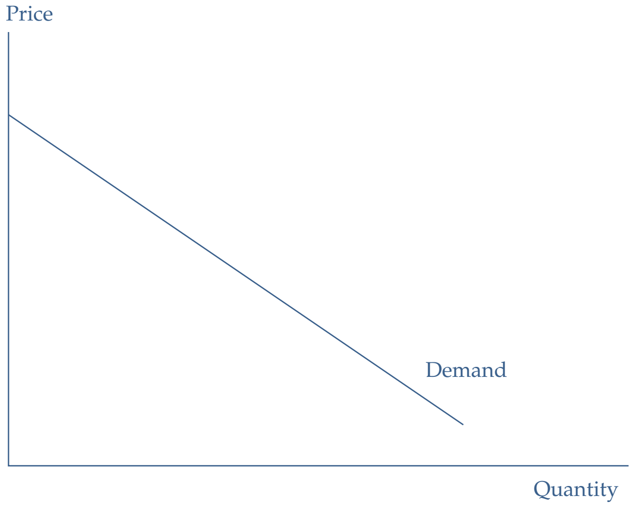
1. There are a large number of potential buyers and sellers.
2. The products offered by the sellers are virtually identical.
3. There are few or easily surmountable barriers to entry and exit.
4. Sellers have no market-pricing power.
5. Non-price competition is absent.

While few markets achieve the distinction of being perfectly competitive, it is useful to establish the outcome associated with this market structure as a benchmark against which other market structures can be compared. The most typical example of perfect competition is found in certain aspects of the agriculture industry, such as the large number of farmers growing corn for animal feed. Corn is a primary source of food for pork, beef, and poultry production. A bushel of corn from Farmer Brown is virtually identical to a bushel of corn from Farmer Lopez. If a hog farmer needs corn to feed his hogs, it does not matter whether the corn comes from Farmer Brown or Farmer Lopez. Furthermore, the aggregate corn market is well defined, with active futures and spot markets. Information about the corn market is easy and inexpensive to access, and there is no way to differentiate the product, such as by advertising. Agribusiness is capital intensive, but where arable land is relatively abundant and water is available, the barriers to entry (e.g., capital and expertise) for corn production are relatively low.

2.1 Demand Analysis in Perfectly Competitive Markets

The price of a homogeneous product sold in a competitive market is determined by the demand and supply in that market. Economists usually represent demand and supply in a market through demand and supply curves in a two-axis plane, where quantity and price are shown on the x-axis and y-axis, respectively. Economists believe that demand functions have negative slopes, as shown in Exhibit 2. That is, at high prices, less is demanded. For normal goods and services, as the price declines, the quantity demanded increases. This concept is based on two effects: the income effect and the substitution effect. The income effect results from the increased purchasing power the consumer has when prices fall. With lower prices, the consumer can afford to purchase more of the product. The substitution effect comes from the increasing attractiveness of the lower-priced product. If soybean prices are unchanged and corn prices decrease, hog farmers will substitute corn for soybeans as feed for their animals.

Exhibit 2 Market Demand in Perfect Competition



Assume the demand for this product can be specified as

$$Q_D = 50 - 2P$$

where Q_D is the quantity of demand and P is the product's price. This demand function can be rearranged in terms of price:

$$P = 25 - 0.5Q_D$$

In this form, total revenue (TR) is equal to price times quantity, or $P \times Q_D$. Thus,

$$\text{TR} = PQ_D = 25Q_D - 0.5Q_D^2$$

Average revenue (AR) can be found by dividing TR by Q_D. Therefore,

$$\text{AR} = \text{TR}/Q_D = \left(25Q_D - 0.5Q_D^2\right)\Big/Q_D = 25 - 0.5Q_D$$

Note that the AR function is identical to the market demand function. The assumption here is that the relationship between price and quantity demanded is linear. Clearly, that may not be the case in the real market. Another simplifying assumption made is that the price of the product is the only determinant of demand. Again, that is not likely in the real market. For example, economic theory suggests that consumer income is another important factor in determining demand. The prices of related goods and services, such as substitutes and complements, are also considered factors affecting demand for a specific product.

Marginal revenue (MR) is the change in total revenue per extra increment sold when the quantity sold changes by a small increment, ΔQ_D. Substituting $(Q_D + \Delta Q_D)$ into the total revenue (TR) equation, marginal revenue can be expressed as:

$$\text{MR} = \frac{\Delta\text{TR}}{\Delta Q_D} = \frac{\left[25\left(Q_D + \Delta Q_D\right) - 0.5\left(Q_D^2 + 2Q_D\Delta Q_D + \Delta Q_D^2\right)\right] - \left[25Q_D - 0.5Q_D^2\right]}{\Delta Q_D}$$

$$= \frac{25\Delta Q_D - Q_D\Delta Q_D - 0.5\Delta Q_D^2}{\Delta Q_D} = 25 - Q_D - 0.5\Delta Q_D$$

For example, suppose $Q_D = 5$ and $\Delta Q_D = 1$, then total revenue increases from 112.50 [= 25(5) – 0.5 (5^2)] to 132 [= 25(6) – 0.5(6^2)], and marginal revenue is 19.5 = (132 – 112.5)/1. Note that marginal revenue is equal to ($25 - Q_D - 0.5\Delta Q_D$). Now suppose that ΔQ_D is much smaller, for example $\Delta Q_D = 0.1$. In this case, total revenue increases to 114.495 [= 25(5.1) – 0.5(5.1^2)], and marginal revenue is 1.995/0.1 = 19.95. It is straightforward to confirm that as ΔQ_D gets smaller marginal revenue gets closer to $20 = 25 - Q_D$. So, for very small changes in the quantity sold we can write marginal revenue as[3]

$$\mathrm{MR} = 25 - Q_D$$

Although we have introduced the concept of marginal revenue in the context of the demand curve for the market as a whole, its usefulness derives from its role in the output and pricing decisions of individual firms. As we will see, marginal revenue and an analogous concept, marginal cost, are critical in determining firms' profit-maximizing strategies.

ELASTICITY OF DEMAND

3

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

Consumers respond differently to changes in the price of different kinds of products and services. The quantity demanded for some products is very price sensitive, while for other products, price changes result in little change in the quantity demanded. Economists refer to the relationship between changes in price and changes in the quantity demanded as the price elasticity of demand. Therefore, the demand for the former group of products—those that are very price sensitive—is said to have high price elasticity, whereas the demand for the latter group is said to have low price elasticity. Understanding the sensitivity of demand changes to changes in price is critical to understanding market structures.

Price elasticity of demand measures the percentage change in the quantity demanded given a percentage change in the price of a given product. Because the relationship of demand to price is negative, the price elasticity of demand would be negative. *Many economists, however, present the price elasticity as an absolute value, so that price elasticity has a positive sign. We will follow that convention.* Higher price elasticity indicates that consumers are very responsive to changes in price. Lower values for price elasticity imply that consumers are not very responsive to price changes. Price elasticity can be measured with the following relationship:

$$\varepsilon_P = -(\%\ \text{change in}\ Q_D) \div (\%\ \text{change in}\ P)$$

where ε_P is price elasticity of demand, Q_D is the quantity demanded, and P is the product's price.

Price elasticity of demand falls into three categories. When demand is very responsive to price change, it is identified as *elastic*. When demand is not responsive to price change, it is identified as *inelastic*. When the percentage change in quantity demanded is exactly the same as the percentage change in price, the demand is called *unitary elastic*.

$\varepsilon_P > 1$ Demand is elastic

$\varepsilon_P = 1$ Demand is unitary elastic

$\varepsilon_P < 1$ Demand is inelastic

---

[3] Readers who are familiar with calculus will recognize this as the derivative of total revenue with respect to the quantity sold.

Price elasticity of demand depends on several factors. *Price elasticity will be higher if there are many close substitutes for the product.* If a product has many good alternatives, consumers will be more sensitive to price changes. For example, carbonated beverages (“soft drinks”) have many close substitutes. It takes strong brand loyalty to keep customer demand high in the soft drink market when one brand’s price is strategically lowered; the price elasticity of demand for Coca-Cola has been estimated to be 3.8. For products with numerous close substitutes, demand is highly elastic. For products with few close substitutes, demand is lower in price elasticity and would be considered price inelastic. The demand for first-class airline tickets is often seen as inelastic because only very wealthy people are expected to buy them; the demand for economy-class tickets is elastic because the typical consumer for this product is more budget-conscious. Consumers do not consider economy-class airline tickets a close substitute for first-class accommodations, particularly on long flights.

The airline ticket example introduces another determinant of price elasticity of demand. *The greater the share of the consumer’s budget spent on the item, the higher the price elasticity of demand*. Expensive items, such as durable goods (e.g., refrigerators and televisions), tend to have higher elasticity measures, while less expensive items, such as potatoes and salt, have lower elasticity values. Consumers will not change their normal salt consumption if the price of salt decreases by 10 percent. Instead, they will buy their next package of salt when they run out, with very little regard to the price change.

The airline ticket also makes a good example for the final factor determining price elasticity. *Price elasticity of demand also depends on the length of time within which the demand schedule is being considered*. Holiday airline travel is highly price elastic. Consumers shop vigorously for vacation flights because they have time to plan their holiday. Business airline travelers typically have less flexibility in determining their schedules. If your business requires a face-to-face meeting with a client, then the price of the ticket is somewhat irrelevant. If gasoline prices increase, there is very little you can do in the short run but pay the higher price. However, evidence of commuter choices indicates that many use alternative transportation methods after the gasoline price spikes. In the long run, higher gasoline prices will lead consumers to change their modes of transportation, trading in less efficient vehicles for automobiles with higher gas mileage or public transit options where available.

There are two extreme cases of price elasticity of demand. One extreme is the **horizontal demand schedule**. This term implies that at a given price, the response in the quantity demanded is infinite. *This is the demand schedule faced by a perfectly competitive firm because it is a price taker*, as in the case of a corn farmer. If the corn farmer tried to charge a higher price than the market price, nobody would buy her product. On the other hand, the farmer has no incentive to sell at a lower price because she can sell all she can produce at the market price. In a perfectly competitive market the quantity supplied by an individual firm has a negligible effect on the market price. In the case of *perfect price elasticity*, the measure is $\varepsilon_P = \infty$.

The other extreme is the **vertical demand schedule**. The vertical demand schedule implies that some fixed quantity is demanded, regardless of price. An example of such demand is the diabetic consumer with the need for a certain amount of insulin. If the price of insulin goes up, the patient will not consume less of it. The amount desired is set by the patient’s medical condition. The measure for *perfect price inelasticity* is $\varepsilon_P = 0$.

The nature of the elasticity calculation and consumer behavior in the marketplace imply that for virtually any product (excluding cases of perfect elasticity and perfect inelasticity), demand is more elastic at higher prices and less elastic (more inelastic) at lower prices. For example, at current low prices, the demand for table salt is very inelastic. However, if table salt increased in price to hundreds of dollars per ounce, consumers would become more responsive to its price changes. Exhibit 3 reports several empirical estimates of price elasticity of demand.

Exhibit 3 Empirical Price Elasticities[4]

Commodity (Good/Service)	Price Elasticity of Market Demand
Alcoholic beverages consumed at home	
Beer	0.84
Wine	0.55
Liquor	0.50
Coffee	
Regular	0.16
Instant	0.36

Shoes	0.73
Soybean meal	1.65
Tomatoes	2.22

OTHER FACTORS AFFECTING DEMAND

4

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

There are two other important forces that influence shifts in consumer demand. One influential factor is consumer income and the other is the price of a related product. For normal goods, as consumer income increases, the demand increases. The degree to which consumers respond to higher incomes by increasing their demand for goods and services is referred to as income elasticity of demand. **Income elasticity of demand** measures the responsiveness of demand to changes in income. The calculation is similar to that of price elasticity, with the percentage change in income replacing the percentage change in price. Note the new calculation below:

$$\varepsilon_Y = (\%\text{ change in } Q_D) \div (\%\text{ change in } Y)$$

where ε_Y is income elasticity of demand, Q_D is the quantity demanded, and Y is consumer income. For normal goods, the measure ε_Y will be a positive value. That is, as consumers' income rises, more of the product is demanded. For products that are considered luxury items, the measure of income elasticity will be greater than one. There are other goods and services that are considered inferior products. For inferior products, as consumer income rises, less of the product is demanded. Inferior products will have negative values for income elasticity. For example, a person on a small income may watch television shows, but if this person had more income, she would prefer going to live concerts and theater performances; in this example, television shows would be the inferior good.

---

[4] Various sources, as noted in McGuigan, Moyer, and Harris (2008), p. 95. These are the elasticities with respect to the product's own price; by convention, they are shown here as positive numbers.

As a technical issue, the difference between price elasticity of demand and income elasticity of demand is that the demand adjustment for price elasticity represents a movement *along the demand schedule* because the demand schedule represents combinations of price and quantity. The demand adjustment for income elasticity represents a *shift in the demand curve* because with a higher income one can afford to purchase more of the good at any price. For a normal good, an increase in income would shift the demand schedule out to the right, away from the origin of the graph, and a decrease in income would shift the demand curve to the left, toward the origin.

The final factor influencing demand for a product is the change in price of a related product, such as a strong substitute or a complementary product. If a close competitor in the beverage market lowers its price, consumers will substitute that product for your product. Thus, your product's demand curve will shift to the left, toward the origin of the graph. **Cross-price elasticity of demand** is the responsiveness of the demand for product A that is associated with the change in price of product B:

$$\varepsilon_X = (\%\text{ change in } Q_{DA}) \div (\%\text{ change in } P_B)$$

where ε_X is cross-price elasticity of demand, Q_{DA} is the quantity demanded of product A, and P_B is the price of product B.

When the cross-price elasticity of demand between two products is *positive*, the two products are considered to be **substitutes**. For example, you may expect to have positive cross-price elasticity between honey and sugar. If the measure of cross-price elasticity is *negative*, the two products are referred to as **complements** of each other. For example, if the price of DVDs goes up, you would expect consumers to buy fewer DVD players. In this case, the cross-price elasticity of demand would have a negative value.

Reviewing cross-price elasticity values provides a simple test for the degree of competition in the market. The more numerous and the closer the substitutes for a product, the lower the pricing power of firms selling in that market; the fewer the substitutes for a product, the greater the pricing power. One interesting application was a US Supreme Court case involving the production and sale of cellophane by DuPont.[5] The court noted that the relevant product market for DuPont's cellophane was the broader flexible packaging materials market. The Supreme Court found the cross-price elasticity of demand between cellophane and other flexible packaging materials to be sufficiently high and exonerated DuPont from a charge of monopolizing the market.

Because price elasticity of demand relates changes in price to changes in the quantity demanded, there must be a logical relationship between marginal revenue and price elasticity. Recall that marginal revenue equals the change in total revenue given a change in output or sales. An increase in total revenue results from a decrease in price that results in an increase in sales. In order for the increase in the quantity demanded to be sufficient to offset the decline in price, the percentage change in quantity demanded must be greater than the percentage decrease in price. The relationship between TR and price elasticity is as follows:

$\varepsilon_P > 1$ Demand is elastic	$\uparrow P \rightarrow \text{TR} \downarrow$ and $\downarrow P \rightarrow \text{TR} \uparrow$
$\varepsilon_P = 1$ Demand is unitary elastic	$\updownarrow P \rightarrow$ no change in TR
$0 < \varepsilon_P < 1$ Demand is inelastic	$\uparrow P \rightarrow \text{TR} \uparrow$ and $\downarrow P \rightarrow \text{TR} \downarrow$

---

[5] *US v. DuPont*, 351 US 377 (1956), as noted in McGuigan, Moyer, and Harris (2008).

Total revenue is maximized when marginal revenue is zero. The logic is that as long as marginal revenue is positive (i.e., each additional unit sold contributes to additional total revenue), total revenue will continue to increase. Only when marginal revenue becomes negative will total revenue begin to decline. Therefore, the percentage decrease in price is greater than the percentage increase in quantity demanded. The relationship between marginal revenue (MR) and price elasticity can be expressed as

$$\text{MR} = P[1 - (1/\varepsilon_P)]$$

An understanding of price elasticity of demand is an important strategic tool. It would be very useful to know in advance what would happen to your firm's total revenue if you increased the product's price. If you are operating in the inelastic portion of the demand curve, increasing the price of the product will increase total revenue. On the other hand, if you are operating in the elastic portion of the product's demand curve, increasing the price will decrease total revenue.

Decision makers can also use the relationship between marginal revenue and price elasticity of demand in other ways. For example, suppose you are a farmer considering planting soybeans or some other feed crop, such as corn. From Exhibit 3, we know that soybean meal's price elasticity of demand has been estimated to be 1.65. We also know that the current (May 2018) soybean meal price is $465.00 per metric ton.[6] Therefore, by solving the equation above, we find that the expected marginal revenue per metric ton of soybean meal is $183.16. Soybeans may prove to be a profitable crop for the farmer. Just a few years earlier, in May of 2014, the price of a metric ton of soybean meal was $578.75. Given the crop's price elasticity of demand, the estimated marginal revenue per metric ton was then $227.97. The higher price translates into higher marginal revenue and might have induced the farmer to plant even more soybeans rather than another feed crop instead.

How do business decision makers decide what level of output to bring to the market? To answer that question, the firm must understand its cost of resources, its production relations, and its supply function. Once the supply function is well defined and understood, it is combined with the demand analysis to determine the profit-maximizing levels of output.

CONSUMER SURPLUS: VALUE MINUS EXPENDITURE

5

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

To this point, we have discussed the fundamentals of supply and demand curves and explained a simple model of how a market can be expected to arrive at an equilibrium combination of price and quantity. While it is certainly necessary for the analyst to understand the basic workings of the market model, it is also crucial to have a sense of why we might care about the nature of the equilibrium. In this section we review the concept of **consumer surplus**, which is helpful in understanding and evaluating business pricing strategies. Consumer surplus is defined as the difference between the value that a consumer places on the units purchased and the amount of money that was required to pay for them. It is a measure of the value gained by the buyer from the transaction.

---

[6] Source: World-Bank Commodity Market Report 2018.

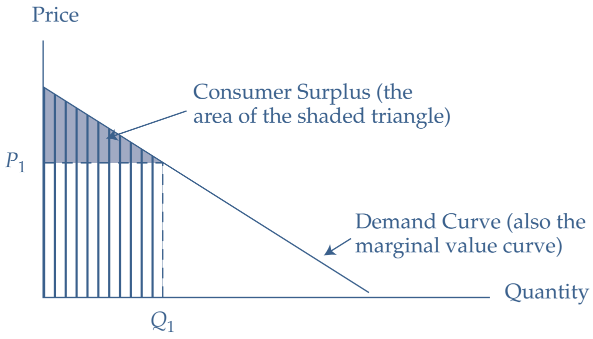
To get an intuitive feel for the concept of consumer surplus, consider the last thing you purchased. Whatever it was, think of how much you paid for it. Now contrast that price with the maximum amount you *would have been willing to pay* rather than go without the item altogether. If those two numbers are different, we say you received some consumer surplus from your purchase. You got a "bargain" because you would have been willing to pay more than you had to pay.

Earlier, we referred to the law of demand, which says that as price falls, consumers are willing to buy more of the good. This observation translates into a negatively sloped demand curve. Alternatively, we could say that the highest price that consumers are willing to pay for an additional unit declines as they consume more and more of a good. In this way, we can interpret their *willingness to pay* as a measure of how much they *value* each additional unit of the good. This is a very important point: To purchase a unit of some good, consumers must give up something else they value. So, the price they are willing to pay for an additional unit of a good is a measure of how much they value that unit, in terms of the other goods they must sacrifice to consume it.

If demand curves are negatively sloped, it must be because the value of each additional unit of the good falls as more of the good is consumed. We shall explore this concept further below, but for now, it is enough to recognize that the demand curve can therefore be considered a **marginal value curve**, because it shows the highest price consumers would be willing to pay for each additional unit. In effect, the demand curve is the willingness of consumers to pay for each additional unit.

This interpretation of the demand curve allows us to measure the total value of consuming any given quantity of a good: It is the sum of all the marginal values of each unit consumed, up to and including the last unit. Graphically, this measure translates into the area under the consumer's demand curve, up to and including the last unit consumed, as shown in Exhibit 4, where the consumer is choosing to buy Q_1 units of the good at a price of P_1. The marginal value of the $Q_1{}^{th}$ unit is clearly P_1 because that is the highest price the consumer is willing to pay for that unit. Importantly, however, the marginal value of each unit *up to* the $Q_1{}^{th}$ is greater than P_1.

Exhibit 4 Consumer Surplus



Note: Consumer surplus is the area beneath the demand curve and above the price paid.

Because the consumer would have been willing to pay more for each of those units than she paid (P_1), we can say she received more value than the cost to her of buying them. This extra value is the buyer's consumer surplus. The *total value* of quantity Q_1 to the buyer is the area of the vertically crosshatched trapezoid in Exhibit 4. The *total expenditure* is only the area of the rectangle with height P_1 and base Q_1 (bottom section). The total consumer surplus received from buying Q_1 units at a level price of

P_1 per unit is the difference between the area under the demand curve and the area of the rectangle $P_1 \times Q_1$. The resulting area is shown as the lightly shaded triangle (upper section).

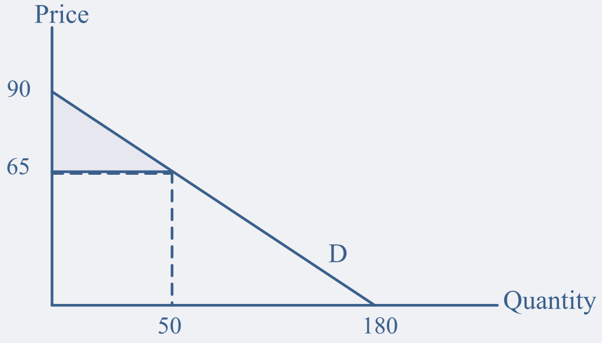
EXAMPLE 1

Consumer Surplus

A market demand function is given by the equation $Q_D = 180 - 2P$. Find the value of consumer surplus if price is equal to 65.

Solution:

First, input 65 into the demand function to find the quantity demanded at that price: $Q_D = 180 - 2(65) = 50$. Then, to make drawing the demand curve easier, invert the demand function by solving for P in terms of Q_D: $P = 90 - 0.5Q_D$. Note that the price intercept is 90 and the quantity intercept is 180. Draw the demand curve:



Find the area of the triangle above the price of 65 and below the demand curve, up to quantity 50: Area = ½ (Base)(Height) = ½ (50)(25) = 625.

SUPPLY ANALYSIS & OPTIMAL PRICE AND OPTIMAL OUTPUT IN PERFECTLY COMPETITIVE MARKETS

6

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

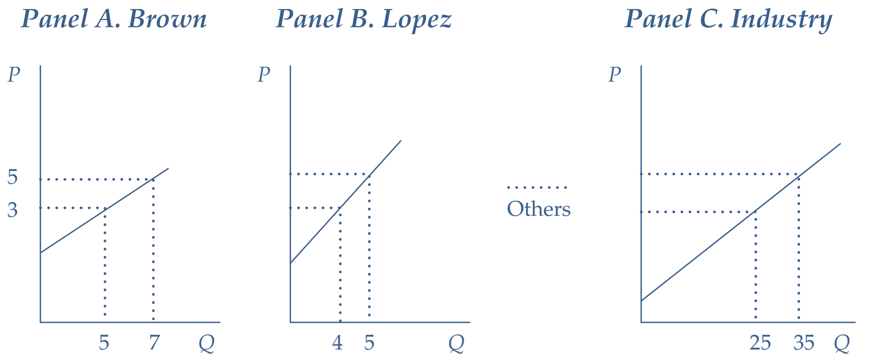
c describe a firm's supply function under each market structure;

d describe and determine the optimal price and output for firms under each market structure;

f describe pricing strategy under each market structure;

Consider two corn farmers, Mr. Brown and Ms. Lopez. They both have land available to them to grow corn and can sell at one price, say 3 currency units per kilogram. They will try to produce as much corn as is profitable at that price. If the price is driven up to 5 currency units per kilogram by new consumers entering the market—say, ethanol producers—Mr. Brown and Ms. Lopez will try to produce more corn. To increase their output levels, they may have to use less productive land, increase irrigation, use more fertilizer, or all three. Their production costs will likely increase. They will both still try to produce as much corn as possible to profit at the new, higher price of 5 currency units per kilogram. Exhibit 5 illustrates this example. Note that the supply functions for the individual firms have positive slopes. Thus, as prices increase, the firms supply greater quantities of the product.

Exhibit 5 Firm and Market Supply in Perfect Competition



Notice that the market supply curve is the sum of the supply curves of the individual firms—Brown, Lopez, and others—that make up the market. Assume that the supply function for the market can be expressed as a linear relationship, as follows:

$$Q_S = 10 + 5P, \text{ or } P = -2 + 0.2Q_S,$$

where Q_S is the quantity supplied and P is the price of the product.

Before we analyze the optimal supply level for the firm, we need to point out that economic costs and profits differ from accounting costs and profits in a significant way. **Economic costs** include all the remuneration needed to keep the productive resource in its current employment or to acquire the resource for productive use.

To evaluate the remuneration needed to keep the resource in its current use and attract new resources for productive use, economists refer to the resource's **opportunity cost**. Opportunity cost is measured by determining the resource's next best opportunity. If a corn farmer could be employed in an alternative position in the labor market with an income of 50,000, then the opportunity cost of the farmer's labor is 50,000. Similarly, the farmer's land and capital could be leased to another farmer or sold and reinvested in another type of business. The return foregone by not doing so is an opportunity cost. In economic terms, total cost includes the full normal market return on all the resources utilized in the business. **Economic profit** is the difference between TR and total cost (TC). Economic profit differs from accounting profit because accounting profit does not include opportunity cost. Accounting profit includes only explicit payments to outside providers of resources (e.g. workers, vendors, lenders) and depreciation based on the historic cost of physical capital.

6.1 Optimal Price and Output in Perfectly Competitive Markets

Carrying forward our examples from earlier sections, we can now combine the market supply and demand functions to solve for the equilibrium price and quantity, where Q^* represents the equilibrium level of both supply and demand.

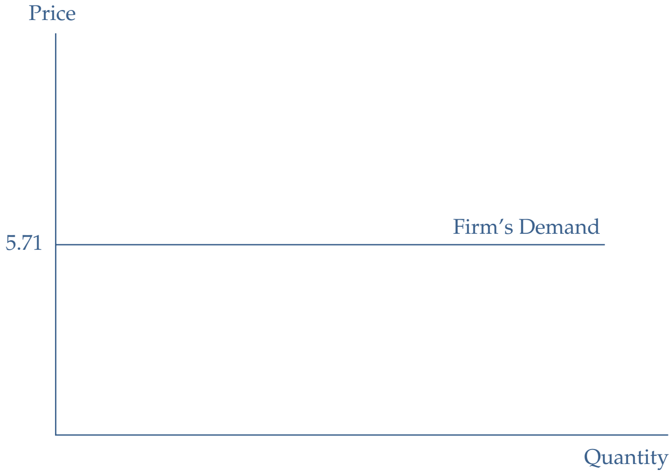
$$\begin{aligned} P = 25 - 0.5Q_D &= -2 + 0.2Q_S = P \\ 25 - 0.5Q_D &= -2 + 0.2Q_S \\ 27 &= 0.7Q^* \\ Q^* &= 38.57 \end{aligned}$$

According to the market demand curve, the equilibrium price is

$$P = 25 - 0.5Q^* = 25 - 0.5(38.57) = 25 - 19.29 = 5.71.$$

With many firms in the market and total output in the market of almost 39 units of the product, the effective market price would be 5.71. This result becomes the demand function for each perfectly competitive firm. Even if a few individual producers could expand production, there would not be a noticeable change in the market equilibrium price. In fact, if any one firm could change the equilibrium market price, the market would not be in perfect competition. Therefore, the demand curve that each perfectly competitive firm faces is a horizontal line at the equilibrium price, as shown in Exhibit 6, even though the demand curve for the whole market is downward sloping.

Exhibit 6 Individual Firm's Demand in Perfect Competition



EXAMPLE 2

Demand Curves in Perfect Competition

Is it possible that the demand schedule faced by Firm A is horizontal while the demand schedule faced by the market as a whole is downward sloping?

A No, because Firm A can change its output based on demand changes.

B No, because a horizontal demand curve means that elasticity is infinite.

C Yes, because consumers can go to another firm if Firm A charges a higher price, and Firm A can sell all it produces at the market price.

Solution:

C is correct. Firm A cannot charge a higher price and has no incentive to sell at a price below the market price.

To analyze the firm's revenue position, recall that average revenue is equivalent to the firm's demand function. Therefore, the horizontal line that represents the firm's demand curve is the firm's AR schedule.

Marginal revenue is the incremental increase in total revenue associated with each additional unit sold. For every extra unit the firm sells, it receives 5.71. Thus, the firm's MR schedule is also the horizontal line at 5.71. TR is calculated by multiplying AR by the quantity of products sold. Total revenue is the area under the AR line at the point where the firm produces the output. In the case of perfect competition, the following conditions hold for the individual firm:

Price = Average revenue = Marginal revenue

The next step is to develop the firm's cost functions. The firm knows that it can sell the entire product it produces at the market's equilibrium price. How much should it produce? That decision is determined by analysis of the firm's costs and revenues. A corn farmer uses three primary resources: land, labor, and capital. In economics, capital is any man-made aid to production. For the corn farmer, his or her capital includes the irrigation system, tractors, harvesters, trucks, grain bins, fertilizer, and so forth. The labor includes the farmer, perhaps members of the farmer's family, and hired labor. In the initial stages of production, only the farmer and the farmer's family are cultivating the land, with a significant investment in capital. They have a tractor, fertilizer, irrigation equipment, grain bins, seed, and a harvester. The investment in land and capital is relatively high compared with the labor input. In this production phase, the average cost of producing a bushel of corn is high. As they begin to expand by adding labor to the collection of expensive land and capital, the average cost of producing corn begins to decline—for example, because one tractor can be used more intensively to plow a larger amount of land. When the combination of land, labor, and capital approaches an efficient range, the average cost of producing a bushel of corn declines.

Given a certain level of technology, there is a limit to the increase in productivity. Eventually something begins to cause declining marginal productivity. That is, each additional unit of input produces a progressively smaller increase in output. This force is called the **law of diminishing returns**. This "law" helps define the shape of the firm's cost functions. Average cost and marginal cost will be U-shaped. Over the initial stages of output, average and marginal costs will decline. At some level of output, the law of diminishing returns will overtake the efficiencies in production and average and marginal costs will increase.

Average cost (AC) is Total cost (TC) divided by Output (Q). Therefore,

$$\text{AC} = \text{TC}/Q$$

Note that we have defined average cost (AC) in terms of total costs. Many authors refer to this as "average total cost" to distinguish it from a related concept, "average variable cost," which omits fixed costs. In the remainder of this reading, *average cost should be understood to mean average total cost*.

Marginal cost (MC) is the change in TC associated with an incremental change in output:

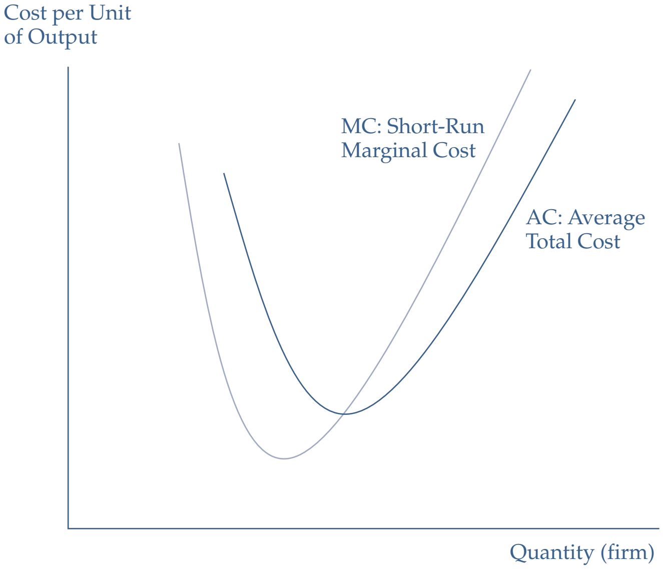
$$\text{MC} = \Delta\text{TC}/\Delta Q$$

By definition, fixed costs do not vary with output, so marginal cost reflects only changes in variable costs.[7] MC declines initially because processes can be made more efficient and specialization makes workers more proficient at their tasks. However, at some higher level of output, MC begins to increase (e.g., must pay workers a higher wage to have them work overtime and, in agriculture, less fertile land must be brought into production). MC and AC will be equal at the level of output where AC is minimized. This is a mathematical necessity and intuitive. If you employ the least expensive labor in the initial phase of production, average and marginal cost will decline. Eventually, additional labor will be more costly. For example, if the labor market is at or near full employment, in order to attract additional workers, you must pay higher wages than they are currently earning elsewhere. Thus, the additional (marginal) labor is more costly, and the higher cost increases the overall average as soon as MC exceeds AC. Exhibit 7 illustrates the relationship between AC and MC.

---

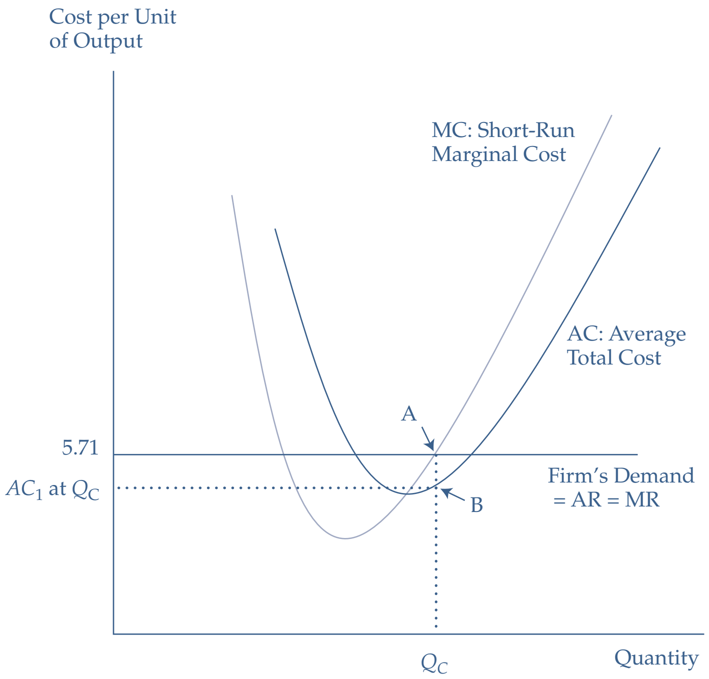
[7] Readers who are familiar with calculus will recognize that MC is simply the derivative of total cost with respect to quantity produced.

Exhibit 7 Individual Firm's Short-Run Cost Schedules



Now combine the revenue and cost functions from Exhibits 6 and 7. In short-run equilibrium, the perfectly competitive firm can earn an economic profit (or an economic loss). In this example, the equilibrium price, 5.71, is higher than the minimum AC. The firm will always maximize profit at an output level where MR = MC. Recall that in perfect competition, the horizontal demand curve is the marginal revenue and average revenue schedules. By setting output at point A in Exhibit 8, where MR = MC, the firm will maximize profits. Total revenue is equal to $P \times Q$—in this case, 5.71 times Q_C. Total cost is equal to Q_C times the average cost of producing Q_C, at point B in Exhibit 8. The difference between the two areas is economic profit.

Exhibit 8 Perfectly Competitive Firm's Short-Run Equilibrium



7

FACTORS AFFECTING LONG-RUN EQUILIBRIUM IN PERFECTLY COMPETITIVE MARKETS

e explain factors affecting long-run equilibrium under each market structure;

f describe pricing strategy under each market structure;

In the long run, economic profit will attract other entrepreneurs to the market, resulting in the production of more output. The aggregate supply will increase, shifting the industry supply (S_1) curve to the right, away from the origin of the graph. For a given demand curve, this increase in supply at each price level will lower the equilibrium price, as shown in Exhibit 9.

In the long run, the perfectly competitive firm will operate at the point where marginal cost equals the minimum of average cost, because at that point, entry is no longer profitable: In equilibrium, price equals not only marginal cost (firm equilibrium) but also minimum average cost, so that total revenues equal total costs. This result implies that the perfectly competitive firm operates with zero economic profit. That is, the firm receives its normal profit (rental cost of capital), which is included in its economic costs. Recall that economic profits occur when total revenue exceeds total cost (and therefore differ from accounting profits). With low entry cost and homogeneous products to sell, the perfectly competitive firm earns zero economic profit in the long run.

Exhibit 10 illustrates the long-run equilibrium position of the perfectly competitive firm. Note that total revenue equals price ($4.50) times quantity ($Q_E$) and total cost equals average cost ($4.50) times quantity ($Q_E$).

The long-run marginal cost schedule is the perfectly competitive firm's supply curve. The firm's demand curve is dictated by the aggregate market's equilibrium price. The basic rule of profit maximization is that MR = MC, as is the case in long-run equilibrium. The firm's demand schedule is the same as the firm's marginal revenue and average revenue. Given its cost of operation, the only decision the perfectly competitive firm faces is how much to produce. The answer is the level of output that maximizes its return, and that level is where MR = MC. The demand curve is perfectly elastic. Of course, the firm constantly tries to find ways to lower its cost in the long run.

SCHUMPETER ON INNOVATION AND PERFECT COMPETITION

The Austrian-American economist Joseph A. Schumpeter[8] pointed out that technical change in economics can happen in two main ways:

1. Innovation of process: a new, more efficient way to produce an existing good or service.
2. Innovation of product: a new product altogether or an innovation upon an existing product.

Innovation of process is related to production methods. For example, instead of mixing cement by hand, since the invention of the electric engine it has been possible to use electric mixers. A more recent innovation has been to use the internet to provide technical support to personal computer users: A technician can remotely log on to the customer's PC and fix problems instead of providing instructions over the phone. The result is likely the same, but the process is more efficient.

Innovation of product is related to the product itself. MP3 players, smart phones, robot surgery, and GPS vehicle monitoring have existed only for a few years. They are new products and services. While portable music players existed before the MP3 player, no similar service existed before GPS monitoring of personal vehicles and freight trucks was invented.

How does the reality of continuous innovation of product and process, which is a characteristic of modern economies, fit into the ideal model of perfect competition, where the product is made by a huge number of tiny, anonymous suppliers? This seems a contradiction because the tiny suppliers cannot all be able to invent new products—and indeed, the markets for portable music players and smart phones do not look like perfect competition.

Schumpeter suggested that perfect competition is more of a long-run type of market. In the short run, a company develops a new process or product and is the only one to take advantage of the innovation. This company likely will have high profits and will outpace any competitors. A second stage is what Schumpeter called the swarming (as when a group of bees leaves a hive to follow a queen): In this case, some entrepreneurs notice the innovation and follow the innovator through imitation. Some of them will fail, while others will succeed and possibly be more successful than the initial innovator. The third stage occurs when the new technology is no longer new because everyone has imitated it. At this point, no economic profits are realized, because the new process or product is no longer a competitive advantage, in the sense that everyone has it—which is when perfect competition prevails and we have long-run equilibrium until a new innovation of process or product is introduced.

---

[8] See part 2 of Schumpeter (1942) for the famous "creative destruction" process.

SUPPLY, DEMAND, OPTIMAL PRICING, AND OPTIMAL OUPUT UNDER MONOPOLISTIC COMPETITION

8

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

c describe a firm's supply function under each market structure;

d describe and determine the optimal price and output for firms under each market structure;

f describe pricing strategy under each market structure;

Early in the 20th century, economists began to realize that most markets did not operate under the conditions of perfect competition.[9] Many market structures exhibited characteristics of strong competitive forces; however, other distinct non-competitive factors played important roles in the market. As the name implies, monopolistic competition is a hybrid market. *The most distinctive factor in monopolistic competition is product differentiation.* Recall the characteristics from Exhibit 1:

1. There are a large number of potential buyers and sellers.
2. The products offered by each seller are close substitutes for the products offered by other firms, and each firm tries to make its product look different.
3. Entry into and exit from the market are possible with fairly low costs.
4. Firms have some pricing power.
5. Suppliers differentiate their products through advertising and other non-price strategies.

While the market is made up of many firms that compose the product group, each producer attempts to distinguish its product from that of the others. Product differentiation is accomplished in a variety of ways. For example, consider the wide variety of communication devices available today. Decades ago, when each communication market was controlled by a regulated single seller (the telephone company), all telephones were alike. In the deregulated market of today, the variety of physical styles and colors is extensive. All versions accomplish many of the same tasks.

The communication device manufacturers and providers differentiate their products with different colors, styles, networks, bundled applications, conditional contracts, functionality, and more. Advertising is usually the avenue pursued to convince consumers there is a difference between the goods in the product group. Successful advertising and trademark branding result in customer loyalty. A good example is the brand loyalty associated with Harley-Davidson motorcycles. Harley-Davidson's customers believe that their motorcycles are truly different from and better than all other motorcycles. The same kind of brand loyalty exists for many fashion creations and cosmetics.

The extent to which the producer is successful in product differentiation determines pricing power in the market. Very successful differentiation results in a market structure that resembles the single-seller market (monopoly). However, because there are relatively low entry and exit costs, competition will, in the long run, drive prices and revenues down toward an equilibrium similar to perfect competition. Thus, the hybrid market displays characteristics found in both perfectly competitive and monopoly markets.

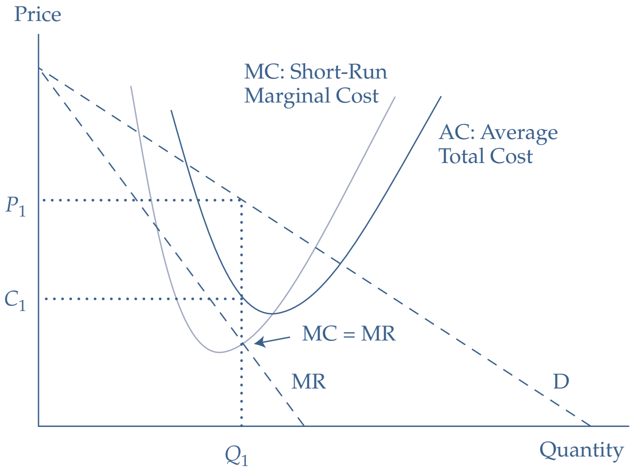
---

[9] Chamberlin (1933).

8.1 Demand Analysis in Monopolistically Competitive Markets

Because each good sold in the product group is somewhat different from the others, the demand curve for each firm in the monopolistic competition market structure is downward sloping to the right. Price and the quantity demanded are negatively related. Lowering the price will increase the quantity demanded, and raising the price will decrease the quantity demanded. There will be ranges of prices within which demand is elastic and (lower) prices at which demand is inelastic. Exhibit 11 illustrates the demand, marginal revenue, and cost structures facing a monopolistically competitive firm in the short run.

Exhibit 11 Short-Run Equilibrium in Monopolistic Competition



In the short run, the profit-maximizing choice is the level of output where MR = MC. Because the product is somewhat different from that of the competitors, the firm can charge the price determined by the demand curve. Therefore, in Exhibit 11, Q_1 is the ideal level of output and P_1 is the price consumers are willing to pay to acquire that quantity. Total revenue is the area of the rectangle $P_1 \times Q_1$.

8.2 Supply Analysis in Monopolistically Competitive Markets

In perfect competition, the firm's supply schedule is represented by the marginal cost schedule. In monopolistic competition, there is no well-defined supply function. The information used to determine the appropriate level of output is based on the intersection of MC and MR. However, the price that will be charged is based on the market demand schedule. The firm's supply curve should measure the quantity the firm is willing to supply at various prices. That information is not represented by either marginal cost or average cost.

8.3 Optimal Price and Output in Monopolistically Competitive Markets

As seen in Section 8.1, in the short run, the profit-maximizing choice is the level of output where MR = MC and total revenue is the area of the rectangle $P_1 \times Q_1$ in Exhibit 11.

The average cost of producing Q_1 units of the product is C_1, and the total cost is the area of the rectangle $C_1 \times Q_1$. The difference between TR and TC is economic profit. The profit relationship is described as

$$\pi = \text{TR} - \text{TC}$$

where π is total profit, TR is total revenue, and TC is total cost.

THE BENEFITS OF IMPERFECT COMPETITION

Is monopolistic competition indeed imperfect—that is, is it a bad thing? At first, one would say that it is an inefficient market structure because prices are higher and the quantity supplied is less than in perfect competition. At the same time, in the real world, we see more markets characterized by monopolistic competition than markets meeting the strict conditions of perfect competition. If monopolistic competition were that inefficient, one wonders, why would it be so common?

A part of the explanation goes back to Schumpeter. Firms try to differentiate their products to meet the needs of customers. Differentiation provides a profit incentive to innovate, experiment with new products and services, and potentially improve the standard of living.

Moreover, because each customer has differing tastes and preferences, slight variations of each good or service are likely to capture the niche of the market that prefers them. An example is the market for candy, where one can find chocolate, licorice, mint, fruit, and many other flavors.

A further reason why monopolistic competition may be good is that people like variety. Traditional economic theories of international trade suggested that countries should buy products from other countries that they cannot produce domestically. Therefore, Norway should buy bananas from a tropical country and sell crude oil in exchange. But this is not the only kind of exchange that happens in reality: For example, Germany imports Honda, Subaru, and Toyota cars from Japan and sells Volkswagen, Porsche, Mercedes, and BMW cars to Japan. In theory, this should not occur because each of the countries produces good cars domestically and does not need to import them. The truth, however (see, for example, Krugman 1989), is that consumers in both countries enjoy variety. Some Japanese drivers prefer to be at the steering wheel of a BMW; others like Hondas, and the same happens in Germany. Variety and product differentiation, therefore, are not necessarily bad things.

LONG-RUN EQUILIBRIUM FOR MONOPOLISTICALLY COMPETITIVE FIRM

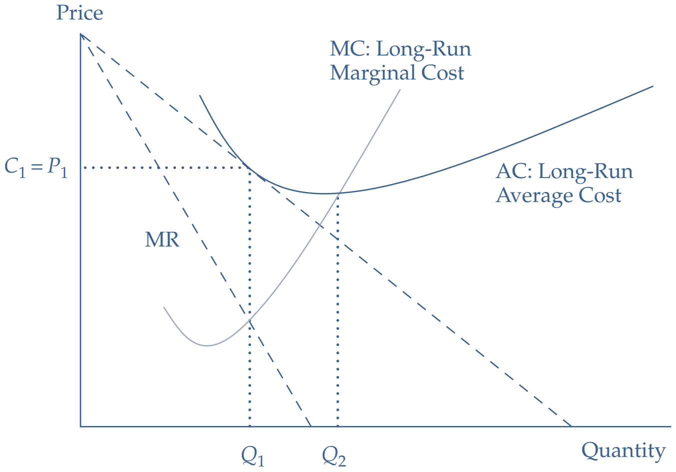
9

e explain factors affecting long-run equilibrium under each market structure;

f describe pricing strategy under each market structure;

Because TC includes all costs associated with production, including opportunity cost, economic profit is a signal to the market, and that signal will attract more competition. Just as with the perfectly competitive market structure, with relatively low entry costs, more firms will enter the market and lure some customers away from the firm making an economic profit. The loss of customers to new entrant firms will drive down the demand for all firms producing similar products. In the long run for the monopolistically competitive firm, economic profit will fall to zero. Exhibit 12 illustrates the condition of long-run equilibrium for monopolistic competition.

Exhibit 12 Long-Run Equilibrium in Monopolistic Competition



In long-run equilibrium, output is still optimal at the level where MR = MC, which is Q_1 in Exhibit 12. Again, the price consumers are willing to pay for any amount of the product is determined from the demand curve. That price is P_1 for the quantity Q_1 in Exhibit 12, and total revenue is the area of the rectangle $P_1 \times Q_1$. Notice that unlike long-run equilibrium in perfect competition, in the market of monopolistic competition, the equilibrium position is at a higher level of average cost than the level of output that minimizes average cost. Average cost does not reach its minimum until output level Q_2 is achieved. Total cost in this long-run equilibrium position is the area of the rectangle $C_1 \times Q_1$. Economic profit is total revenue minus total cost. In Exhibit 12, economic profit is zero because total revenue equals total cost: $P_1 \times Q_1 = C_1 \times Q_1$.

In the hybrid market of monopolistic competition, zero economic profit in long-run equilibrium resembles perfect competition. However, the long-run level of output, Q_1, is less than Q_2, which corresponds to the minimum average cost of production and would be the long run level of output in a perfectly competitive market. In addition, the economic cost in monopolistic competition includes some cost associated with product differentiation, such as advertising. In perfect competition, there are no costs associated with advertising or marketing because all products are homogeneous. Prices are lower, but consumers may have little variety.

10

OLIGOPOLY & DEMAND ANALYSIS AND PRICING STRATEGIES IN OLIGOPOLY MARKETS: PRICING INDEPENDENCE PORTION

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

f describe pricing strategy under each market structure;

An oligopoly market structure is characterized by only a few firms doing business in a relevant market. The products must all be similar and generally be substitutes for one another. In some oligopoly markets, the goods or services may be differentiated by marketing and strong brand recognition, as in the markets for breakfast cereals and for bottled or canned beverages. Other examples of oligopoly markets are made up of homogeneous products with little or no attempt at product differentiation, such as petroleum and cement. *The most distinctive characteristic of oligopoly markets is the small number of firms that dominate the market. There are so few firms in the relevant market that their pricing decisions are interdependent.* That is, each firm's pricing decision is based on the expected retaliation by the other firms. Recall from Exhibit 1 the characteristics of oligopoly markets:

1. There are a small number of potential sellers.
2. The products offered by each seller are close substitutes for the products offered by other firms and may be differentiated by brand or homogeneous and unbranded.
3. Entry into the market is difficult, with fairly high costs and significant barriers to competition.
4. Firms typically have substantial pricing power.
5. Products are often highly differentiated through marketing, features, and other non-price strategies.

Because there are so few firms, each firm can have some degree of pricing power, which can result in substantial profits. Another by-product of the oligopoly market structure is the attractiveness of price collusion. Even without price collusion, a dominant firm may easily become the price maker in the market. Oligopoly markets without collusion typically have the most sophisticated pricing strategies. Examples of non-colluding oligopolies include the US tobacco market and the Thai beer market. In 2004, four firms controlled 99 percent of the US tobacco industry.[10] Brands owned by Singha Co. and by ThaiBev controlled over 90 percent of the Thai beer market in 2009. (This situation is expected to change soon, as the Association of Southeast Asian Nations trade agreement will open the doors to competition from other ASEAN producers.) Perhaps the most well-known oligopoly market with collusion is the OPEC cartel, which seeks to control prices in the petroleum market by fostering agreements among oil-producing countries.

10.1 Demand Analysis and Pricing Strategies in Oligopoly Markets

Oligopoly markets' demand curves depend on the degree of pricing interdependence. In a market where collusion is present, the aggregate market demand curve is divided up by the individual production participants. Under non-colluding market conditions, each firm faces an individual demand curve. Furthermore, non-colluding oligopoly market demand characteristics depend on the pricing strategies adopted by the participating firms. There are three basic pricing strategies: pricing interdependence, the Cournot assumption, and the Nash equilibrium.

---

[10] These examples are based on "Industry Surveys," Net Advantage Database, Standard & Poor's; and Market Share Reports, Gale Research, annual issues, as noted in McGuigan, Moyer, and Harris (2016).

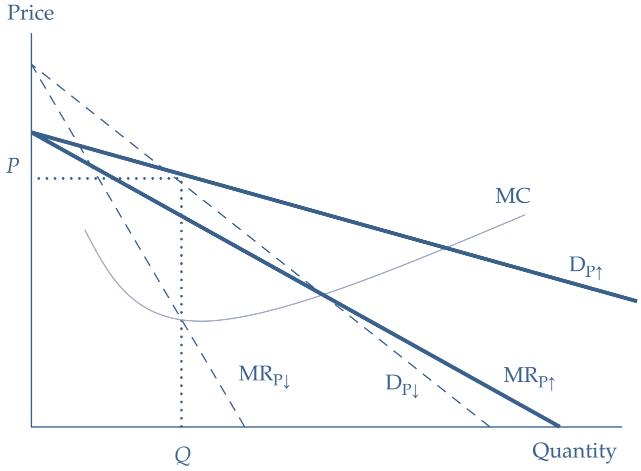
The first pricing strategy is to assume pricing interdependence among the firms in the oligopoly. A good example of this situation is any market where there are "price wars," such as the commercial airline industry. For example, flying out of their hubs in Atlanta, both Delta Air Lines and AirTran Airways jointly serve several cities. AirTran is a low-cost carrier and typically offers lower fares to destinations out of Atlanta. Delta tends to match the lower fares for those cities also served by AirTran when the departure and arrival times are similar to its own. However, when Delta offers service to the same cities at different time slots, Delta's ticket prices are higher.

The most common pricing strategy assumption in these price war markets is that competitors will match a price reduction and ignore a price increase. The logic is that by lowering its price to match a competitor's price reduction, the firm will not experience a reduction in customer demand. Conversely, by not matching the price increase, the firm stands to attract customers away from the firm that raised its prices. The oligopolist's demand relationship must represent the potential increase in market share when rivals' price increases are not matched and no significant change in market share when rivals' price decreases are matched.

Given a prevailing price, the price elasticity of demand will be much greater if the price is increased and less if the price is decreased. The firm's customers are more responsive to price increases because its rivals have lower prices. Alternatively, the firm's customers are less responsive to price decreases because its rivals will match its price change.

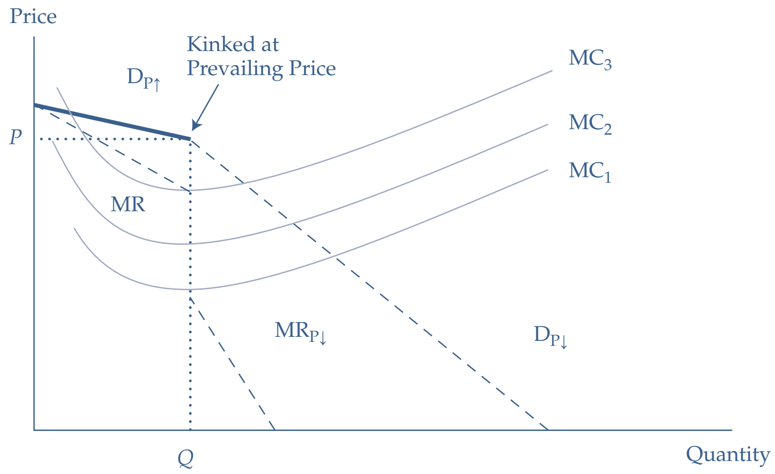
This implies that the oligopolistic firm faces two different demand structures, one associated with price increases and another relating to price reductions. Each demand function will have its own marginal revenue structure as well. Consider the demand and marginal revenue functions in Exhibit 13(A). The functions $D_{P\uparrow}$ and $MR_{P\uparrow}$ represent the demand and marginal revenue schedules associated with higher prices, while the functions $D_{P\downarrow}$ and $MR_{P\downarrow}$ represent the lower prices' demand and marginal revenue schedules. The two demand schedules intersect at the prevailing price (i.e., the price where price increase and price decrease are both equal to zero).

Exhibit 13(A) Kinked Demand Curve in Oligopoly Market



This oligopolistic pricing strategy results in a kinked demand curve, with the two segments representing the different competitor reactions to price changes. The kink in the demand curve also yields a discontinuous marginal revenue structure, with one part associated with the price increase segment of demand and the other relating to the price decrease segment. Therefore, the firm's overall demand equals the relevant portion of $D_{P\uparrow}$ and the relevant portion of $D_{P\downarrow}$. Exhibit 13(B) represents the firm's new demand and marginal revenue schedules. The firm's demand schedule in Exhibit 13(B) is segment $D_{P\uparrow}$ and $D_{P\downarrow}$, where overall demand $D = D_{P\uparrow} + D_{P\downarrow}$.

Exhibit 13(B) Kinked Demand Curve in Oligopoly Market



Notice in Exhibit 13(B) that a wide variety of cost structures are consistent with the prevailing price. If the firm has relatively low marginal costs, MC_1, the profit-maximizing pricing rule established earlier, MR = MC, still holds for the oligopoly firm. Marginal cost can rise to MC_2 and MC_3 before the firm's profitability is challenged. If the marginal cost curve MC_2 passes through the gap in marginal revenue, the most profitable price and output combination remains unchanged at the prevailing price and original level of output.

Criticism of the kinked demand curve analysis focuses on its inability to determine what the prevailing price is from the outset. The kinked demand curve analysis does help explain why stable prices have been observed in oligopoly markets and is therefore a useful tool for analyzing such markets. However, because it cannot determine the original prevailing price, it is considered an incomplete pricing analysis.

OLIGOPOLY & DEMAND ANALYSIS AND PRICING STRATEGIES IN OLIGOPOLY MARKETS: THE COURNOT ASSUMPTION PART

11

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

f describe pricing strategy under each market structure;

The second pricing strategy was first developed by French economist Augustin Cournot in 1838. In the **Cournot assumption**, each firm determines its profit-maximizing production level by assuming that the other firms' output will not change. This assumption simplifies pricing strategy because there is no need to guess what the other firm will do to retaliate. It also provides a useful approach to analyzing real-world behavior in oligopoly markets. Take the most basic oligopoly market situation, a two-firm duopoly market.[11] In equilibrium, neither firm has an incentive to change output, given the other firm's production level. Each firm attempts to maximize its own profits under the assumption that the other firm will continue producing the same level of output in the future. The Cournot strategy assumes that this pattern continues until each firm reaches its long-run equilibrium position. In long-run equilibrium, output and price are stable: There is no change in price or output that will increase profits for either firm.

Consider this example of a duopoly market. Assume that the aggregate market demand has been estimated to be

$$Q_D = 450 - P$$

The supply function is represented by constant marginal cost MC = 30.

The Cournot strategy's solution can be found by setting $Q_D = q_1 + q_2$, where q_1 and q_2 represent the output levels of the two firms. Each firm seeks to maximize profit, and each firm believes the other firm will not change output as it changes its own output (Cournot's assumption). The firm will maximize profit where MR = MC. Rearranging the aggregate demand function in terms of price, we get:

$$P = 450 - Q_D = 450 - q_1 - q_2, \text{ and MC} = 30$$

Total revenue for each of the two firms is found by multiplying price and quantity:

$$\text{TR}_1 = Pq_1 = \left(450 - q_1 - q_2\right)q_1 = 450q_1 - q_1^2 - q_1q_2, \text{ and}$$

$$\text{TR}_2 = Pq_2 = \left(450 - q_1 - q_2\right)q_2 = 450q_2 - q_2q_1 - q_2^2$$

Marginal revenue is defined as the change in total revenue, given a change in sales (q_1 or q_2).[12] For the profit-maximizing output, set MR = MC, or

$$450 - 2q_1 - q_2 = 30$$

and

$$450 - q_1 - 2q_2 = 30$$

Find the simultaneous equilibrium for the two firms by solving the two equations with two unknowns:

$$450 - 2q_1 - q_2 = 450 - q_1 - 2q_2$$

Because $q_2 = q_1$ under Cournot's assumption, insert this solution into the demand function and solve as

$$450 - 2q_1 - q_1 = 450 - 3q_1 = 30$$

Therefore, $q_1 = 140$, $q_2 = 140$, and $Q = 280$.
The price is $P = 450 - 280 = 170$.

In the Cournot strategic pricing solution, the market equilibrium price will be 170 and the aggregate output will be 280 units. This result, known as the Cournot equilibrium, differs from the perfectly competitive market equilibrium because the perfectly competitive price will be lower and the perfectly competitive output will be higher. In general, non-competitive markets have higher prices and lower levels of output in equilibrium when compared with perfect competition. In competition, the equilibrium is reached where price equals marginal cost.

$$P_C = \text{MR}_C = \text{MC, so } 450 - Q = 30$$

---

[11] The smallest possible oligopoly market is a duopoly, which is made up of only two sellers.

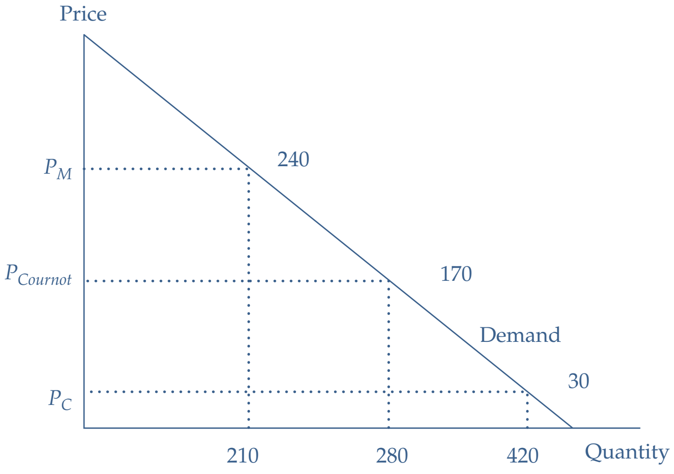
[12] The marginal revenue formulas can be obtained using the technique introduced in Section 2.1. For the market demand function, total revenue is $P \times Q = 450Q - Q^2$ and our technique yields $\text{MR} = \Delta\text{TR}/\Delta Q = 450 - 2Q$. For the individual firms in the Cournot duopoly, $\text{MR}_1 = \Delta\text{TR}_1/\Delta q_1 = 450 - 2q_1 - q_2$, and $\text{MR}_2 = \Delta\text{TR}_2/\Delta q_2 = 450 - q_1 - 2q_2$. Each of these marginal revenue formulas is, of course, the derivative of the relevant total revenue formula with respect to the relevant quantity.

where P_C is the competitive firm's equilibrium price.

$Q = 420$, and $P_C = 30$.

Exhibit 14 describes the oligopoly, competitive, and monopoly market equilibrium positions, where P_M is the monopoly optimum price, P_C is the competitive price, and $P_{Cournot}$ is the oligopoly price under the Cournot assumption.

Exhibit 14 Cournot Equilibrium in Duopoly Market



In the later discussion regarding monopoly market structure, equilibrium will be established where MR = MC. That solution is also shown in Exhibit 14. The monopoly firm's demand schedule is the aggregate market demand schedule. Therefore, the solution is

$$\text{MR} = \text{MC}$$

From Footnote 10, MR = $450 - 2Q$; therefore,

$$450 - 2Q = 30 \quad \text{and} \quad Q = 210$$

From the aggregate demand function, solve for price:

$$P_M = 450 - 210 = 240$$

Note that the Cournot solution falls between the competitive equilibrium and the monopoly solution.

It can be shown that as the number of firms increases from two to three, from three to four, and so on, the output and price equilibrium positions move toward the competitive equilibrium solution. This result has historically been the theoretical basis for the antitrust policies established in the United States.

OLIGOPOLY & DEMAND ANALYSIS AND PRICING STRATEGIES IN OLIGOPOLY MARKETS: THE NASH EQUILIBRIUM PART

12

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

f describe pricing strategy under each market structure;

The third pricing strategy is attributed to one of the 1994 Nobel Prize winners, John Nash, who first developed the general concepts. In the previous analysis, the concept of market equilibrium occurs when firms are achieving their optimum remuneration under the circumstances they face. In this optimum environment, the firm has no motive to change price or output level. Existing firms are earning a normal return (zero economic profit), leaving no motive for entry to or exit from the market. All firms in the market are producing at the output level where price equals the average cost of production.

In **game theory** (the set of tools that decision makers use to consider responses by rival decision makers), the **Nash equilibrium** is present when two or more participants in a non-cooperative game have no incentive to deviate from their respective equilibrium strategies after they have considered and anticipated their opponent's rational choices or strategies. In the context of oligopoly markets, the Nash equilibrium is an equilibrium defined by the characteristic that none of the oligopolists can increase its profits by unilaterally changing its pricing strategy. The assumption is made that each participating firm does the best it can, given the reactions of its rivals. Each firm anticipates that the other firms will react to any change made by competitors by doing the best they can under the altered circumstances. The firms in the oligopoly market have interdependent actions. The actions are non-cooperative, with each firm making decisions that maximize its own profits. The firms do not collude in an effort to maximize joint profits. The equilibrium is reached when all firms are doing the best they can, given the actions of their rivals.

Exhibit 15 illustrates the duopoly result from the Nash equilibrium. Assume there are two firms in the market, ArcCo and BatCo. ArcCo and BatCo can charge high prices or low prices for the product. The market outcomes are shown in Exhibit 15.

Exhibit 15 Nash Equilibrium in Duopoly Market

ArcCo – Low Price 50 70 BatCo – Low Price	ArcCo – Low Price 80 0 BatCo – High Price
ArcCo – High Price 300 350 BatCo – Low Price	ArcCo – High Price 500 300 BatCo – High Price

For example, the top left solution indicates that when both ArcCo and BatCo offer the product at low prices, ArcCo earns a profit of 50 and BatCo earns 70. The top right solution shows that if ArcCo offers the product at a low price, BatCo earns zero profits. The solution with the maximum joint profits is the lower right equilibrium, where both firms charge high prices for the product. Joint profits are 800 in this solution.

However, the Nash equilibrium requires that each firm behaves in its own best interest. BatCo can improve its position by offering the product at low prices when ArcCo is charging high prices. In the lower left solution, BatCo maximizes its profits at 350. While ArcCo can earn 500 in its best solution, it can do so only if BatCo also agrees to charge high prices. This option is clearly not in BatCo's best interest because it can increase its return from 300 to 350 by charging lower prices.

This scenario brings up the possibility of collusion. If ArcCo agrees to share at least 51 of its 500 when both companies are charging high prices, BatCo should also be willing to charge high prices. While, in general, such collusion is unlawful in most countries, it remains a tempting alternative. Clearly, conditions in oligopolistic industries encourage collusion, with a small number of competitors and interdependent pricing behavior. Collusion is motivated by several factors: increased profits, reduced cash flow uncertainty, and improved opportunities to construct barriers to entry.

When collusive agreements are made openly and formally, the firms involved are called a **cartel**. In some cases, collusion is successful; other times, the forces of competition overpower collusive behavior. There are six major factors that affect the chances of successful collusion.[13]

1. *The number and size distribution of sellers.* Successful collusion is more likely if the number of firms is small or if one firm is dominant. Collusion becomes more difficult as the number of firms increases or if the few firms have similar market shares. When the firms have similar market shares, the competitive forces tend to overshadow the benefits of collusion.
2. *The similarity of the products.* When the products are homogeneous, collusion is more successful. The more differentiated the products, the less likely it is that collusion will succeed.
3. *Cost structure.* The more similar the firms' cost structures, the more likely it is that collusion will succeed.
4. *Order size and frequency.* Successful collusion is more likely when orders are frequent, received on a regular basis, and relatively small. Frequent small orders, received regularly, diminish the opportunities and rewards for cheating on the collusive agreement.
5. *The strength and severity of retaliation.* Oligopolists will be less likely to break the collusive agreement if the threat of retaliation by the other firms in the market is severe.
6. *The degree of external competition.* The main reason to enter into the formal collusion is to increase overall profitability of the market, and rising profits attract competition. For example, in 2016 the average extraction cost of a barrel of crude oil from Saudi Arabia was approximately $9, while the average cost from United States shale oil fields was roughly $23.50. The cost of extracting oil from the Canadian tar sands in 2016 was roughly $27 per barrel. It is more likely that crude oil producers in the gulf countries will successfully collude because of the similarity in their cost structures (roughly $9–$10 per barrel). If OPEC had held crude oil prices down below $30 per barrel, there would have been a viable economic argument to develop US shale oil fields through fracking or expand extraction from Canada's tar sands. OPEC's successful cartel raised crude oil prices to the point where outside sources became economically possible and in doing so increased the competition the cartel faces.[14]

---

[13] McGuigan, Moyer, and Harris (2016).

[14] "Barrel Breakdown," *Wall Street Journal*, April 15, 2016.

There are other possible oligopoly strategies that are associated with decision making based on game theory. The Cournot equilibrium and the Nash equilibrium are examples of specific strategic games. A strategic game is any interdependent behavioral choice employed by individuals or groups that share a common goal (e.g., military units, sports teams, or business decision makers). Another prominent decision-making strategy in oligopolistic markets is the first-mover advantage in the **Stackelberg model**, named after the economist who first conceptualized the strategy.[15] The important difference between the Cournot model and the Stackelberg model is that Cournot assumes that in a duopoly market, decision making is simultaneous, while Stackelberg assumes that decisions are made sequentially. In the Stackelberg model, the leader firm chooses its output first and then the follower firm chooses after observing the leader's output. It can be shown that the leader firm has a distinct advantage, being a first mover.[16] In the Stackelberg game, the leader can aggressively overproduce to force the follower to scale back its production or even punish or eliminate the weaker opponent. This approach is sometimes referred to as a "top dog" strategy.[17] The leader earns more than in Cournot's simultaneous game, while the follower earns less. Many other strategic games are possible in oligopoly markets. The important conclusion is that the optimal strategy of the firm depends on what its adversary does. The price and marginal revenue the firm receives for its product depend on both its decisions and its adversary's decisions.

13 SUPPLY ANALYSIS & OPTIMAL PRICE AND OUTPUT & LONG-RUN EQUILIBRIUM IN OLIGOPOLY MARKETS

As in monopolistic competition, the oligopolist does not have a well-defined supply function. That is, there is no way to determine the oligopolist's optimal levels of output and price independent of demand conditions and competitor's strategies. However, the oligopolist still has a cost function that determines the optimal level of supply. Therefore, the profit-maximizing rule established earlier is still valid: The level of output that maximizes profit is where MR = MC. The price to charge is determined by what price consumers are willing to pay for that quantity of the product. Therefore, the equilibrium price comes from the demand curve, while the output level comes from the relationship between marginal revenue and marginal cost.

Consider an oligopoly market in which one of the firms is dominant and thus able to be the price leader. Dominant firms generally have 40 percent or greater market share. When one firm dominates an oligopoly market, it does so because it has greater capacity, has a lower cost structure, was first to market, or has greater customer loyalty than other firms in the market.

Assuming there is no collusion, the dominant firm becomes the price maker, and therefore its actions are similar to monopoly behavior in its segment of the market. The other firms in the market follow the pricing patterns of the dominant firm. Why wouldn't the price followers attempt to gain market share by undercutting the dominant firm's price? The most common explanation is that the dominant firm's supremacy often stems from a lower cost of production. Usually, the price followers would rather charge a price that is even higher than the dominant firm's price choice. If they attempt to undercut the dominant firm, the followers risk a price war with a lower-cost producer that can threaten their survival. Some believe that one explanation for the price leadership position of the dominant firm is simply convenience. Only one firm has to make the pricing decisions, and the others can simply follow its lead.

---

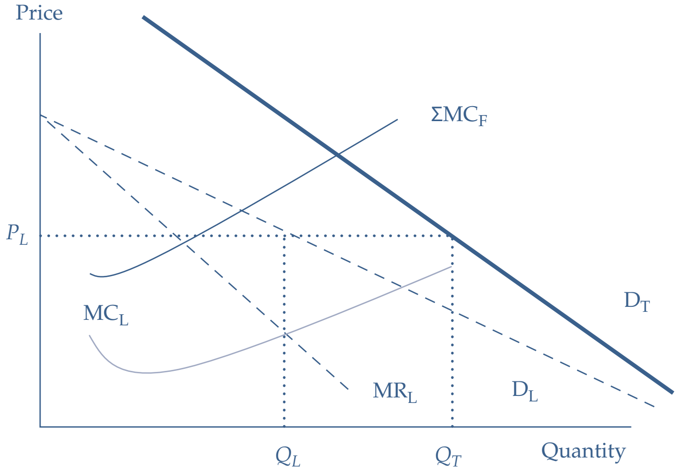
[15] Von Stackelberg (1952). See also Kelly (2011) for a comparison between the Cournot and Stackelberg equilibriums.

[16] Nicholson and Snyder (2016).

[17] Fudenberg and Tirole (1984).

Exhibit 16 establishes the dominant firm's pricing decision. The dominant firm's demand schedule, D_L, is a substantial share of the total market demand, D_T. The low-cost position of the dominant firm is represented by its marginal cost, MC_L. The sum of the marginal costs of the price followers is established as ΣMC_F and represents a higher cost of production than that of the price leader.

Exhibit 16 Dominant Oligopolist's Price Leadership



There is an important reason why the total demand curve and the leader demand curve are not parallel in Exhibit 16: Remember that the leader is the low-cost producer. Therefore, as price decreases, fewer of the smaller suppliers will be able to profitably remain in the market, and several will exit because they do not want to sell below cost. Therefore, the leader will have a larger market share as P decreases, which implies that Q_L increases at a low price, exactly as shown by a steeper D_T in the diagram.

The price leader identifies its profit-maximizing output where $MR_L = MC_L$, at output Q_L. This is the quantity it wants to supply; however, the price it will charge is determined by its segment of the total demand function, D_L. At price P_L, the dominant firm will supply quantity Q_L of total demand, D_T. The price followers will supply the difference to the market, $(Q_T - Q_L) = Q_F$. Therefore, neither the dominant firm nor the follower firms have a single functional relationship that determines the quantity supplied at various prices.

13.1 Optimal Price and Output in Oligopoly Markets

From the discussion above, clearly there is no single optimum price and output analysis that fits all oligopoly market situations. The interdependence among the few firms that make up the oligopoly market provides a complex set of pricing alternatives, depending on the circumstances in each market. In the case of the kinked demand curve, the optimum price is the prevailing price at the kink in the demand function. However, as previously noted, the kinked demand curve analysis does not provide insight into what established the prevailing price in the first place.

Perhaps the case of the dominant firm, with the other firms following the price leader, is the most obvious. In that case, the optimal price is determined at the output level where MR = MC. The profit-maximizing price is then determined by the output position of the segment of the demand function faced by the dominant firm. The price followers have little incentive to change the leader's price. In the case of the Cournot assumption, each firm assumes that the other firms will not alter their output following the dominant firm's selection of its price and output level.

Therefore, again, the optimum price is determined by the output level where MR = MC. In the case of the Nash equilibrium, each firm will react to the circumstances it faces, maximizing its own profit. These adjustments continue until there are stable prices and levels of output. Because of the interdependence, there is no certainty as to the individual firm's price and output level.

13.2 Factors Affecting Long-Run Equilibrium in Oligopoly Markets

Long-run economic profits are possible for firms operating in oligopoly markets. However, history has shown that, over time, the market share of the dominant firm declines. Profits attract entry by other firms into the oligopoly market. Over time, the marginal costs of the entrant firms decrease because they adopt more efficient production techniques, the dominant firm's demand and marginal revenue shrink, and the profitability of the dominant firm declines. In the early 1900s, J.P. Morgan, Elbert Gary, Andrew Carnegie, and Charles M. Schwab created the United States Steel Corporation (US Steel). When it was first formed in 1901, US Steel controlled 66 percent of the market. By 1920, US Steel's market share had declined to 46 percent, and by 1925 its market share was 42 percent.

In the long run, optimal pricing strategy must include the reactions of rival firms. History has proven that pricing wars should be avoided because any gains in market share are temporary. Decreasing prices to drive competitors away lowers total revenue to all participants in the oligopoly market. Innovation may be a way—though sometimes an uneconomical one—to maintain market leadership.

OLIGOPOLIES: APPEARANCE VERSUS BEHAVIOR

When is an oligopoly not an oligopoly? There are two extreme cases of this situation. A normal oligopoly has a few firms producing a differentiated good, and this differentiation gives them pricing power.

At one end of the spectrum, we have the oligopoly with a credible threat of entry. In practice, if the oligopolists are producing a good or service that can be easily replicated, has limited economies of scale, and is not protected by brand recognition or patents, they will not be able to charge high prices. The easier it is for a new supplier to enter the market, the lower the margins. In practice, this oligopoly will behave very much like a perfectly competitive market.

At the opposite end of the spectrum, we have the case of the cartel. Here, the oligopolists collude and act as if they were a single firm. In practice, a very effective cartel enacts a cooperative strategy. As shown in Sections 11 and 12, instead of going to a Nash equilibrium, the cartel participants go to the more lucrative (for them) cooperative equilibrium.

A cartel may be explicit (that is, based on a contract) or implicit (based on signals). An example of signals in a duopoly would be that one of the firms reduces its prices and the other does not. Because the firm not cutting prices refuses to start a price war, the firm that cut prices may interpret this signal as a "suggestion" to raise prices to a higher level than before, so that profits may increase for both.

MONOPOLY & DEMAND & SUPPLY & OPTIMAL PRICE AND OUTPUT IN MONOPOLY MARKETS

14

a describe characteristics of perfect competition, monopolistic competition, oligopoly, and pure monopoly;

b explain relationships between price, marginal revenue, marginal cost, economic profit, and the elasticity of demand under each market structure;

c describe a firm's supply function under each market structure;

d describe and determine the optimal price and output for firms under each market structure;

e explain factors affecting long-run equilibrium under each market structure;

f describe pricing strategy under each market structure;

Monopoly market structure is at the opposite end of the spectrum from perfect competition. For various reasons, there are significant barriers to entry such that a single firm produces a highly specialized product and faces no threat of competition. There are no good substitutes for the product in the relevant market, and the market demand function is the same as the individual firm's demand schedule. *The distinguishing characteristics of monopoly are that a single firm represents the market and significant barriers to entry exist.* Exhibit 1 identified the characteristics of monopoly markets:

1. There is a single seller of a highly differentiated product.
2. The product offered by the seller has no close substitute.
3. Entry into the market is very difficult, with high costs and significant barriers to competition.
4. The firm has considerable pricing power.
5. The product is differentiated through non-price strategies such as advertising.

Monopoly markets are unusual. With a single seller dominating the market, power over price decisions is significant. For a single seller to achieve this power, there must be factors that allow the monopoly to exist. One obvious source of monopoly power would be a patent or copyright that prevents other firms from entering the market. Patent and copyright laws exist to reward intellectual capital and investment in research and development. In so doing, they provide significant barriers to entry.

Another possible source of market power is control over critical resources used for production. One example is De Beers Consolidated Mines Limited. De Beers owned or controlled all diamond mining operations in South Africa and established pricing agreements with other important diamond producers. In doing so, De Beers was able to control the prices for cut diamonds for decades. Technically, De Beers was a near-monopoly dominant firm rather than a pure monopoly, although its pricing procedure for cut diamonds resembled monopoly behavior.

Perhaps the most common form of monopolistic market power occurs as the result of government-controlled authorization. In most urban areas, a single source of water and sewer services is offered. In some cases, these services are offered by a government-controlled entity. In other cases, private companies provide the services under government regulation. Such "natural" monopolies require a large initial investment that benefits from economies of scale; therefore, government may authorize a single seller to provide a certain service because having multiple sellers would be too costly. For example, electricity in most markets is provided by a single seller. Economies of scale result when significant capital investment benefits from declining long-run average costs. In the case of electricity, a large gas-fueled power plant producing electricity for a large area is substantially more efficient than having a small diesel generator for every building. That is, the average cost of generating and delivering a kilowatt of electricity will be substantially lower with the single power station, but the initial fixed cost of building the power station and the lines delivering electricity to each home, factory, and office will be very high.

In the case of natural monopolies, limiting the market to a single seller is considered beneficial to society. One water and sewer system is deemed better for the community than dozens of competitors because building multiple infrastructures for running water and sewer service would be particularly expensive and complicated. One electrical power grid supplying electricity for a community can make large capital investments in generating plants and lower the long-run average cost, while multiple power grids would lead to a potentially dangerous maze of wires. Clearly, not all monopolies are in a position to make significant economic profits. Regulators, such as public utility commissions in the United States, attempt to determine what a normal return for the monopoly owners' investment should be, and they set prices accordingly. Nevertheless, monopolists attempt to maximize profits.

Not all monopolies originate from "natural" barriers. For some monopolists, barriers to entry do not derive from increasing returns to scale. We mentioned that marketing and brand loyalty are sources of product differentiation in monopolistic competition. In some highly successful cases, strong brand loyalty can become a formidable barrier to entry. For example, if the Swiss watchmaker Rolex is unusually successful in establishing brand loyalty, so that its customers think there is no close substitute for its product, then the company will have monopoly-like pricing power over its market.

The final potential source of market power is the increasing returns associated with network effects. Network effects result from synergies related to increasing market penetration. By achieving a critical level of adoption, Microsoft was able to extend its market power through the network effect—for example, because most computer users know how to use Microsoft Word. Therefore, for firms, Word is cheaper to adopt than other programs because almost every new hire will be proficient in using the software and will need no further training. At some level of market share, a network-based product or service (think of Facebook or eBay) reaches a point where each additional share point increases the probability that another user will adopt.[18] These network effects increase the value to other potential adopters. In Microsoft's case, the network effects crowded out other potential competitors, including Netscape's internet browser, that might have led to applications bypassing Windows. Eventually, Microsoft's operating system's market share reached 92 percent of the global market. Similar situations occur in financial markets: If a publicly listed share or a derivative contract is more frequently traded on a certain exchange, market participants wishing to sell or buy the security will go to the more liquid exchange because they expect to find a better price and faster execution there.

14.1 Demand Analysis in Monopoly Markets

The monopolist's demand schedule is the aggregate demand for the product in the relevant market. Because of the income effect and the substitution effect, demand is negatively related to price, as usual. The slope of the demand curve is negative and therefore downward sloping. The general form of the demand relationship is

$$Q_D = a - bP \qquad \text{or, rewritten,} \qquad P = a/b - (1/b)Q_D$$

$$\text{Therefore, total revenue} = \text{TR} = P \times Q = (a/b)Q_D - (1/b)Q_D^2$$

---

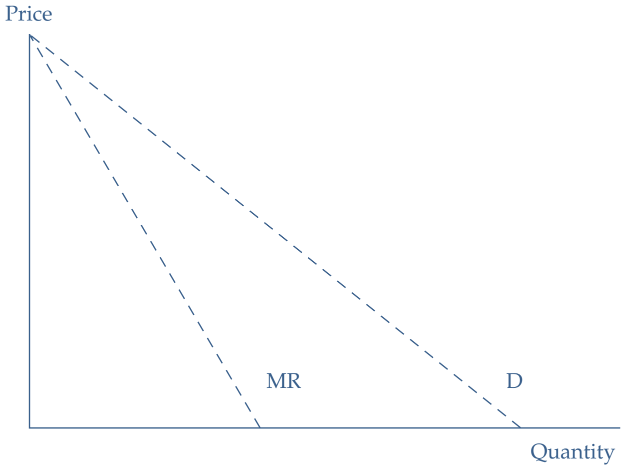
[18] When a network-based device reaches a 30 percent share, the next 50 percentage points are cheaper to promote, according to McGuigan, Moyer, and Harris (2016).

Marginal revenue is the change in revenue given a change in the quantity demanded. Because an increase in quantity requires a lower price, the marginal revenue schedule is steeper than the demand schedule. If the demand schedule is linear, then the marginal revenue curve is twice as steep as the demand schedule.[19]

$$MR = \Delta TR/\Delta Q = (a/b) - (2/b)Q_D$$

The demand and marginal revenue relationship is expressed in Exhibit 17.

Exhibit 17 Monopolist's Demand and Marginal Revenue



Suppose a company operating on a remote island is the single seller of natural gas. Demand for its product can be expressed as

$Q_D = 400 - 0.5P$, which can be rearranged as
$P = 800 - 2Q_D$

Total revenue is $P \times Q = TR = 800Q_D - 2Q_D^2$, and marginal revenue is $MR = 800 - 4Q_D$.[20]

In Exhibit 17, the demand curve's intercept is 800 and the slope is –2. The marginal revenue curve in Exhibit 17 has an intercept of 800 and a slope of –4.

Average revenue is TR/Q_D; therefore, $AR = 800 - 2Q_D$, which is the same as the demand function. In the monopoly market model, average revenue is the same as the market demand schedule.

14.2 Supply Analysis in Monopoly Markets

A monopolist's supply analysis is based on the firm's cost structure. As in the market structures of monopolistic competition and oligopoly, the monopolist does not have a well-defined supply function that determines the optimal output level and the price to charge. The optimal output is the profit-maximizing output level. The profit-maximizing level of output occurs where marginal revenue equals marginal cost, MR = MC.

---

[19] Marginal revenue can be found using the technique shown in Section 2.1 or, for readers who are familiar with calculus, by taking the derivative of the total revenue function: $MR = \Delta TR/\Delta Q = (a/b) - (2/b)Q_D$.

[20] $MR = \Delta TR/\Delta Q = 800 - 4Q$.

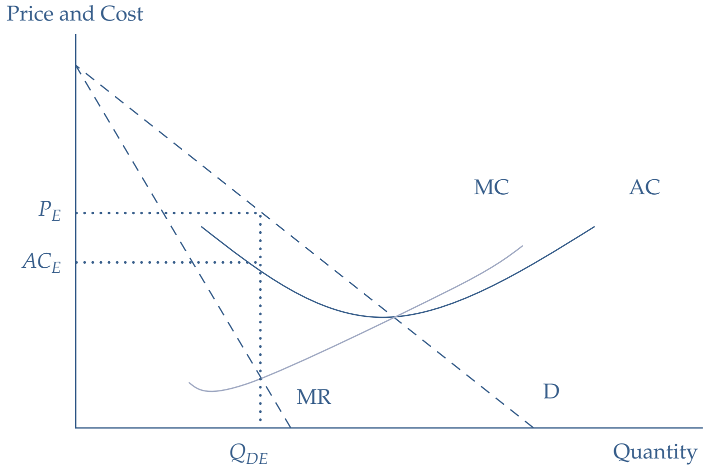
Assume the natural gas company has determined that its total cost can be expressed as

$$\text{TC} = 20{,}000 + 50Q + 3Q^2$$

Marginal cost is $\Delta\text{TC}/\Delta Q = \text{MC} = 50 + 6Q$.[21]

Supply and demand can be combined to determine the profit-maximizing level of output. Exhibit 18 combines the monopolist's demand and cost functions.

Exhibit 18 Monopolist's Demand, Marginal Revenue, and Cost Structures



In Exhibit 18, the demand and marginal revenue functions are clearly defined by the aggregate market. However, the monopolist does not have a supply curve. The quantity that maximizes profit is determined by the intersection of MC and MR, Q_{DE}.

The price consumers are willing to pay for this level of output is P_E, as determined by the demand curve, P_E.

The profit-maximizing level of output is MR = MC: $800 - 4Q_D = 50 + 6Q_D$; therefore, $Q_D = 75$ when profit is maximized.

Total profit equals total revenue minus total cost:

$$\pi = 800Q - 2Q_D^2 - \left(20{,}000 + 50Q_D + 3Q_D^2\right) = -20{,}000 + 750Q_D - 5Q_D^2$$

Profit is represented by the difference between the area of the rectangle $Q_{DE} \times P_E$, representing total revenue, and the area of the rectangle $Q_{DE} \times AC_E$, representing total cost.

MONOPOLISTS AND THEIR INCENTIVES

In theoretical models, which usually take product quality and technology as given, monopolists can choose to vary either price or quantity. In real life, they also can vary their product.

A monopolist can choose to limit quality if producing a higher-quality product is costly and higher quality does not increase profits accordingly. For example, the quality of domestically produced cars in most developed countries improved dramatically once imports became more available. Before the opening of borders to imports, the single incumbent that dominated the market (for example, Fiat in Italy) or the small group of incumbents acting as a collusive oligopoly (such as the Detroit “Big Three” in the United States) were the effective monopolists of their domestic automobile markets. Rust corrosion, limited reliability, and poor gas mileage were common.[22]

---

[21] The marginal cost equation can be found in this case by applying the technique used to find the marginal revenue equation in Section 2.1, or by taking the derivative of the total cost function.

Similarly, regulated utilities may have limited incentives to innovate. Several studies, including Gómez-Ibáñez (2003), have found that state-owned and other monopoly telephone utilities tended to provide very poor service before competition was introduced. Poor service may not be limited to poor connection quality but may also include extensive delays in adding new users and limited introduction of new services, such as caller ID or automatic answering services.

Intuitively, a monopolist will not spend resources on quality control, research and development, or even customer relations unless there is a threat of entry of a new competitor or unless there is a clear link between such expenses and a profit increase. In contrast, in competitive markets, including oligopoly, innovation and quality are often ways to differentiate the product and increase profits.

14.3 Optimal Price and Output in Monopoly Markets

Continuing the natural gas example from above, the total profit function can be solved using the quadratic formula.[23] Another method to solve the profit function is to evaluate $\Delta\pi/\Delta Q_D$ and set it equal to zero. This identifies the point at which profit is unaffected by changes in output.[24] Of course, this will give the same result as we found by equating marginal revenue with marginal cost. The monopoly will maximize profits when $Q^* = 75$ units of output and the price is set from the demand curve at 650.

$$P^* = 800 - 2(75) = 650 \text{ per unit}$$

To find total maximum profits, substitute these values into the profit function above:

$$\pi = -20{,}000 + 750Q_D - 5Q_D^2 = -20{,}000 + 750(75) - 5\left(75^2\right) = 8{,}125$$

Note that the price and output combination that maximizes profit occurs in the elastic portion of the demand curve in Exhibit 18. This must be so because marginal revenue and marginal cost will always intersect where marginal revenue is positive. This fact implies that quantity demanded responds more than proportionately to prices changes, i.e. demand is elastic, at the point at which MC = MR. As noted earlier, the relationship between marginal revenue and price elasticity, E_P, is:

$$\text{MR} = P[1 - 1/E_P]$$

In monopoly, MR = MC; therefore,

$$P[1 - 1/E_P] = \text{MC}$$

The firm can use this relationship to determine the profit-maximizing price if the firm knows its cost structure and the price elasticity of demand, E_P. For example, assume the firm knows that its marginal cost is constant at 75 and recent market analysis indicates that price elasticity is estimated to be 1.5. The optimal price is solved as

$$P[1 - 1/1.5] = 75 \text{ and}$$

$$P = 225$$

---

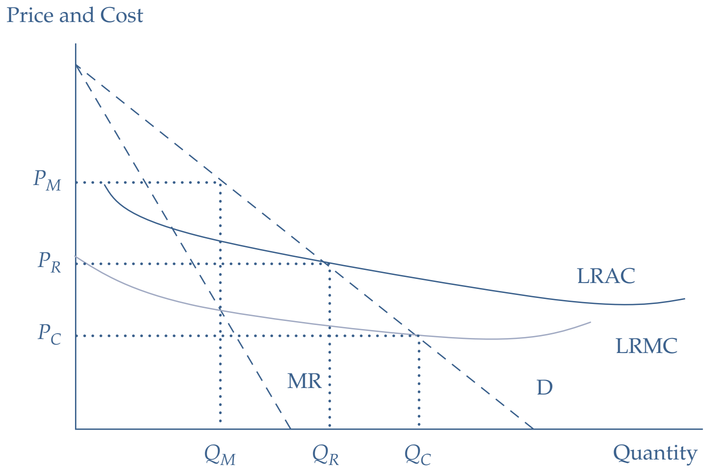
[22] For more on this topic, see Banker, Khosla, and Sinha (1998).

[23] The quadratic formula, where $aQ^2 + bQ + c = 0$, is $Q = \left\{-b \pm \sqrt{\left(b^2 - 4ac\right)}\right\} \Big/ 2a$.

[24] Maximum profit occurs where $\Delta\pi/\Delta Q_D = 0 = 750 - 10Q_D$. Therefore, profits are maximized at $Q_D = 75$.

Exhibit 18 indicated that the monopolist wants to produce at Q_E and charge the price of P_E. Suppose this is a natural monopoly that is operating as a government franchise under regulation. Natural monopolies are usually found where production is based on significant economies of scale and declining cost structure in the market. Examples include electric power generation, natural gas distribution, and the water and sewer industries. These are often called public utilities. Exhibit 19 illustrates such a market in long-run equilibrium.

Exhibit 19 Natural Monopoly in a Regulated Pricing Environment



In Exhibit 19, three possible pricing and output solutions are presented. The first is what the monopolist would do without regulation: The monopolist would seek to maximize profits by producing Q_M units of the product, where long-run marginal cost equals marginal revenue, LRMC = MR. To maximize profits, the monopolist would raise the price to the level the demand curve will accept, P_M.

In perfect competition, the price and output equilibrium occurs where price is equal to the marginal cost of producing the incremental unit of the product. In a competitive market, the quantity produced would be higher, Q_C, and the price lower, P_C. For this regulated monopoly, the competitive solution would be unfair because at output Q_C, the price P_C would not cover the average cost of production. One possibility is to subsidize the difference between the long-run average cost, LRAC, and the competitive price, P_C, for each unit sold.

Another solution is for the regulator to set the price at the point where long-run average cost equals average revenue. Recall that the demand curve represents the average revenue the firm receives at each output level. The government regulator will attempt to determine the monopolistic firm's long-run average cost and set the output and price so that the firm receives a fair return on the owners' invested capital. The regulatory solution is output level Q_R, with the price set at P_R. Therefore, the regulatory solution is found between the unregulated monopoly equilibrium and the competitive equilibrium.

15 PRICE DISCRIMINATION AND CONSUMER SURPLUS

- f describe pricing strategy under each market structure;

Monopolists can either be more or less effective in taking advantage of their market structure. At one extreme, we have a monopolist that charges prices and supplies quantities that are the same as they would be in perfect competition; this scenario may be a result of regulation or threat of entry (if the monopolist charged more, another company could come in and price the former monopolist out of the market). At the opposite extreme, hated by all consumers and economists, is the monopolist that extracts the entire consumer surplus. This scenario is called **first-degree price discrimination**, where a monopolist can charge each customer the highest price the customer is willing to pay. This is called price discrimination because the monopolist charges a different price to each client. How can this be? For example, if the monopolist knows the exact demand schedule of the customer, then the monopolist can capture the entire consumer surplus. In practice, the monopolist can measure how often the product is used and charges the customer the highest price the consumer is willing to pay for that unit of good. Another possibility is that public price disclosure is non-existent, so that no customer knows what the other customers are paying. Interestingly, not every consumer is worse off in this case, because some consumers may be charged a price that is below that of perfect competition, as long as the marginal revenue exceeds the marginal cost.

In **second-degree price discrimination** the monopolist offers a menu of quantity-based pricing options designed to induce customers to self-select based on how highly they value the product. Such mechanisms include volume discounts, volume surcharges, coupons, product bundling, and restrictions on use. In practice, producers can use not just the quantity but also the quality (e.g., “professional grade”) to charge more to customers that value the product highly.

Third-degree price discrimination happens when customers are segregated by demographic or other traits. For example, some econometric software is licensed this way: A student version can handle only small datasets and is sold for a low price; a professional version can handle very large datasets and is sold at a much higher price because corporations need to compute the estimates for their business and are therefore willing to pay more for a license. Another example is that airlines know that passengers who want to fly somewhere and come back the same day are most likely business people; therefore, one-day roundtrip tickets are generally more expensive than tickets with a return flight at a later date or over a weekend.

Price discrimination has many practical applications when the seller has pricing power. The best way to understand how this concept works is to think of consumer surplus: As seen in this reading, a consumer may be willing to pay more for the first unit of a good, but to buy a second unit she will want to pay a lower price, thus getting a better deal on the first unit. In practice, sellers can sometimes use income and substitution effects to their advantage. Think of something you often buy, perhaps lunch at your favorite café. How much would you be willing to pay for a “lunch club membership card” that would allow you to purchase lunches at, say, half price? If the café could extract from you the maximum amount each month that you would be willing to pay for the half-price option, then it would successfully have removed the income effect from you in the form of a monthly fixed fee. Notice that a downward-sloping demand curve implies that you would end up buying more lunches each month than before you purchased the discount card, even though you would be no better or worse off than before. This is a way that sellers are sometimes able to extract consumer surplus by means of creative pricing schemes. It’s a common practice among big-box retailers, sports clubs, and other users of what is called “two-part tariff pricing,” as in the example below.

EXAMPLE 3

Price Discrimination

Nicole's monthly demand for visits to her health club is given by the following equation: $Q_D = 20 - 4P$, where Q_D is visits per month and P is euros per visit. The health club's marginal cost is fixed at €2 per visit.

1. Draw Nicole's demand curve for health club visits per month.
2. If the club charged a price per visit equal to its marginal cost, how many visits would Nicole make per month?
3. How much consumer surplus would Nicole enjoy at that price?
4. How much could the club charge Nicole each month for a membership fee?

Solution to 1:

$Q_D = 20 - 4P$, so when $P = 0$, $Q_D = 20$. Inverting, $P = 5 - 0.25Q_D$, so when $Q = 0$, $P = 5$.

Solution to 2:

$Q_D = 20 - 4(2) = 12$. Nicole would make 12 visits per month at a price of €2 per visit.

Solution to 3:

Nicole's consumer surplus can be measured as the area under her demand curve and above the price she pays for a total of 12 visits, or $(0.5)(12)(3) = 18$. Nicole would enjoy a consumer surplus of €18 per month.

Solution to 4:

The club could extract all of Nicole's consumer surplus by charging her a monthly membership fee of €18 plus a per-visit price of €2. This pricing method is called a two-part tariff because it assesses one price per unit of the item purchased plus a per-month fee (sometimes called an "entry fee") equal to the buyer's consumer surplus evaluated at the per-unit price.

16 FACTORS AFFECTING LONG-RUN EQUILIBRIUM IN MONOPOLY MARKETS

e explain factors affecting long-run equilibrium under each market structure;

The unregulated monopoly market structure can produce economic profits in the long run. In the long run, all factors of production are variable, while in the short run, some factors of production are fixed. Generally, the short-run factor that is fixed is the capital investment, such as the factory, machinery, production technology, available arable land, and so forth. The long-run solution allows for all inputs, including technology, to change. In order to maintain a monopoly market position in the long run, the firm must be protected by substantial and ongoing barriers to entry. If the monopoly position is the result of a patent, then new patents must be continuously added to prevent the entry of other firms into the market.

For regulated monopolies, such as natural monopolies, there are a variety of long-run solutions. One solution is to set the price equal to marginal cost, $P = \text{MC}$. However, that price will not likely be high enough to cover the average cost of production, as Exhibit 19 illustrated. The answer is to provide a subsidy sufficient to compensate the firm. The national rail system in the United States, Amtrak, is an example of a regulated monopoly operating with a government subsidy.

National ownership of the monopoly is another solution. Nationalization of the natural monopoly has been a popular solution in Europe and other parts of the world. The United States has generally avoided this potential solution. One problem with this arrangement is that once a price is established, consumers are unwilling to accept price increases, even as factor costs increase. Politically, raising prices on products from government-owned enterprises is highly unpopular.

Establishing a governmental entity that regulates an authorized monopoly is another popular solution. Exhibit 19 illustrated the appropriate decision rule. The regulator sets price equal to long-run average cost, $P_R = \text{LRAC}$. This solution assures that investors will receive a normal return for the risk they are taking in the market. Given that no other competitors are allowed, the risk is lower than in a highly competitive market environment. The challenge facing the regulator is determining the authentic risk-related return and the monopolist's realistic long-run average cost.

The final solution is to franchise the monopolistic firm through a bidding war. Again, the public goal is to select the winning firm based on price equaling long-run average cost. Retail outlets at rail stations and airports and concession outlets at stadiums are examples of government franchises. The long-run success of the monopoly franchise depends on its ability to meet the goal of pricing its products at the level of its long-run average cost.

EXAMPLE 4

Monopolies and Efficiency

Are monopolies *always* inefficient?

A No, because if they charge more than average cost they are nationalized.

B Yes, because they charge all consumers more than perfectly competitive markets would.

C No, because economies of scale and regulation (or threat of entry) may give a better outcome for buyers than perfect competition.

Solution:

C is correct. Economies of scale and regulation may make monopolies more efficient than perfect competition.

IDENTIFICATION OF MARKET STRUCTURE

17

g describe the use and limitations of concentration measures in identifying market structure;

h identify the type of market structure within which a firm operates.

Monopoly markets and other situations where companies have pricing power can be inefficient because producers constrain output to cause an increase in prices. Therefore, there will be less of the good being consumed and it will be sold at a higher price, which is generally inefficient for the overall market. As a result, many countries have introduced competition law to regulate the degree of competition in many industries.

Market power in the real world is not always as clear as it is in textbook examples. Governments and regulators often have the difficult task of measuring market power and establishing whether a firm has a dominant position that may resemble a monopoly. A few historical examples of this are as follows:

1. In the 1990s, US regulators prosecuted agricultural corporation Archer Daniels Midland for conspiring with Japanese competitors to fix the price of lysine, an amino acid used as an animal feed additive. The antitrust action resulted in a settlement that involved over US$100 million in fines paid by the cartel members.
2. In the 1970s, US antitrust authorities broke up the local telephone monopoly, leaving AT&T the long-distance business (and opening that business to competitors), and required AT&T to divest itself of the local telephone companies it owned. This antitrust decision brought competition, innovation, and lower prices to the US telephone market.
3. European regulators (specifically, the European Commission) have affected the mergers and monopoly positions of European corporations (as in the case of the companies Roche, Rhone-Poulenc, and BASF, which were at the center of a vitamin price-fixing case) as well as non-European companies (such as Intel) that do business in Europe. Moreover, the merger between the US company General Electric and the European company Honeywell was denied by the European Commission on grounds of excessive market concentration.

Quantifying excessive market concentration is difficult. Sometimes, regulators need to measure whether something that has not yet occurred might generate excessive market power. For example, a merger between two companies might allow the combined company to be a monopolist or quasi monopolist in a certain market.

A financial analyst hearing news about a possible merger should always consider the impact of competition law (sometimes called antitrust law)—that is, whether a proposed merger may be blocked by regulators in the interest of preserving a competitive market.

17.1 Econometric Approaches

How should one measure market power? The theoretical answer is to estimate the elasticity of demand and supply in a market. If demand is very elastic, the market must be very close to perfect competition. If demand is rigid (inelastic), companies *may* have market power. This is the approach taken in the cellophane case mentioned in Section 4.

From the econometric point of view, this estimation requires some attention. The problem is that observed price and quantity are the equilibrium values of price and quantity and do not represent the value of either supply or demand. Technically, this is called the problem of endogeneity, in the sense that the equilibrium price and quantity are jointly determined by the interaction of demand and supply. Therefore, to have an appropriate estimation of demand and supply, we will need to use a model with two equations, namely, an equation of demanded quantity (as a function of price, income of the buyers, and other variables) and an equation of supplied quantity (as a function of price, production costs, and other variables). The estimated parameters will then allow us to compute elasticity.

Regression analysis is useful in computing elasticity but requires a large number of observations. Therefore, one may use a time-series approach and, for example, look at 20 years of quarterly sales data for a market. However, the market structure may have changed radically over those 20 years, and the estimated elasticity may not apply to the current situation. Moreover, the supply curve may change due to a merger among large competitors, and the estimation based on past data may not be informative regarding the future state of the market post merger.

An alternative approach is a cross-sectional regression analysis. Instead of looking at total sales and average prices in a market over time (the time-series approach mentioned above), we can look at sales from different companies in the market during the same year, or even at single transactions from many buyers and companies. Clearly, this approach requires substantial data-gathering effort, and therefore, this estimation method can be complicated. Moreover, different specifications of the explanatory variables (for example, using total GDP rather than median household income or per-capita GDP to represent income) may sometimes lead to dramatically different estimates.

17.2 Simpler Measures

Trying to avoid the above drawbacks, analysts often use simpler measures to estimate elasticity. The simplest measure is the concentration ratio, which is the sum of the market shares of the largest *N* firms. To compute this ratio, one would, for example, add the sales values of the largest 10 firms and divide this figure by total market sales. This number is always between zero (perfect competition) and 100 percent (monopoly).

The main advantage of the concentration ratio is that it is simple to compute, as shown above. The disadvantage is that it does not directly quantify market power. In other words, is a high concentration ratio a clear signal of monopoly power? The analysis of entry in Section 1 explains clearly that this is not the case: A company may be the only incumbent in a market, but if the barriers to entry are low, the simple presence of a *potential* entrant may be sufficient to convince the incumbent to behave like a firm in perfect competition. For example, a sugar wholesaler may be the only one in a country, but the knowledge that other large wholesalers in the food industry might easily add imported sugar to their range of products should convince the sugar wholesaler to price its product as if it were in perfect competition.

Another disadvantage of the concentration ratio is that it tends to be unaffected by mergers among the top market incumbents. For example, if the largest and second-largest incumbents merge, the pricing power of the combined entity is likely to be larger than that of the two pre-existing companies. But the concentration ratio may not change much.

CALCULATING THE CONCENTRATION RATIO

Suppose there are eight producers of a certain good in a market. The largest producer has 35 percent of the market, the second largest has 25 percent, the third has 20 percent, the fourth has 10 percent, and the remaining four have 2.5 percent each. If we computed the concentration ratio of the top three producers, it would be 35 + 25 + 20 = 80 percent, while the concentration ratio of the top four producers would be 35 + 25 + 20 + 10 = 90 percent.

If the two largest companies merged, the new concentration ratio for the top three producers would be 60 (the sum of the market shares of the merged companies) + 20 + 10 = 90 percent, and the concentration ratio for the four top producers would be 92.5 percent. Therefore, this merger affects the concentration ratio very mildly, even though it creates a substantial entity that controls 60 percent of the market.

For example, the effect of consolidation in the US retail gasoline market has resulted in increasing degrees of concentration. In 1992, the top four companies in the US retail gasoline market shared 33 percent of the market. By 2001, the top four companies controlled 78 percent of the market (Exxon Mobil 24 percent, Shell 20 percent, BP/Amoco/Arco 18 percent, and Chevron/Texaco 16 percent).

To avoid the known issues with concentration ratios, economists O.C. Herfindahl and A.O. Hirschman suggested an index where the market shares of the top N companies are first squared and then added. If one firm controls the whole market (a monopoly), the Herfindahl–Hirschman index (HHI) equals 1. If there are M firms in the industry with equal market shares, then the HHI equals $(1/M)$. This provides a useful gauge for interpreting an HHI. For example, an HHI of 0.20 would be analogous to having the market shared equally by 5 firms.

The HHI for the top three companies in the example in the box above would be $0.35^2 + 0.25^2 + 0.20^2 = 0.225$ before the merger, while after the merger, it would be $0.60^2 + 0.20^2 + 0.10^2 = 0.410$, which is substantially higher than the initial 0.225. The HHI is widely used by competition regulators; however, just like the concentration ratio, the HHI does not take the possibility of entry into account, nor does it consider the elasticity of demand. Therefore, the HHI has limited use for a financial analyst trying to estimate the potential profitability of a company or group of companies.

EXAMPLE 5

The Herfindahl–Hirschman Index

Suppose a market has 10 suppliers, each of them with 10 percent of the market. What are the concentration ratio and the HHI of the top four firms?

A Concentration ratio 4 percent and HHI 40

B Concentration ratio 40 percent and HHI 0.4

C Concentration ratio 40 percent and HHI 0.04

Solution:

C is correct. The concentration ratio for the top four firms is 10 + 10 + 10 + 10 = 40 percent, and the HHI is $0.10^2 \times 4 = 0.01 \times 4 = 0.04$.

SUMMARY

In this reading, we have surveyed how economists classify market structures. We have analyzed the distinctions between the different structures that are important for understanding demand and supply relations, optimal price and output, and the factors affecting long-run profitability. We also provided guidelines for identifying market structure in practice. Among our conclusions are the following:

- Economic market structures can be grouped into four categories: perfect competition, monopolistic competition, oligopoly, and monopoly.
- The categories differ because of the following characteristics: The number of producers is many in perfect and monopolistic competition, few in oligopoly, and one in monopoly. The degree of product differentiation, the pricing power

of the producer, the barriers to entry of new producers, and the level of non-price competition (e.g., advertising) are all low in perfect competition, moderate in monopolistic competition, high in oligopoly, and generally highest in monopoly.

- A financial analyst must understand the characteristics of market structures in order to better forecast a firm's future profit stream.
- The optimal marginal revenue equals marginal cost. However, only in perfect competition does the marginal revenue equal price. In the remaining structures, price generally exceeds marginal revenue because a firm can sell more units only by reducing the per unit price.
- The quantity sold is highest in perfect competition. The price in perfect competition is usually lowest, but this depends on factors such as demand elasticity and increasing returns to scale (which may reduce the producer's marginal cost). Monopolists, oligopolists, and producers in monopolistic competition attempt to differentiate their products so that they can charge higher prices.
- Typically, monopolists sell a smaller quantity at a higher price. Investors may benefit from being shareholders of monopolistic firms that have large margins and substantial positive cash flows.
- Competitive firms do not earn economic profit. There will be a market compensation for the rental of capital and of management services, but the lack of pricing power implies that there will be no extra margins.
- While in the short run firms in any market structure can have economic profits, the more competitive a market is and the lower the barriers to entry, the faster the extra profits will fade. In the long run, new entrants shrink margins and push the least efficient firms out of the market.
- Oligopoly is characterized by the importance of strategic behavior. Firms can change the price, quantity, quality, and advertisement of the product to gain an advantage over their competitors. Several types of equilibrium (e.g., Nash, Cournot, kinked demand curve) may occur that affect the likelihood of each of the incumbents (and potential entrants in the long run) having economic profits. Price wars may be started to force weaker competitors to abandon the market.
- Measuring market power is complicated. Ideally, econometric estimates of the elasticity of demand and supply should be computed. However, because of the lack of reliable data and the fact that elasticity changes over time (so that past data may not apply to the current situation), regulators and economists often use simpler measures. The concentration ratio is simple, but the HHI, with little more computation required, often produces a better figure for decision making.

PRACTICE PROBLEMS

1 A market structure characterized by many sellers with each having some pricing power and product differentiation is *best* described as:

A oligopoly.

B perfect competition.

C monopolistic competition.

2 A market structure with relatively few sellers of a homogeneous or standardized product is *best* described as:

A oligopoly.

B monopoly.

C perfect competition.

3 Market competitors are *least likely* to use advertising as a tool of differentiation in an industry structure identified as:

A monopoly.

B perfect competition.

C monopolistic competition.

4 Upsilon Natural Gas, Inc. is a monopoly enjoying very high barriers to entry. Its marginal cost is \$40 and its average cost is \$70. A recent market study has determined the price elasticity of demand is 1.5. The company will *most likely* set its price at:

A \$40.

B \$70.

C \$120.

5 The demand schedule in a perfectly competitive market is given by P = 93 – 1.5Q (for Q ≤ 62) and the long-run cost structure of each company is:

Total cost: $256 + 2Q + 4Q^2$

Average cost: $256/Q + 2 + 4Q$

Marginal cost: $2 + 8Q$

New companies will enter the market at any price greater than:

A 8.

B 66.

C 81.

6 Companies *most likely* have a well-defined supply function when the market structure is:

A oligopoly.

B perfect competition.

C monopolistic competition.

7 Aquarius, Inc. is the dominant company and the price leader in its market. One of the other companies in the market attempts to gain market share by undercutting the price set by Aquarius. The market share of Aquarius will *most likely*:

A increase.

© 2011 CFA Institute. All rights reserved.

B decrease.

C stay the same.

8 SigmaSoft and ThetaTech are the dominant makers of computer system software. The market has two components: a large mass-market component in which demand is price sensitive, and a smaller performance-oriented component in which demand is much less price sensitive. SigmaSoft's product is considered to be technically superior. Each company can choose one of two strategies:

- *Open architecture (Open):* Mass market focus allowing other software venders to develop products for its platform.
- *Proprietary (Prop):* Allow only its own software applications to run on its platform.

Depending upon the strategy each company selects, their profits would be:

SigmaSoft – Open **400** **600** **ThetaTech – Open**	**SigmaSoft – Prop** **650** **700** **ThetaTech – Open**
SigmaSoft – Open **800** **300** **ThetaTech – Prop**	**SigmaSoft – Prop** **600** **400** **ThetaTech – Prop**

The Nash equilibrium for these companies is:

A proprietary for SigmaSoft and proprietary for ThetaTech.

B open architecture for SigmaSoft and proprietary for ThetaTech.

C proprietary for SigmaSoft and open architecture for ThetaTech.

9 A company doing business in a monopolistically competitive market will *most likely* maximize profits when its output quantity is set such that:

A average cost is minimized.

B marginal revenue equals average cost.

C marginal revenue equals marginal cost.

10 Oligopolistic pricing strategy *most likely* results in a demand curve that is:

A kinked.

B vertical.

C horizontal.

11 Collusion is *less likely* in a market when:

A the product is homogeneous.

B companies have similar market shares.

C the cost structures of companies are similar.

12 If companies earn economic profits in a perfectly competitive market, over the long run the supply curve will *most likely*:

A shift to the left.

B shift to the right.

C remain unchanged.

13 Over time, the market share of the dominant company in an oligopolistic market will *most likely*:

A increase.

B decrease.

C remain the same.

14 A government entity that regulates an authorized monopoly will *most likely* base regulated prices on:

A marginal cost.

B long run average cost.

C first degree price discrimination.

15 An analyst gathers the following market share data for an industry:

Company	Sales (in millions of €)
ABC	300
Brown	250
Coral	200
Delta	150
Erie	100
All others	50

The industry's four-company concentration ratio is *closest* to:

A 71%.

B 86%.

C 95%.

16 An analyst gathered the following market share data for an industry comprised of five companies:

Company	Market Share (%)
Zeta	35
Yusef	25
Xenon	20
Waters	10
Vlastos	10

The industry's three-firm Herfindahl–Hirschmann Index is *closest* to:

A 0.185.

B 0.225.

C 0.235.

17 One disadvantage of the Herfindahl–Hirschmann Index is that the index:

A is difficult to compute.

B fails to reflect low barriers to entry.

C fails to reflect the effect of mergers in the industry.

18 In an industry comprised of three companies, which are small-scale manufacturers of an easily replicable product unprotected by brand recognition or patents, the *most* representative model of company behavior is:

A oligopoly.

B perfect competition.

C monopolistic competition.

19 Deep River Manufacturing is one of many companies in an industry that make a food product. Deep River units are identical up to the point they are labeled. Deep River produces its labeled brand, which sells for \$2.20 per unit, and "house brands" for seven different grocery chains which sell for \$2.00 per unit. Each grocery chain sells both the Deep River brand and its house brand. The *best* characterization of Deep River's market is:

A oligopoly.

B perfect competition.

C monopolistic competition.

SOLUTIONS

1 C is correct. Monopolistic competition is characterized by many sellers, differentiated products, and some pricing power.

2 A is correct. Few sellers of a homogeneous or standardized product characterizes an oligopoly.

3 B is correct. The product produced in a perfectly competitive market cannot be differentiated by advertising or any other means.

4 C is correct. Profits are maximized when MR = MC. For a monopoly, MR = $P[1 - 1/E_p]$. Setting this equal to MC and solving for P:

$$\$40 = P[1 - (1/1.5)] = P \times 0.333$$
$$P = \$120$$

5 B is correct. The long-run competitive equilibrium occurs where MC = AC = P for each company. Equating MC and AC implies $2 + 8Q = 256/Q + 2 + 4Q$.

Solving for Q gives $Q = 8$. Equating MC with price gives $P = 2 + 8Q = 66$. Any price above 66 yields an economic profit because P = MC > AC, so new companies will enter the market.

6 B is correct. A company in a perfectly competitive market must accept whatever price the market dictates. The marginal cost schedule of a company in a perfectly competitive market determines its supply function.

7 A is correct. As prices decrease, smaller companies will leave the market rather than sell below cost. The market share of Aquarius, the price leader, will increase.

8 C is correct. In the Nash model, each company considers the other's reaction in selecting its strategy. In equilibrium, neither company has an incentive to change its strategy. ThetaTech is better off with open architecture regardless of what SigmaSoft decides. Given this choice, SigmaSoft is better off with a proprietary platform. Neither company will change its decision unilaterally.

9 C is correct. The profit maximizing choice is the level of output where marginal revenue equals marginal cost.

10 A is correct. The oligopolist faces two different demand structures, one for price increases and another for price decreases. Competitors will lower prices to match a price reduction, but will not match a price increase. The result is a kinked demand curve.

11 B is correct. When companies have similar market shares, competitive forces tend to outweigh the benefits of collusion.

12 B is correct. The economic profit will attract new entrants to the market and encourage existing companies to expand capacity.

13 B is correct. The dominant company's market share tends to decrease as profits attract entry by other companies.

14 B is correct. This allows the investors to receive a normal return for the risk they are taking in the market.

15 B is correct. The top four companies in the industry comprise 86 percent of industry sales: (300 + 250 + 200 + 150)/(300 + 250 + 200 + 150 + 100 + 50) = 900/1050 = 86%.

16 B is correct. The three-firm Herfindahl–Hirschmann Index is $0.35^2 + 0.25^2 + 0.20^2 = 0.225$.

17 B is correct. The Herfindahl–Hirschmann Index does not reflect low barriers to entry that may restrict the market power of companies currently in the market.

18 B is correct. The credible threat of entry holds down prices and multiple incumbents are offering undifferentiated products.

19 C is correct. There are many competitors in the market, but some product differentiation exists, as the price differential between Deep River's brand and the house brands indicates.

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**m.** describe sources, measurement, and sustainability of economic growth;
☐	**n.** describe the production function approach to analyzing the sources of economic growth;
☐	**o.** define and contrast input growth with growth of total factor productivity as components of economic growth.

1

INTRODUCTION

In the field of economics, *microeconomics* is the study of the economic activity and behavior of individual economic units, such as a household, a company, or a market for a particular good or service, and *macroeconomics* is the study of the aggregate activities of households, companies, and markets. Macroeconomics focuses on national aggregates, such as total *investment*, the amount spent by all businesses on plant and equipment; total *consumption*, the amount spent by all households on goods and services; the rate of change in the general level of prices; and the overall level of interest rates.

Macroeconomic analysis examines a nation's aggregate output and income, its competitive and comparative advantages, the productivity of its labor force, its price level and inflation rate, and the actions of its national government and central bank. The objective of macroeconomic analysis is to address such fundamental questions as the following:

- What is an economy's aggregate output, and how is aggregate income measured?
- What factors determine the level of aggregate output/income for an economy?
- What are the levels of aggregate demand and aggregate supply of goods and services within the country?
- Is the level of output increasing or decreasing, and at what rate?
- Is the general price level stable, rising, or falling?
- Is unemployment rising or falling?
- Are households spending or saving more?
- Are workers able to produce more output for a given level of inputs?
- Are businesses investing in and expanding their productive capacity?
- Are exports (imports) rising or falling?

From an investment perspective, investors must be able to evaluate a country's current economic environment and to forecast its future economic environment in order to identify asset classes and securities that will benefit from economic trends occurring within that country. Macroeconomic variables—such as the level of inflation, unemployment, consumption, government spending, and investment—have different effects on the growth and profitability of industries within a country, the companies within those industries, and the returns of the securities issued by those companies.

The following section describes gross domestic product and related measures of domestic output and income. Short-run and long-run aggregate demand and supply curves are discussed next, followed by the causes of shifts and movements along those curves, as well as factors that affect equilibrium levels of output, prices, and interest rates. The last section discusses sources, sustainability, and measures of economic growth.

AGGREGATE OUTPUT AND INCOME

2

a calculate and explain gross domestic product (GDP) using expenditure and income approaches

b compare the sum-of-value-added and value-of-final-output methods of calculating GDP

The **aggregate output** of an economy is the value of all the goods and services produced during a specified period. The **aggregate income** of an economy is the value of all the payments earned by the suppliers of factors used in the production of goods and services. Because the value of the output produced must accrue to the factors of production, aggregate output and aggregate income within an economy must be equal.

There are four broad forms of payments (i.e., income): compensation of employees, rent, interest, and profits. Compensation of employees includes wages and benefits (primarily employer contributions to private pension plans and health insurance) that individuals receive in exchange for providing labor. **Rent** is payment for the use of property. **Interest** is payment for lending funds. **Profit** is the return that owners of a company receive for the use of their capital and the assumption of financial risk when making their investments. We can think of the sum of rent, interest, and profit as the *operating surplus* of a company. It represents the return on all capital used by the business.

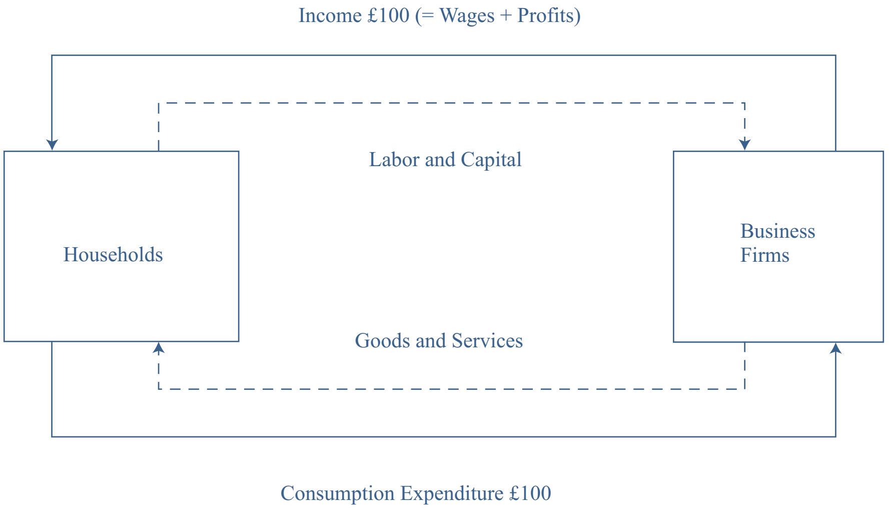
Although businesses are the direct owners of much of the property and physical capital in the economy, by virtue of owning the businesses, households are the ultimate owners of these assets and hence the ultimate recipients of the profits. In reality, of course, a portion of profits are usually retained within businesses to help finance maintenance and expansion of capacity. Similarly, because the government is viewed as operating on a non-profit basis, any revenue it receives from ownership of companies and/or property may be viewed as being passed back to households in the form of lower taxes. Therefore, for simplicity, it is standard in macroeconomics to attribute all income to the household sector unless the analysis depends on a more precise accounting.

Aggregate *expenditure*, the total amount spent on the goods and services produced in the (domestic) economy during the period, must also be equal to aggregate output and aggregate income. Some of this expenditure, however, may come from other countries in the form of net exports. Thus, aggregate output, aggregate income, and aggregate expenditure all refer to different ways of decomposing the same quantity.

Exhibit 1 illustrates the flow of inputs, output, income, and expenditures in a very simple economy. Households supply the factors of production (labor and capital) to businesses in exchange for wages and profit (aggregate income) totaling £100. These flows are shown by the top two arrows. Companies use the inputs to produce goods and services (aggregate output) that they sell to households (aggregate expenditure) for £100. The output and expenditure flows are shown by the bottom two arrows. Aggregate output, income, and expenditure are all equal to £100.

In this simplified example, households spend all of their income on domestically produced goods and services. They do not buy non-domestic goods, save for the future, or pay taxes. Similarly, businesses do not sell internationally or to the government, and they do not invest to increase their productive capacity. These important components of the economy will be added in a later section. But first we need to discuss how output and income are measured.

Exhibit 1 Output, Income, and Expenditure in a Simple Economy: The Circular Flow



2.1 Gross Domestic Product

Gross domestic product (GDP) measures

- the market value of all final goods and services produced within the economy during a given period (output definition) or, equivalently,
- the aggregate income earned by all households, all companies, and the government within the economy during a given period (income definition).

Intuitively, GDP measures the flow of output and income in the economy. GDP represents the broadest measure of the value of economic activity occurring within a country during a given period.

Therefore, GDP can be determined in two different ways. In the income approach, GDP is calculated as the total amount earned by households and companies in the economy. In the expenditure approach, GDP is calculated as the total amount spent on the goods and services produced within the economy during a given period. For the economy as a whole, total income must equal total expenditures, so the two approaches yield the same result.

Many developed countries use a standardized methodology for measuring GDP. This methodology is described in the official handbook of the Organisation for Economic Co-Operation and Development (Paris: OECD Publishing). The OECD reports the national accounts for many developed nations. In the United States, the National Income and Product Accounts (also called NIPA, or national accounts, for short) is the official US government accounting of all the income and expenditure flows in the US economy. The national accounts are the responsibility of the US Department of Commerce and are published in its *Survey of Current Business*. In Canada, similar data are available from Statistics Canada, whereas in China, the National Bureau of Statistics of China provides GDP data.

To ensure that GDP is measured consistently over time and across countries, the following three broad criteria are used:

- All goods and services included in the calculation of GDP *must be produced during the measurement period*. Therefore, items produced in previous periods—such as houses, cars, machinery, or equipment—are excluded. In addition, transfer payments from the government sector to individuals, such as unemployment compensation or welfare benefits, are excluded. Capital gains that accrue to individuals when their assets appreciate in value are also excluded.
- The only goods and services included in the calculation of GDP are those whose value *can be determined by being sold in the market*. This criterion enables the price of goods or services to be objectively determined. For example, a liter of extra virgin olive oil is more valuable than a liter of spring water because extra virgin olive oil has a higher market price than spring water does. The value of labor used in activities that are not sold on the market, such as commuting or gardening, is also excluded from GDP. Byproducts of production processes are also excluded if they have no explicit market value, such as air pollution, water pollution, and acid rain.
- Only the market value of final goods and services is included in GDP. Final goods and services are those that are not resold. *Intermediate goods* are goods that are resold or used to produce another good. Note that "intermediate goods" should not be confused with inventories and "final goods" should not be confused with so-called final sales. The value of intermediate goods is excluded from GDP because additional value is added during the production process, and all the value added during the entire production process is reflected in the final sale price of the finished good. An alternative approach to measuring GDP is summing all the value added during the production and distribution processes. The most direct approach, however, is to sum the market value of all the final goods and services produced within the economy during a given period.

Two distinct, but closely related, measurement methods can be used to calculate GDP based on expenditures: value of final output and sum of value added. Exhibit 2 illustrates these two methods. In this example, a farmer sells wheat to a miller. The miller grinds the wheat into flour and sells it to a baker, who makes bread and sells it to a retailer. Finally, the bread is sold to retail customers. The wheat and flour are both intermediate goods in this example because they are used as inputs to produce another good. Thus, they are not counted (directly) in GDP. For the purposes of GDP, the value of the final product is €1.00, which includes the value added by the bread retailer as a distributor of the bread. If, in contrast, the baker sold directly to the public, the value counted in GDP would be the price at which the baker sold the bread, €0.78. The left column of the exhibit shows the total revenue received at each stage of the process, whereas the right column shows the value added at each stage. Note that the market value of the final product (€1.00) is equal to the sum of the value added at each of the stages. Thus, the contribution to GDP can be measured as either the final sale price or the sum of the value added at each stage.

Exhibit 2 Value of Final Product Equals Income Created

	Receipts at Each Stage (€)	Value Added (= Income Created) at Each Stage (€)	
Receipts of farmer from miller	0.15	0.15	Value added by farmer
Receipts of miller from baker	0.46	0.31	Value added by miller

(continued)

Exhibit 2 (Continued)

	Receipts at Each Stage (€)	Value Added (= Income Created) at Each Stage (€)	
Receipts of baker from retailer	0.78	0.32	Value added by baker
Receipts of retailer from final customer	1.00	0.22	Value added by retailer
	1.00	1.00	
	Value of final output	Total value added = Total income created	

EXAMPLE 1

Contribution of Automobile Production to GDP

Exhibit 3 provides simplified information on the cost of producing an automobile in the United States at various stages of the production process. The example assumes the automobile is produced and sold domestically and assumes no imported material is used. Calculate the contribution of automobile production to GDP using the value-added method, and show that it is equivalent to the expenditure method. What effect would the use of imported steel or plastics have on GDP?

Exhibit 3 Cost of Producing Automobiles

Stage of Production	Sales Value ($)
1 Production of basic materials	
Steel	1,000
Plastics	3,000
Semiconductors	1,000
2 Assembly of automobile (manufacturer price)	15,000
3 Wholesale price for automobile dealer	16,000
4 Retail price	18,000

Solution:

GDP includes only the value of final goods and ignores intermediate goods in order to avoid double counting. Thus, the final sale price of $18,000 and not the total sales value of $54,000 (summing sales at all the levels of production) would be included in GDP. Alternatively, we can avoid double counting by calculating and summing the value added at each stage. At each stage of production, the difference between what a company pays for its inputs and what it receives for the product is its contribution to GDP. The value added for each stage of production is computed as follows:

Stage of Production	Sales Value ($)	Value Added ($)	
1 Production of basic materials			
Steel	1,000	1,000	
Plastics	3,000	3,000	
Semiconductors	1,000	1,000	
Total inputs		5,000	(sum of three inputs)
2 Assembly of car (manufacturer price)	15,000	10,000	= (15,000 – 5,000)
3 Wholesale price for car dealer	16,000	1,000	= (16,000 – 15,000)
4 Retail price	18,000	2,000	= (18,000 – 16,000)
Total expenditures	18,000		
Total value added		18,000	

Thus, the sum of the value added by each stage of production is equal to $18,000, which is equal to the final selling price of the automobile. If some of the inputs (steel, plastics, or semiconductors) are imported, the value added would be reduced by the amount paid for the imports.

2.1.1 *Goods and Services Included at Imputed Values*

As a general rule, only the value of goods and services whose *value can be determined by being sold in the market* are included in the measurement of GDP. Owner-occupied housing and government services, however, are two examples of services that are not sold in the marketplace but are still included in the measurement of GDP.

When a household (individual) rents a place to live, she is buying housing services. The household pays the owner of the property rent in exchange for shelter. The income that a property owner receives is included in the calculation of GDP. When a household purchases a home, however, it is implicitly paying itself in exchange for the shelter. As a result, the government must estimate (impute) a value for this owner-occupied rent, which is then added to GDP.

The value of government services provided by police officers, firemen, judges, and other government officials is a key factor that affects the level of economic activity. Valuing these services is difficult, however, because they are not sold in a market like other services; individual customers cannot decide how much to consume or how much they are willing to pay. Therefore, these services are simply included in GDP at their cost (e.g., wages paid) with no value added attributed to the production process.

For simplicity and global comparability, the number of goods and services with imputed values that are included in the measurement of GDP are limited. In general, non-market activity is excluded from GDP. Thus, activities performed for one's own benefit, such as cooking, cleaning, and home repair, are excluded. Activities in the so-called underground economy are also excluded. The underground economy reflects economic activity that people hide from the government either because it is illegal or because they are attempting to evade taxation. Undocumented laborers who are paid "off the books" are one example. The illegal drug trade is another. Similarly, barter transactions, such as neighbors exchanging services with each other (e.g., helping your neighbor repair his fence in exchange for him plowing your garden), are excluded from GDP.

Exhibit 4 shows a historical study on the estimated size of the underground economy in various countries as a percentage of nominal GDP. The estimates range from 8% in the United States to 60% in Peru. Based on these estimates, the US national income accounts fail to account for roughly 7.4% (= 8/108) of economic activity, whereas in Peru, the national accounts miss roughly 37.5% (= 60/160) of the economy. For most of the countries shown, the national accounts miss 12%–20% of the economy.

Exhibit 4 Underground Economy As a Percentage of Nominal GDP (2006)

Country	Underground Economy As a Percentage of Nominal GDP (%)
Peru	60.0
Mexico	32.1
South Korea	27.5
Costa Rica	26.8
Greece	26.0
India	24.4
Italy	23.1
Spain	20.2
Sweden	16.3
Germany	15.4
Canada	14.1
China	14.0
France	13.2
Japan	8.9
United States	8.0

Source: Friedrich Schneider and Andreas Buehm, Linz University, 2009.

It should be clear from these estimates of the underground economy that the reliability of official GDP data varies considerably across countries. Failure to capture a significant portion of activity is one problem. Poor data collection practices and unreliable statistical methods within the official accounts are also potential problems.

2.1.2 *Nominal and Real GDP*

c compare nominal and real GDP and calculate and interpret the GDP deflator

To evaluate an economy's health, it is often useful to remove the effect of changes in the general price level on GDP because higher (lower) income driven solely by changes in the price level is not indicative of a higher (lower) level of economic activity. To account for these effects, economists use **real GDP**, which indicates what would have been the total expenditures on the output of goods and services if prices were unchanged. **Per capita real GDP** (real GDP divided by the size of the population) has often been used as a measure of the average standard of living in a country.

Suppose we are interested in measuring the GDP of an economy. For the sake of simplicity, suppose that the economy consists of a single automobile maker and that in 2019, 300,000 vehicles are produced with an average market price of €18,750. GDP in 2019 would be €5,625,000,000. Economists define the value of goods and services measured at current prices as **nominal GDP**. Suppose that in 2020, 300,000 vehicles are again produced but that the average market price for a vehicle increases by 7% to €20,062.50. GDP in 2020 would be €6,018,750,000. Even though no more cars were produced in 2020 than in 2019, it appears that the economy grew by (€6,018,750,000/€5,625,000,000) – 1 = 7% between 2019 and 2020, although it actually did not grow at all.

Nominal and real GDP can be expressed as

$$\text{Nominal GDP}_t = P_t \times Q_t$$

where

P_t = prices in year t
Q_t = quantity produced in year t

$$\text{Real GDP}_t = P_B \times Q_t$$

where

P_B = prices in the base year

Taking the base year to be 2019 and putting in the 2019 and 2020 numbers gives the following:

$$\text{Nominal GDP}_{2019} = (€18{,}750 \times 300{,}000) = €5{,}625{,}000{,}000$$

$$\text{Real GDP}_{2019} = (€18{,}750 \times 300{,}000) = €5{,}625{,}000{,}000$$

$$\text{Nominal GDP}_{2020} = (€20{,}062.50 \times 300{,}000) = €6{,}018{,}750{,}000$$

$$\text{Real GDP}_{2020} = (€18{,}750 \times 300{,}000) = €5{,}625{,}000{,}000$$

In this example, real GDP did not change between 2019 and 2020 because the total output remained the same: 300,000 vehicles. The difference between nominal GDP in 2020 and real GDP in 2020 was the 7% inflation rate.

Now suppose that the auto manufacturer produced 3% more vehicles in 2020 than in 2019 (i.e., production in 2020 was 309,000 vehicles). Real GDP would increase by 3% from 2019 to 2020. With a 7% increase in prices, nominal GDP for 2020 would now be as follows:

$$\begin{aligned}\text{Nominal GDP}_{2020} &= (1.03 \times 300{,}000) \times (1.07 \times €18{,}750)\\ &= (309{,}000 \times €20{,}062.50)\\ &= €6{,}199{,}312{,}500\end{aligned}$$

The **implicit price deflator for GDP**, or simply the **GDP deflator**, is defined as follows:

$$\text{GDP deflator} = \frac{\text{Value of current year output at current year prices}}{\text{Value of current year output at base year prices}} \times 100$$

Thus, in the example, the GDP deflator for 2020 is [(309,000 × €20,062.50)/ (309,000 × €18,750)](100) = (1.07)(100) = 107. The GDP deflator broadly measures the aggregate changes in prices across the overall economy, and hence changes in the deflator provide a useful gauge of inflation within the economy.

Real GDP is equal to nominal GDP divided by the GDP deflator scaled by 100:

$$\text{Real GDP} = \text{Nominal GDP}/(\text{GDP deflator}/100)$$

This relation gives the GDP deflator its name. That is, the measure of GDP in terms of current prices, nominal GDP, is adjusted for inflation by dividing it by the deflator. The expression also shows that the GDP deflator is the ratio of nominal GDP to real GDP scaled by 100:

$$\text{GDP deflator} = (\text{Nominal GDP}/\text{Real GDP}) \times 100$$

Thus, real GDP for 2020 would be

$$\begin{aligned}\text{Real GDP}_{2020} &= \text{Nominal GDP/(GDP deflator/100)}\\ &= \text{€}6{,}199{,}312{,}500/(107/100)\\ &= \text{€}5{,}793{,}750{,}000\end{aligned}$$

Note that €5,793,750,000 represents 3% real growth over 2019 GDP and 3% higher real GDP for 2020 than under the assumption of no growth in unit car sales in 2020.

What would be the increase in *nominal* GDP for 2020 compared with 2019 with the 3% greater automobile production and 7% inflation?

$$(\text{Nominal GDP}_{2020}/\text{Nominal GDP}_{2019}) - 1$$

$$= (\text{€}6{,}199{,}312{,}500/\text{€}5{,}625{,}000{,}000) - 1$$

$$= 0.102$$

So, nominal GDP would increase by 10.2%, which equals (1.07 × 1.03) − 1, or approximately 7% + 3% = 10%. Which number is more informative about growth in economic activity: 3% real growth or 10.2% nominal growth? The real growth rate is more informative because it exactly captures increases in output. Nominal growth, by blending price changes with output changes, is less directly informative about output changes.In summary, real economic growth is measured by the percentage change in real GDP. When measuring real economic activity or when comparing one nation's economy with another, real GDP and real GDP growth should be used because they more closely reflect the quantity of output available for consumption and investment.

EXAMPLE 2

Calculating the GDP Deflator

John Lambert is an equity analyst with Equitytrust, an investment management firm that primarily invests in domestic stocks and bonds in a hypothetical country. Equitytrust's investment policy committee is concerned about the possibility of inflation. The implicit GDP deflator is an important measure of the overall price level in the economy, and changes in the deflator provide an important gauge of inflation within the economy. Released GDP data are shown in Exhibit 5. The committee asks Lambert to use the GDP data to calculate the implicit GDP price deflator from 2016 to 2020 and the inflation rate for 2020.

Exhibit 5 Real and Nominal GDP

	Seasonally adjusted at annual rates (SAAR)				
	2016	**2017**	**2018**	**2019**	**2020**
GDP at market prices	1,822,808	1,897,531	1,990,183	1,994,911	2,035,506
Real GDP	1,659,195	1,698,153	1,747,478	1,762,561	1,786,677

Solution:

The implicit GDP price deflator measures inflation across all sectors of the economy, including the consumer, business, government, exports, and imports. It is calculated as the ratio of nominal to real GDP and reported as an index number with the base year deflator equal to 100. The implicit GDP price deflator for the economy for 2020 is calculated as (2,035,506/1,786,677) × 100 = 113.9. The results for the other years are shown in the following table:

	2016	2017	2018	2019	2020
GDP at market prices ($ millions)	1,822,808	1,897,531	1,990,183	1,994,911	2,035,506
Real GDP (2007 $ millions)	1,659,195	1,698,153	1,747,478	1,762,561	1,786,677
Implicit GDP price deflator	113.9	111.7	113.9	113.2	113.9

For 2016, the annual inflation rate is equal to [(113.9/113.2) – 1] or 0.62 percent. This shows that Canada experienced a very low rate of inflation in 2016.

2.2 The Components of GDP

d compare GDP, national income, personal income, and personal disposable income

Having defined GDP and discussed how it is measured, we can now consider the major components of GDP, the flows among the four major sectors of the economy—the household sector, the business sector, the government sector, and the foreign or external sector (consisting of transactions with the "rest of the world")—and the markets through which they interact. An expression for GDP, based on the expenditure approach, is

$$\text{GDP} = C + I + G + (X - M) = (C + G^C) + (I + G^I) + (X - M) \tag{1}$$

where

C = consumer spending on final goods and services
I = gross private domestic investment, which includes business investment in capital goods (e.g., fixed capital such as plant and equipment) and changes in inventory (**inventory investment**)
G = government spending on final goods and services for both current consumption and investment in capital goods = $G^C + G^I$
X = exports
M = imports

Exhibit 6 shows the flow of expenditures, income, and financing among the four sectors of the economy and the three principal markets. In the exhibit, solid arrows point in the direction of expenditure on final goods and services. For simplicity, corresponding flows of output are not shown separately. The flow of factors of production is also shown with a solid arrow. Financial flows, including income and net taxes, are shown with dashed arrows pointing to the recipient of funds.

Government Spending (G)
Net Exports (X–M)
Government
Rest of the World
Financial Markets
Government Borrowing
Net Foreign Borrowing/Lending
Household Savings (S)
Business Financing: Debt and Equity

2.2.1 *The Household and Business Sectors*

The very top portion of Exhibit 6 shows the services of labor, land, and capital flowing through the *factor market* to business firms and the flow of income back from firms to households. Households spend part of their income on consumption (C) and save (S) part of their income for future consumption. Current consumption expenditure flows through the *goods market* to the business sector. Household saving flows into the *financial markets*, where it provides funding for businesses that need to borrow or raise equity capital. Firms borrow or raise equity primarily to finance investment (I) in inventory, property, plant, and equipment. Investment (I) is shown flowing from firms through the goods market and back to firms because the business sector both demands and produces the goods needed to build productive capacity (*capital goods*).

In most developed economies, such as Italy and the United States, expenditures on capital goods represent a significant portion of GDP. Investments (expenditures) on capital goods accounted for approximately 12.3% of Italy's GDP in 2015, while in the United States investments accounted for approximately 16.2% of GDP during the same period. In some developing countries, notably China (45.4%) and India (32.9%), investment spending accounts for a substantially larger share of the economy (according to OECD.Stat). As we will examine in greater detail later, investment spending is an important determinant of an economy's long-term growth rate. At the same time, investment spending is the most volatile component of the economy, and changes in capital spending—especially spending on inventories—are one of the main factors causing short-run economic fluctuations.

2.2.2 *The Government Sector*

The government sector collects taxes from households and businesses. For simplicity, only the taxes collected from the household sector are shown in Exhibit 6. In turn, the government sector purchases goods and services (G) for both consumption and investment from the business sector. For example, the government sector hires construction companies to build roads, schools, and other infrastructure goods. Government expenditure (*G*) also reflects spending on the military, police and fire protection, the postal service, and other government services. To keep Exhibit 6 simple, however, we combine consumption and investment expenditures into government expenditure, *G*.

Governments also make transfer payments to households. In general, such payments are designed to address social objectives such as maintaining minimum living standards, providing health care, and assisting the unemployed with retraining and temporary support. In Exhibit 6, transfer payments are subtracted from taxes and reflected in net taxes (*T*).

Transfer payments are not included in government expenditures on goods and services (*G*) because they represent a monetary transfer by the government of tax revenue back to individuals, with no corresponding receipt of goods or services. The household spending facilitated by the transfer payments is, of course, included in consumption (*C*) and, hence, GDP. It is worth noting that transfers do not always take the form of direct payments to beneficiaries. Instead, the government may pay for or even directly provide goods or services to individuals. For example, universal health care programs often work in this way.

If, as is usually the case, government expenditure (*G*) exceeds net taxes (*T*), then the government has a *fiscal deficit* and must borrow in the financial markets. Thus, the government may compete with businesses in the financial markets for the funds generated by household saving. The only other potential source of funds in an economy is capital flows from the rest of the world, discussed in the next section.

In 2015, the ratio of general government spending (which includes central government as well as state, provincial, and local government) to GDP in Italy was 50.4%, while in the United States it was 37.7%. In countries where the government provides more services, such as universal health care in Italy, the government's contribution to GDP is greater. France's government sector represents 57.0% of GDP. In other countries, the public sector makes up a smaller share. In Mexico, for example, government spending is 24.5% of GDP. Exhibit 7 shows data on tax revenues, general government spending, and transfer payments as a share of nominal GDP.

Exhibit 7 General Government Spending and Taxes as a Percentage of GDP (2015)

		General Government Spending as a Percentage of GDP

Note: n.a. = not available
Source: Government at a Glance, 2017 edition (stats.oecd.org).

2.2.3 *The External Sector*

Trade and capital flows involving the rest of the world are shown in the bottom right quadrant of Exhibit 6. Net exports ($X - M$) reflects the difference between the value of goods and services sold internationally—exports (X)—and the portion of domestic consumption (C), investment (I), and government expenditure (G) that represents purchases of goods and services from the rest of the world—imports (M).

A **balance of trade deficit** means that the domestic economy is spending more on international goods and services than other nations' economies are spending on domestic goods and services. It also means that the country is spending more than it produces because domestic saving is insufficient to finance domestic investment plus the government's fiscal balance. A trade deficit must be funded by borrowing from the rest of the world through the financial markets. The rest of the world is able to provide this financing because, by definition, it must be running a corresponding trade surplus and is spending less than it produces.

It bears emphasizing that trade and capital flows between an economy and the rest of the world must balance. One area's deficit is another's surplus, and vice versa. This dynamic is an accounting identity that must hold. In effect, having allowed a country to run a trade deficit, other nations must, in aggregate, finance it. The financing terms, however, may or may not be attractive.

Exhibit 8 reports trade balances for the United States with selected countries. Note that in 2016, China was the United States' largest trading partner, in terms of sending goods to the United States (US imports). Mexico and Canada, members of NAFTA along with the United States, were second and third in sending goods to the United Sates but were also important consumers of US goods (US exports). Over all its trading partners, the US balance of trade deficit in 2016 was US$734,316.3 million.

Exhibit 8 US International Trade in Goods—Selected Countries, 2016 (US$ millions)

	Exports	Imports	Balance
Total, all countries	1,454,624.2	2,188,940.5	−734,316.3

2.3 GDP, National Income, Personal Income, and Personal Disposable Income

This section examines the calculation of GDP and other income measures in detail by means of an analysis of data from Statistics Canada.

Exhibit 9a provides data on the level of Canadian GDP and its components measured at market prices (nominal GDP) as part of Example 3.

Exhibit 9a GDP Measures for the Canadian Economy
(C$ millions at market prices, seasonally adjusted at annual rates)

	2014	2015	2016	2017	2018
Expenditure-Based:					
Final consumption expenditure	**1,517,376**	**1,566,215**	**1,610,954**	**1,684,563**	**1,754,326**
Household final consumption expenditure	1,086,253	1,122,079	1,153,668	1,208,438	1,255,327
Non-profit institutions serving households' final consumption expenditure	26,826	28,575	30,951	31,976	33,207
General governments final consumption expenditure	404,297	415,561	426,335	444,149	465,792
Gross fixed capital formation	**486,542**	**474,732**	**461,262**	**486,760**	**501,247**
Business gross fixed capital formation	410,591	395,432	382,196	401,686	409,835
Non-profit institutions serving households' gross fixed capital formation	3,145	2,956	2,212	2,290	2,325

Gross domestic income at market prices	1,994,898	1,990,441	2,025,535	2,141,107	2,223,856

Source: Statistics Canada. Table 36-10-0222-01 and Table: 36-10-0221-01 GDP, expenditure-based & income-based, annual (x C$1,000,000).

Exhibit 9a shows the two approaches to measuring GDP: 1) expenditures on final output measured as the sum of sales to the final users and 2) the sum of the factor incomes generated in the production of final output. In theory, the two approaches should provide the same estimate of GDP. As shown in the exhibit, however, they differ in practice because of the use of different data sources. The difference is accounted for by a *statistical discrepancy*. Market analysts more closely follow the expenditure approach because the expenditure data are more timely and reliable than data for the income components.

Using the expenditure approach, Statistics Canada measures Canadian GDP as follows:

GDP = Consumer spending on goods and services
+ Business gross fixed investment
+ Change in inventories
+ Government spending on goods and services
+ Government gross fixed investment
+ Exports – Imports
+ Statistical discrepancy

Canadian national income accounts explicitly allocate government expenditures between consumption expenditure and gross fixed capital formation. Not all countries make this distinction. The United States, for example, does not. Also note that the investment in business inventories must be included in expenditures. Otherwise, goods produced but not yet sold would be left out of GDP.

The income-based approach calculates gross domestic income (GDI) as the sum of factor incomes and essentially measures the cost of producing final output. Two of the costs entering into the gross value of output, however, are not really earned by a factor of production. These items, depreciation and indirect taxes, are discussed next. GDP is estimated in the income approach as follows (note that construction of the national income accounts varies across countries):

GDP = Gross domestic income (GDI)
= Net domestic income + Consumption of fixed capital (CFC) + Statistical discrepancy

where gross domestic income is the income received by all factors of production used in the generation of final output:

Gross domestic income = Compensation of employees
+ Gross operating surplus
+ Gross mixed income
+ Taxes less subsidies on production
+ Taxes less subsidies on products and imports

Compensation of employees consists of 1) wages and salaries including direct compensation in cash or in kind plus 2) "employers' social contributions" that supplement wages, which are primarily payments for government-sponsored social security schemes including pensions and health insurance.

Gross operating surplus is related to corporate profits and includes private corporations, non-profit corporations, and government corporations. Gross operating surplus is the surplus arising from operations and does not take out charges for rent, interest, or similar charges on financial assets or natural resources used by the business. As such, gross operating surplus essentially measures the return on capital used by the business as a whole, rather than the return to the owners of the business (profit).

Gross mixed income is the same concept applied to unincorporated business in the economy. It is measured in the same way as gross operating surplus and has three major components: 1) farm income, 2) non-farm income excluding rent, and 3) rental income.

"Indirect business taxes less subsidies" reflects taxes and subsidies included in the final price of the good or service. It is the (net) portion of **national income** that is directly paid to the government. In the Canadian accounts, these are measured in two ways: 1) "taxes less subsidies on products and imports," which include sales taxes, fuel taxes, and import duties, and 2) "taxes less subsidies on factors of production," which are mainly property taxes and payroll taxes.

The consumption of fixed capital (CFC) is a measure of the wear and tear (depreciation) of the capital stock that occurs in the production of goods and services. This measure acknowledges the fact that some income/output must be allocated to the replacement of the existing capital stock as it wears out. Loosely speaking, one may think of Profit + CFC as the gross surplus earned by capital, with the CFC being the amount that must be earned and reinvested to maintain the existing productivity of the capital.

Along with the GDP report, Statistics Canada and other government statistical agencies provide information on personal income (called Primary Household Income in the Canadian accounts) and personal saving (called Household Net Saving), as shown in Exhibit 9b. **Personal income** is a broad measure of household income and measures the ability of consumers to make purchases. As such, it is one of the key determinants of consumption spending. Primary Household Income includes all income received by households, whether earned or unearned. It includes compensation of employees plus net mixed income from unincorporated businesses plus net property income.

Exhibit 9b Household Income and Saving for the Canadian Economy (C$ millions at market prices, seasonally adjusted at annual rates)

Household saving rate (%)	3.9	4.5	2.0	2.1	calc

Source: Statistics Canada. Table 36-10-0224-01 Household sector, current accounts, provincial and territorial, annual.

Household disposable income (HDI) is equal to personal income less personal taxes. In reality, households both pay taxes to the government and receive some income from governments (transfer payments such as social insurance payments, unemployment compensation, and disability payments) that is not earned. Thus HDI is calculated as household primary income less net current transfers paid. This calculation measures the amount of after-tax income that households have to spend on goods and services or to save. Thus, it is the most relevant, and most closely watched, measure of income for household spending and saving decisions.

Finally, household net saving is equal to HDI adjusted for two items: subtracting household final consumption expenditures and adding the net change in pension entitlements.

EXAMPLE 3

Canadian GDP Release and Other Measures of Production and Income

The investment policy committee at Equitytrust asks John Lambert to review the Canadian GDP data shown in Exhibits 9a and 9b.

1. Calculate 2018 GDP using the expenditure approach, and indicate how the expenditures are represented in Exhibit 6.
2. Calculate 2018 GDP using the income approach.
3. Calculate personal income for 2018.
4. Using the Canadian data for 2018, calculate the level of household saving (S), the saving rate, and net payments (T) by the household sector to government.
5. Calculate the impact of international trade on the Canadian economy in 2018 and Canada's net foreign borrowing/lending in 2018.
6. Calculate the amount of net fixed capital formation across all sectors in 2018.

Solutions:

(all numbers in millions)

Solution to 1:

In the expenditure approach, nominal GDP is calculated as the sum of spending by the major sectors in the economy:

GDP = Final consumption expenditures + Gross fixed capital formation + Investment in Inventories + Exports − Imports + Statistical discrepancySubstituting the numbers from Exhibit 9a,

GDP = 1,754,326 + 501,247 + 11,904 + 713,351 − 756,913 − 59
= C$2,223,856.

In Exhibit 6, these expenditures are represented by the arrows pointing to the goods market and by the arrow pointing back to firms labeled as $C + I + G + (X - M)$. Note that G in Exhibit 6 is captured here partly in final consumption expenditures and partly in gross fixed capital formation for the Canadian national income accounts.

Solution to 2:

On the income side, nominal GDP is equal to gross domestic income—the sum of income received by the factors of production—given by the following equation:

Gross domestic income = Compensation of employees + Gross operating surplus + Gross mixed income+ Indirect business taxes − Subsidies + Statistical discrepancy

Substituting in the numbers from Exhibit 9a, we get indirect business taxes less subsidies as equal to the sum of taxes less subsidies on production plus taxes less subsidies on products and imports = 98,698 + 148,921 = C$247,619. Using this result,

GDP = GDI = 1,120,520 + 590,510 + 265,147 + 247,619 + 60
= C$2,223,856.

Solution to 3:

Personal income (household primary income) is calculated as

Household Primary Income = Compensation of employees + Net mixed income + Net property incomeSubstituting in the numbers from Exhibit 9b,

Household primary income = 1,117,091 + 199,212 + 140,370
= C$1,456,673.

Solution to 4:

Household saving is equal to personal disposable income less household final consumption expenditures plus the change in pension entitlements. Household final consumption (C) is given in Exhibit 9a as C$1,255,327. Substituting in the appropriate numbers, Household net saving = Household primary income − Net current transfers paid − Household final consumption expenditure + Net change in pension entitlements = 1,456,673 − (555,884 − 333,602) − 1,255,327 + 43,087 = C$22,151.

The Canadian saving rate for 2018 = (22,151/1,117,091) = 2%.

Net "taxes" paid by the household sector consists of two components: 1) transfers paid by households to the government minus 2) government transfer payments received by households. From Exhibit 9b, government transfer payments to households for 2018 were C$333,602. The transfer payments by households to government in 2018 was C$555,884. Thus the net payments *to* government by households in 2018 was:

555,884 – 333,602 = C$222,282

Solution to 5:

It is clear from Exhibit 9a that the international sector generally has a large effect each year on the Canadian economy. In 2018, exports were C$713,351, or roughly 32% of Canadian GDP. Imports were higher than exports at C$756,913 in 2018, indicating that Canada had a trade deficit of 713,351 – 756,913 = C$43,562. This figure is roughly the same size as the trade deficit in 2017.

Canada funds its trade deficit by borrowing from the rest of the world through the financial markets. In 2018, this involved borrowing C$43,562 from the rest of the world. Trade and capital flows between an economy and the rest of the world must balance. A trade deficit must be funded by a capital inflow.

Solution to 6:

Net fixed capital formation is equal to gross fixed capital formation found in the expenditure accounts less consumption of fixed capital (CFC) by corporations, government and non-profits, and unincorporated businesses found in the income accounts. In 2018, gross fixed capital formation was C$501,247, and CFC was (228,666 + 74,564 + 65,935) for corporations, government and non-profits, and unincorporated businesses, respectively.

Thus net fixed capital formation in the Canadian economy for 2018 was 501,247 – 369,165 = C$132,082.

2.4 Relationship among Saving, Investment, the Fiscal Balance and the Trade Balance

e explain the fundamental relationship among saving, investment, the fiscal balance, and the trade balance

Total expenditure on domestically produced output comes from four sources: household consumption (C), investments (I), government spending (G), and net exports ($X - M$). This can be expressed as follows:

$$\text{Expenditure} = C + I + G + (X - M)$$

Personal disposable income is equal to GDP (Y) plus transfer payments (F) minus retained earnings and depreciation (= business saving, S_B) minus direct and indirect taxes (R). Households allocate disposable income between consumption of goods and services (C) and household saving (S_H). Therefore,

$$Y + F - S_B - R = C + S_H$$

Rearranging this equation, we get

$$Y = C + S + T$$

where $T = (R - F)$ denotes net taxes and $S = (S_B + S_H)$ denotes total private sector saving.

Because total expenditures must be identical to aggregate income (Y), we have the following relationship:

$$C + S + T = C + I + G + (X - M)$$

By rearranging this equation, we get the following fundamental relationship among domestic saving, investment, the fiscal balance, and the trade balance:

$$S = I + (G - T) + (X - M) \quad (2)$$

This equation shows that domestic private saving is used or absorbed in one of three ways: investment spending (I), financing government deficits ($G - T$), and building up financial claims against overseas economies [positive trade balance, $(X - M) > 0$]. If there is a trade deficit [$(X - M) < 0$], then domestic private saving is being supplemented by inflows of foreign saving and other countries' economies are building up financial claims against the domestic economy.

By rearranging the identity, we can examine the implications of government deficits and surpluses:

$$G - T = (S - I) - (X - M)$$

A fiscal deficit [$(G - T) > 0$] implies that the private sector must save more than it invests [$(S - I) > 0$] or the country must run a trade deficit [$(X - M) < 0$] with corresponding inflow of foreign saving—or both.

EXAMPLE 4

Foreign Capital Inflows Help Finance Government Deficits

The budgetary situation changed dramatically in Canada during 2009, the first year of the financial crisis. The Department of Finance Canada reported that in 2009, the combined federal–provincial governments had a deficit of C$84,249 (all amounts in C$ millions). Thus, the government sector operated at a deficit that needed to be financed. How was this deficit financed?

Solution:

Using the formula $G - T = (S - I) - (X - M)$ shows that a budget deficit is financed through either higher domestic saving (S), lower business investment (I), or international borrowing ($X - M$).

In 2009, private sector saving exceeded investment spending by C$58,588 (319,802 – 277,574). Thus, domestic private saving financed more than 69.5% of the 2009 government deficit (58,588/84,249).

To finance the rest of the government deficit, foreign imports (M) would have to exceed exports (X) by C$25,661. The actual trade deficit (amount of foreign borrowing) in 2009 was C$26,169, slightly greater than the amount required. This difference largely results from the statistical discrepancy caused by different data sources being used for expenditure-based and income-based estimates of GDP.

Equation 2 is the key relationship that must hold in order for aggregate income and aggregate expenditure to be equal. Up to this point, we have treated it as simply an accounting identity. We now need to think of it as the outcome of explicit decisions on the part of households, businesses, government, and people in other countries. When we do so, we face the question of what underlies these decisions and how the requisite balance is established.

Economists have found that the dominant determinant of consumption spending is disposable income ($Y - S_B - T$). This relationship can be expressed formally by indicating that consumption is a function $\mathbf{C}(\cdot)$ of disposable income,

$$C = \mathbf{C}(Y - S_B - T)$$

or, dropping the technically correct but practically insignificant adjustment for retained earnings and depreciation (S_B), a function of GDP minus net taxes:

$$C = \mathbf{C}(Y - T)$$

When households receive an additional unit of income, some proportion of this additional income is spent and the remainder is saved. The **marginal propensity to consume** (MPC) represents the proportion of an additional unit of disposable income that is consumed or spent. Because the amount that is not spent is saved, the **marginal propensity to save** (MPS) is MPS = 1 − MPC.

According to the consumption function, either an increase in real income or a decrease in taxes will increase aggregate consumption. Somewhat more sophisticated models of consumption recognize that consumption depends not only on current disposable income but also on wealth. Except for the very rich, individuals tend to spend a higher fraction of their current income as their wealth increases because with higher current wealth, there is less need to save to provide for future consumption.

Exhibit 10 shows household consumption expenditures as a percentage of GDP for selected countries.

Exhibit 10 Household Final Consumption Expenditures as a Percentage of GDP, 2018

United States	68.0%
Mexico	64.8
Italy	60.3
Japan	55.6
Canada	57.9
France	53.9
Germany	52.1

Source: The World Bank, https://data.worldbank.org/indicator/NE.CON.PRVT.ZS

These figures reflect the *average propensity to consume* (APC)—that is, the ratio C/Y—rather than a measure of how the next unit of income would be divided between spending and saving, the MPC. However, they are reasonable proxies for the MPC in each country. Comparing Germany's 55.0% APC with Mexico's 67.8%, the implication is that the Mexican economy is more sensitive to changes in disposable household income than is the German economy. All else being equal, macroeconomic policies that increase disposable household income, such as lowering government taxes, would have a larger effect on the economies of Mexico (67.8%) and the United States (68.3%) than similar policies would have in Germany (55.0%) or France (55.4%).

Companies are the primary source of investment spending (I). They make investment decisions in order to expand their stock of physical capital, such as building new factories or adding new equipment to existing facilities. A definition of physical capital is *any manmade aid to production*. Companies also buy investment goods, such as manufacturing plants and equipment to replace existing facilities and equipment that wear out. Total investment, including replacement of worn-out capital, is called *gross investment*, as opposed to *net investment*, which reflects only the addition of new capacity. GDP includes gross investment; hence the name *gross* domestic product. Total investment spending in such developed countries as Italy, Germany, the United Kingdom, and the United States ranged between 12% and 16% of GDP in 2015 (OECD. Stat Extracts: Country Statistical Profiles 2017, stats.oecd.org).

Investment decisions depend primarily on two factors: the level of interest rates and aggregate output/income. The level of interest rates reflects the cost of financing investment. The level of aggregate output serves as a proxy for the expected profitability of new investments. When an economy is underutilizing its resources, interest rates are typically very low, and yet investment spending often remains dormant because the expected return on new investments is also low. Conversely, when output is high and companies have little spare capacity, the expected return on new investments is high. Thus, investment decisions may be modeled as a decreasing function $\boldsymbol{I}(\cdot,\cdot)$ of the **real interest rate** (nominal interest rate minus the expected rate of inflation) and an increasing function of the level of aggregate output. Formally,

$$I = \boldsymbol{I}(r, Y)$$

where I is investment spending, r is the real interest rate, and Y is, as usual, aggregate income. This investment function leaves out some important drivers of investment decisions, such as the availability of new and better **technology**. Nonetheless, it reflects the two most important considerations: the cost of funding (represented by the real interest rate) and the expected profitability of the new capital (proxied by the level of aggregate output).

Many government spending decisions are insensitive to the current level of economic activity, the level of interest rates, the currency exchange rate, and other economic factors. Thus, economists often treat the level of government spending on goods and services (G) as an *exogenous* policy variable determined outside the macroeconomic model. In essence, this means that the adjustments required to maintain the balance among aggregate spending, income, and output must occur primarily within the private sector.

Tax policy may also be viewed as an exogenous policy tool. The actual amount of net taxes (T) collected, however, is closely tied to the level of economic activity. Most countries impose income taxes or value-added taxes (VAT) or both that increase with the level of income or expenditure. Similarly, at least some transfer payments to the household sector are usually based on economic need and are hence inversely related to aggregate income. Each of these factors makes net taxes (T) rise and fall with aggregate income, Y. The government's fiscal balance can be represented as

$$G - T = \bar{\boldsymbol{G}} - t(Y)$$

where $\bar{\boldsymbol{G}}$ is the exogenous level of government expenditure and $t(Y)$ indicates that net taxes are an (increasing) function of aggregate income, Y. The fiscal balance decreases (smaller deficit or larger surplus) as aggregate income (Y) increases and increases as income declines. This effect is called an *automatic stabilizer* because it tends to mitigate changes in aggregate output.

Net exports ($X - M$) are primarily a function of income in the domestic country and in the rest of the world and of the relative prices of domestic and non-domestic goods and services. As domestic income rises, some of the additional demand that is induced will be for imported goods. Thus, net exports will decline. An increase in income in the rest of the world will lead to an increase in demand for the domestic country's products and hence an increase net exports. A decrease in the relative price of domestically produced goods and services, perhaps because of a depreciation in the domestic currency, will shift demand toward these products and hence increase net exports.

3 AGGREGATE DEMAND AND AGGREGATE SUPPLY

f explain how the aggregate demand curve is generated

Short-term fluctuations in an economy's output arise for a number of reasons. The fluctuations of output and price level can have a significant effect on issuers of securities and therefore come under close scrutiny by practitioners and policymakers.

We will build a model of aggregate demand and aggregate supply and use it to discuss how aggregate output and the level of prices are determined in the economy. **Aggregate demand** (AD) represents the quantity of goods and services that households, businesses, government, and international customers want to buy at any given level of prices. **Aggregate supply** (AS) represents the quantity of goods and services that producers are willing to supply at any given level of prices. It also reflects the amount of labor and capital that households are willing to offer into the marketplace at given real wage rates and cost of capital.

3.1 Aggregate Demand

f explain how the aggregate demand curve is generated

As we will see, the **aggregate demand curve** looks like the ordinary demand curves that we encounter in microeconomics: quantity demanded increases as the price level declines. But our intuitive understanding of that relationship—lower price allows us to buy more of a good *with a given level of income*—does not apply here because income is not fixed. Instead, aggregate income/expenditure (GDP) is to be determined within the model along with the price level. Thus, we need to explain the relationship between price and quantity demanded somewhat differently.

The aggregate demand curve represents the combinations of aggregate income and the price level at which two conditions are satisfied. First, aggregate expenditure equals aggregate income. As indicated in our discussion of GDP accounting, this relation must always be true after the fact. Second, the available real money supply is willingly held by households and businesses. Recall that GDP is defined as

$$\text{GDP} = C + I + G + (X - M),$$

where

C = consumer spending on final goods and services
I = gross private domestic investment
G = government spending on final goods and services
X = exports
M = imports

We assume that government spending (G) is exogenous, set by government policy. To explain why the aggregate demand curve slopes downward, we analyze how the price level in the economy affects the consumption (C), investment (I), and net export ($X - M$) components of GDP. The downward slope of the aggregate demand curve results from three effects: the **wealth effect**, the **interest rate effect**, and the **real exchange rate effect**. We assume that the nominal money supply is held constant.

3.1.1 *Wealth Effect*

The **wealth effect** is based on the concept of purchasing power of nominal wealth, including nominal value of the money held by consumers, physically or in a bank account. Nominal wealth does not change: One British pound is always worth one British pound. Similarly, one euro is worth one euro, and one yen is worth one yen.

The real value, however—the value of money in terms of goods and services—is *not* fixed. It fluctuates with the prices of goods and services. Assume that our favorite loaf of bread costs one pound (£1 = one loaf of bread). If we have £10 in a pocket, then we have money that is equivalent to 10 loaves of bread. The real money holdings are therefore 10 loaves of bread.

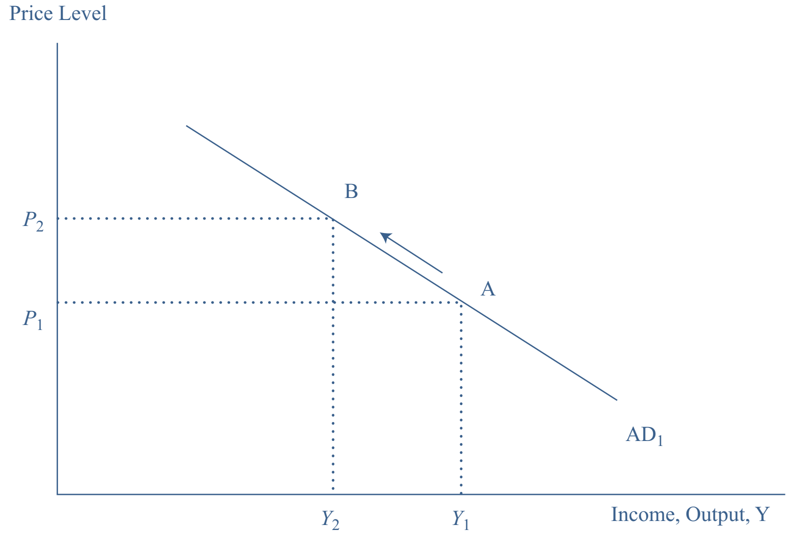
$$\frac{£10}{\left(\frac{£1}{\text{loaf}}\right)} = 10 \text{ loaves}$$

If the price of a loaf of bread increases to £2 (£2 = one loaf of bread), the same £10 is now worth only five loaves of bread. Our real money holdings, and therefore our real wealth, have decreased. Conversely, if the price of a loaf of bread decreases to one-half pound (£0.50 = one loaf of bread), the same £10 is now worth 20 loaves of bread. Our real money holdings, and therefore our real wealth, have increased.

The effect of the change in the price level and the resulting change in the real value of money holdings give the wealth effect its name, because as the real value of our money holdings changes, so does our real wealth.

The wealth effect is one reason that the aggregate demand curve is downward sloping. An increase in the price level decreases the quantity of goods and services that can be purchased with the fixed quantity of nominal wealth—consumers are less wealthy (in real terms) and therefore demand fewer goods and services. Exhibit 11 illustrates this dynamic as the movement from Point A to Point B. An increase in the price level from P_1 to P_2 reduces income from Y_1 to Y_2. Conversely, a decrease in the price level increases the quantity of goods and services that can be purchased with the fixed quantity of money available—consumers are wealthier (in real terms) and therefore demand more goods and services.

Exhibit 11 The Aggregate Demand Curve



3.1.2 *The Interest Rate Effect*

When the price level changes, the demand for money also changes. For example, if the price for your lunch today is 10 euros (€10 = lunch), then we need to have 10 euros in our pocket to eat lunch. Now, assume that the price of lunch doubles to 20 euros (€20 = lunch). If we want to eat lunch, we need to get more money—our demand for money increases. With a fixed supply of money, the price of money increases. Because the price of money is the interest rate, then as the price level increases, the interest rate increases.

The converse is also true. If the price of lunch decreases to five euros (€5 = lunch), we don't need to carry around as much money as before – our demand for money decreases. With a fixed supply of money, the price of money decreases. Therefore, as the price level decreases, the interest rate decreases.

Why not just keep extra "lunches" (money) in our pocket? Because holding extra money in such liquid form means that we are giving up the interest that we could be earning by lending the money out to others (*e.g.* through purchasing a government or corporate bond or just leaving the money in a bank account and letting the bank do the lending for us). The interest we would earn is the opportunity cost of keeping money in our pocket. So, when the price level decreases, we will want to keep more of our money in interest-bearing assets and our demand for money decreases.

Changes in the interest rate affect the quantity of goods and services demanded. If interest rates increase, businesses invest less because their borrowing costs increase. This shift leads to fewer profitable projects to invest in and also negatively affects the demand for commercial real estate. In addition, higher interest rates lead to lower consumption—especially for large purchases such as automobiles or residential real estate, which are usually purchased with loans. If interest rates decrease, then businesses have more profitable projects to invest in, and consumers would be expected to spend more.

This leads us to the **interest rate effect**. A higher price level creates greater demand for money, which raises the interest rate. The higher interest rate decreases demand for investment and consumption expenditures, which leads to less demand for goods and services. Conversely, a lower price level leads to a lower demand for money, which leads to a lower interest rate. The lower interest rate increases demand for investment and consumption expenditures, which leads to more demand for goods and services.

3.1.3 *The Real Exchange Rate Effect*

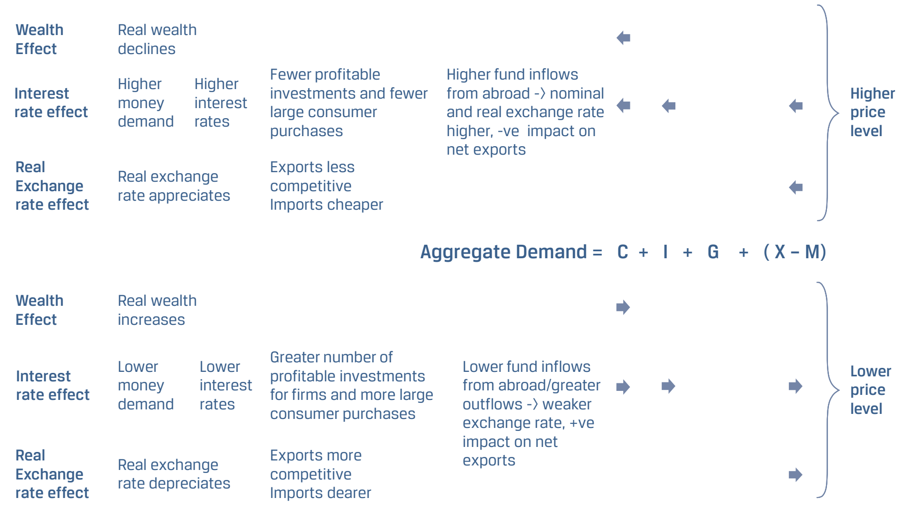
An increase in the domestic price level causes appreciation of the real exchange rate. Real exchange rates will be explained later, but for the purpose of this discussion, it is important to understand that the real exchange rate is the observed, quoted nominal exchange rate adjusted for price level. So a higher price level affects the real exchange rate and makes domestic goods more expensive in other countries, reducing exports. It also makes non-domestic goods less expensive domestically, increasing imports. The result is lower demand for domestic goods and services. Conversely, a decrease in the domestic price level (assuming the price level abroad remains unchanged) leads to a depreciation of the real exchange rate. This decrease in the real exchange rate makes domestic goods less expensive in other countries, increasing exports, and non-domestic goods more expensive domestically, decreasing imports. The result is higher demand for domestic goods and services. This dynamic gives us the **real exchange rate effect**.

An additional channel affecting exchange rates involves the interest rate effect. When interest rates increase (because of a higher price level), non-domestic investors increase their demand for the domestic currency in the foreign exchange market because they want to earn the higher return on their savings. This increased demand causes the domestic currency to appreciate, which in turn increases the real exchange rate.

When interest rates decrease (because of a lower price level), a similar but opposite effect occurs. Domestic savers seek higher returns in non-domestic markets. This increased supply of the domestic currency in the foreign exchange market causes the domestic currency to depreciate, which in turn decreases the real exchange rate.

The interest rate effect just described is an additional channel through which a higher price level leads to a higher real exchange rate. The two effects are complementary, operate in the same direction and magnify the impact of the change in price level on aggregate demand. Exhibit 12 provides a summary.

Exhibit 12 Deriving Aggregate Demand Curve: Summary of Key Effects



Wealth Effect
Real wealth declines
Interest rate effect
Higher money demand
Higher interest rates
Fewer profitable investments and fewer large consumer purchases
Higher fund inflows from abroad -) nominal and real exchange rate higher, -ve impact on net exports
Real Exchange rate effect
Real exchange rate appreciates
Exports less competitive Imports cheaper
Higher price level
Aggregate Demand = C + I + G + (X – M)
Wealth Effect
Real wealth increases
Interest rate effect
Lower money demand
Lower interest rates
Greater number of profitable investments for firms and more large consumer purchases
Lower fund inflows from abroad/greater outflows -) weaker exchange rate, +ve impact on net exports
Real Exchange rate effect
Real exchange rate depreciates
Exports more competitive Imports dearer
Lower price level

EXAMPLE 5

Slope of the Aggregate Demand Curve

Considering the movement along the aggregate demand curve, which of the following statements best explains the interest rate effect when the price level decreases?

A Decrease in money demand, with a fixed money supply, leads to lower interest rates. Lower interest rates induce businesses to invest more because there is now a greater number of profitable projects. Consumers also spend more when interest rates are lower. Lower interest rates also weaken the exchange rate, boosting net exports. These effects cause output to be higher at a lower price level.

B Decrease in money demand, with a fixed money supply, leads to lower interest rates. Lower interest rates induce businesses to invest less because there are now fewer profitable projects. Lower interest rates also weaken the exchange rate, boosting net exports.

C Decrease in money demand, with a fixed money supply, leads to higher interest rates, which induce businesses to invest less and consumers to save more. Higher interest rates cause the exchange rate to appreciate, boosting net exports.

Solution:

A is correct. B is incorrect because the statement suggests that lower interest rates lead to less business investment. C is incorrect because the statement suggests that a lower price level leads to higher interest rates.

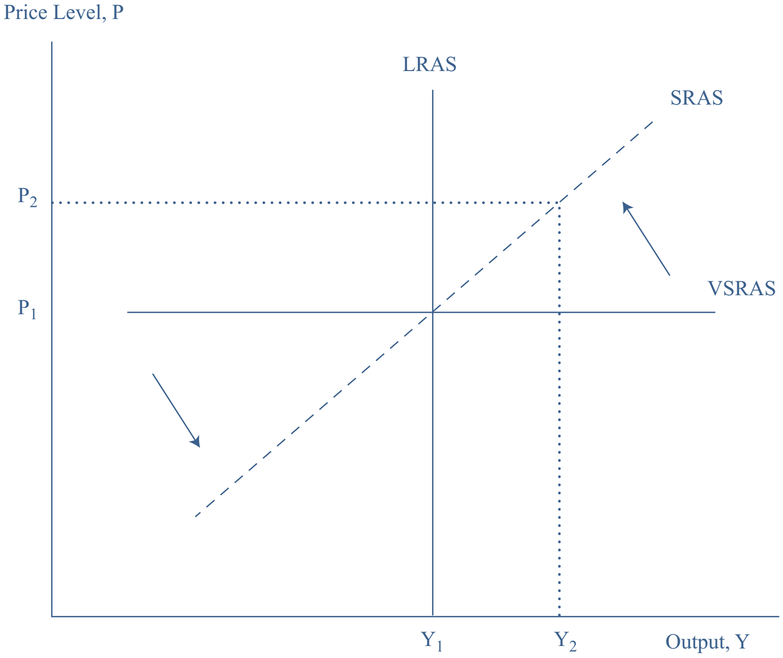
3.2 Aggregate Supply

g explain the aggregate supply curve in the short run and long run

Aggregate demand tells us only the relationship between the price level and the amount of output demanded at those prices. To understand what price and output level will prevail in the economy, we need to add aggregate supply, the amount of output producers are willing to provide at various prices. The **aggregate supply curve** (AS curve) represents the level of domestic output that companies will produce at each price level. Unlike the demand side, we must distinguish between the short- and long-run AS curves, which differ with respect to how wages and other input prices respond to changes in final output prices. "Long run" and "short run" are relative terms and are necessarily imprecise with respect to calendar time. The "long run" is long enough that wages, prices, and expectations can adjust but not long enough that physical capital is a variable input. Capital and the available technology to use that capital remain fixed. This condition implies a period of at least a few years and perhaps a decade. The truly long run, in which even the capital stock is variable, may be thought of as covering multiple decades. Consideration of the very long run is postponed to our subsequent discussion of economic growth.

In the very short run, perhaps a few months or quarters, companies will increase or decrease output to some degree without changing prices. Exhibit 13 illustrates this dynamic with the horizontal line labeled VSRAS. If demand is somewhat stronger than expected, companies earn higher profit by increasing output as long as they can cover their variable costs. So they will run their plant and equipment more intensively, demand more effort from their salaried employees, and increase the hours of employees who are paid on the basis of hours worked. If demand is somewhat weaker than projected, companies can run their plants less intensively, cut labor hours, and use staff to perform maintenance and carry out efficiency-enhancing projects that are often postponed during busier periods.

Exhibit 13 Aggregate Supply Curve



Over somewhat longer periods, the AS curve is upward sloping because more costs become variable. This dynamic is represented by the short-run aggregate supply (SRAS) curve in Exhibit 13. In most businesses, wages are adjusted once a year, but for companies with union contracts, several years may pass before the contracts expire. The prices for raw materials and other inputs may also be established under long-term contracts. Hence, wages and other input costs are relatively inflexible in the short run and do not fully adjust to changes in output prices. As the price level rises, most companies enjoy higher profit margins and hence expand production. In Exhibit 13, when prices move from P_1 to P_2, the quantity of aggregate output supplied increases from Y_1 to Y_2. Conversely, a reduction in the price level squeezes profit margins and causes companies to reduce production.

Over time, however, wages and other input prices tend to "catch up" with the prices of final goods and services. In other words, wages and prices that are inflexible or slow to adjust in the short run adjust to changes in the price level over the long run. Thus, over the long run, when the aggregate price level changes, wages and other input prices change proportionately so that the higher aggregate price level has no effect on aggregate supply. This dynamic is illustrated by the vertical long-run aggregate supply (LRAS) curve in Exhibit 13. As prices move from P_1 to P_2, the quantity of output supplied remains at Y_1 in the long run. The only change that occurs is that prices shift to a higher level (from P_1 to P_2).

The position of the LRAS curve is determined by the potential output of the economy. The amount of output produced depends on the fixed amount of capital and labor and the available technology. This classical model of aggregate supply can be expressed as

$$Y = \boldsymbol{F}\left(\overline{K}, \overline{L}\right) = \overline{Y}$$

where $\overline{K}$ is the fixed amount of capital and $\overline{L}$ is the available labor supply. The stock of capital is assumed to incorporate the existing technological base. Note that investment (I) reflects replacement of worn-out capital plus the change in capital, ΔK. Over short periods, net investment is assumed to have a negligible effect on aggregate supply. The available labor supply is also held constant, and workers are assumed to have a given set of skills. The long-run equilibrium level of output, Y_1 in Exhibit 13, is referred to as the *full employment*, or *natural*, level of output. At this level of output, the economy's resources are deemed to be fully employed, and (labor) *unemployment is at its natural rate*. This concept of a natural rate of unemployment assumes the macroeconomy is currently operating at an efficient and unconstrained level of production. Companies have enough spare capacity to avoid bottlenecks, and there is a modest, stable pool of unemployed workers (job seekers equal job vacancies) looking for and transitioning into new jobs.

3.3 Shifts in the Aggregate Demand Curve

h explain causes of movements along and shifts in aggregate demand and supply curves

i describe how fluctuations in aggregate demand and aggregate supply cause short-run changes in the economy and the business cycle

In the next two sections, the aggregate demand (AD) and aggregate supply (AS) models are used to address three critical macroeconomic questions:

1. What causes an economy to expand or contract?

2 What causes inflation and changes in the level of unemployment?

3 What determines an economy's rate of sustainable growth, and how can it be measured?

Before addressing these questions, we need to distinguish between 1) the long-run growth rate of real GDP and 2) short-run fluctuations in real GDP around this long-run trend.

The business cycle is a direct result of short-term fluctuations of real GDP. It consists of periods of economic expansion and contraction. In an expansion, real GDP is increasing, the unemployment rate is declining, and capacity utilization is rising. In a contraction, real GDP is decreasing, the unemployment rate is rising, and capacity utilization is declining. Shifts in the AD and AS curves determine the short-run changes in the economy associated with the business cycle. In addition, the AD–AS model provides a framework for estimating the sustainable growth rate of an economy, which is addressed in Section 4.

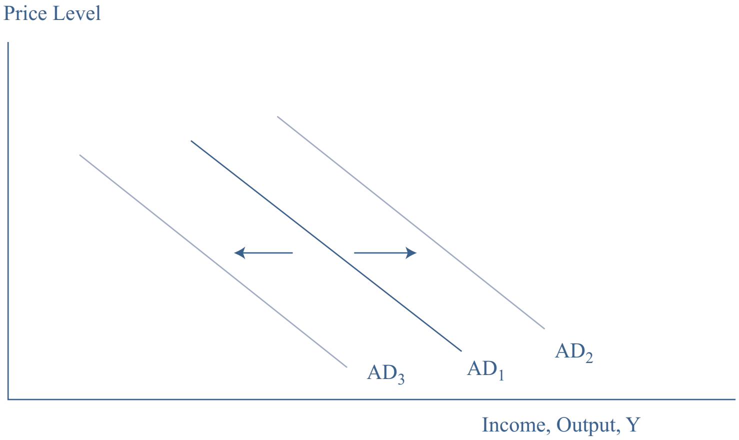
From an asset allocation perspective, it is important to determine the current phase of the business cycle as well as how fast the economy is growing relative to its sustainable growth rate. The expected rate of return on equities and fixed-income securities, for example, depends on estimates of the growth rate of GDP and inflation. For equities, GDP growth is the primary determinant of aggregate corporate profits. For fixed-income securities, the expected rate of inflation determines the spread between real and nominal rates of return. In order to use the AD and AS model to analyze the economy and to make investment decisions, we need to first understand what factors cause the curves to shift.

3.3.1 *Shifts in Aggregate Demand*

In addition to price, factors that influence the level of spending by households, companies, governments, and people in other countries (i.e., the aggregate level of expenditures) will cause the AD curve to shift. A shift to the right represents an increase in aggregate demand at any price level. Exhibit 14 shows this dynamic as a shift from AD_1 to AD_2. A shift to the left represents a decrease in aggregate demand at any price level. This dynamic is indicated by a move from AD_1 to AD_3. Key factors that directly or indirectly influence the level of aggregate expenditures and cause the aggregate demand curve to shift include changes in the following:

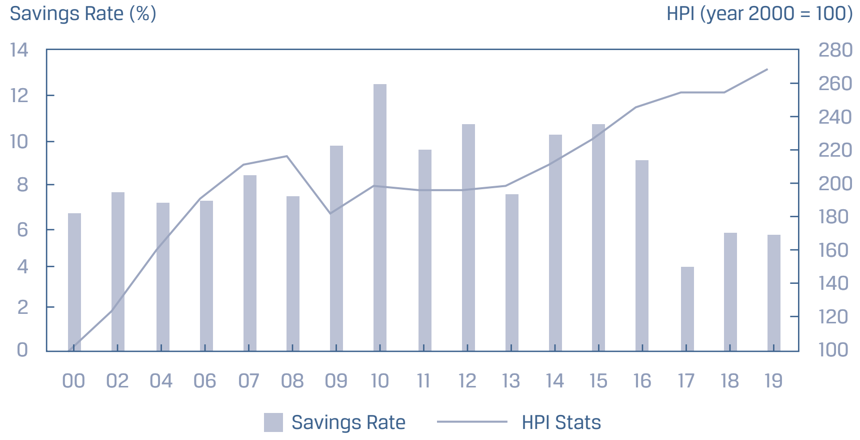
- household wealth,
- consumer and business expectations,
- capacity utilization,
- monetary policy,
- the exchange rate,
- growth in the global economy, and
- fiscal policy (government spending and taxes).

Exhibit 14 Shifts in the Aggregate Demand Curve



Household Wealth Household wealth includes the value of both financial assets (e.g., cash, savings accounts, investment securities, and pensions) and real assets (e.g., real estate). The primary reason households save a portion of their current income is to accumulate wealth for consumption in the future. The proportion of disposable income that households save depends partly on the value of the financial and real assets that they have already accumulated. If these assets increase in value, households will tend to save less and spend a greater proportion of their income because they will still be able to meet their wealth accumulation goals. As a result, an increase in household wealth increases consumer spending and shifts the aggregate demand curve to the right. In contrast, a decline in wealth will reduce consumer spending and shift the AD curve to the left. This dynamic, often referred to as the **wealth effect**, provides one explanation for how changes in equity prices affect economic activity. Higher equity prices increase household wealth, which increases consumer spending and reduces the amount saved out of current income. Economic studies estimate that an increase or decrease in wealth in developed countries increases or decreases annual consumer spending by 3%–7% of the change in wealth (Case, Quigley, and Shiller 2005). A smaller but still statistically significant wealth effect has been found in a number of emerging markets (developing countries) (Funke 2004).

Exhibit 15 Housing Prices and the Saving Rate in the United Kingdom, 2000–2019



Source: Office of National Statistics, United Kingdom.

EXAMPLE 6

The Wealth Effect on Saving and Consumption

The importance of the wealth effect on consumption, and its relationship to housing prices, was evident in the sharp global economic downturn. A major factor associated with the economic downturn was the sharp fall in housing prices, especially in countries that experienced a housing boom earlier in the decade, such as the United States, the United Kingdom, Spain, and Ireland. In each of these countries, consumers reduced spending sharply and raised the level of saving in response to the decline in wealth. Do the data in Exhibit 15 provide support for the wealth effect?

Solution:

Housing prices in the United Kingdom rose by nearly 111% [(211.1 – 100)/100] between 2000 and 2007. During this period, the saving rate averaged 7.2% of income up until 2008. As predicted, when housing prices fell by 11% between 2008 and 2009, the saving rate rose dramatically from 7.2% in 2008 to 12.4% in 2010. Of course, the decline in housing prices was not the only factor contributing to the increase in the saving rate. Stock prices also declined during this period, further reducing wealth in the United Kingdom, and the slowdown raised uncertainty over future jobs and income. Then, as the economy recovered, house prices rose again from 2013, which led to a (lagged) decline in the saving rate.

Consumer and Business Expectations Psychology has an important impact on consumer and business spending. When consumers are confident about their future income and the stability/safety of their jobs, they tend to spend a higher portion of their disposable income. This dynamic shifts the AD curve to the right. Consumer spending declines and the AD curve shifts to the left when consumers become less confident. Similarly, when businesses are optimistic about their future growth and profitability, they spend (invest) more on capital projects, which also shifts the AD curve to the right.

Capacity Utilization Capacity utilization is a measure of how fully an economy's production capacity is being used. Companies with excess capacity have little incentive to invest in new property, plant, and equipment. In contrast, when companies are operating at or near full capacity, they will need to increase investment spending in order to expand production. Data from the OECD and the US Federal Reserve indicate that when aggregate capacity utilization reaches 82%–85%, production blockages arise, prompting companies to increase their level of investment spending. This dynamic shifts the AD curve to the right.

Fiscal Policy **Fiscal policy** is the use of taxes and government spending to affect the level of aggregate expenditures. An increase in government spending, one of the direct components of AD, shifts the AD curve to the right, whereas a decrease in government spending shifts the AD curve to the left. Taxes affect GDP indirectly through their effect on consumer spending and business investment. Lower taxes will increase the proportion of personal income and corporate pre-tax profits that consumers and businesses have available to spend and will shift the AD curve to the right. In contrast, higher taxes will shift the AD curve to the left.

Monetary Policy *Money* is generally defined as currency in circulation plus deposits at commercial banks. **Monetary policy** refers to action taken by a nation's central bank to affect aggregate output and prices through changes in bank reserves, reserve requirements, or its target interest rate.

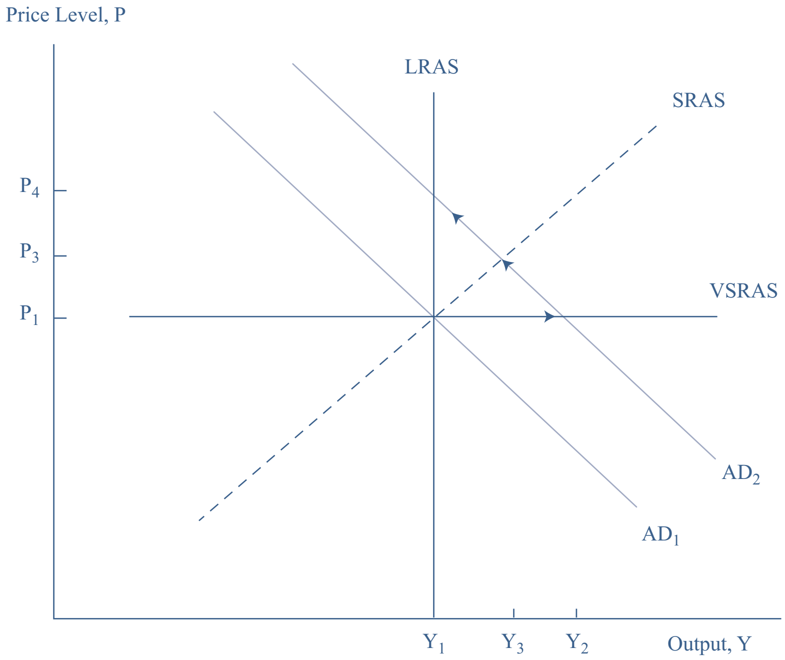
Most countries have fractional reserve banking systems in which each bank must hold reserves (vault cash plus deposits at the central bank) at least equal to the required reserve ratio times its customer deposits. Banks with excess reserves can lend them to banks that need reserves to meet their reserve requirements. The central bank can increase the money supply by 1) buying securities from banks, 2) lowering the required reserve ratio if such a tool is available, and/or 3) reducing its target for the interest rate at which banks borrow and lend reserves among themselves. In each case, the opposite action would decrease the money supply.

When the central bank buys securities from banks in an open-market operation, it pays for them with a corresponding increase in bank reserves. This dynamic increases the amount of deposits banks can accept from their customers—that is, the money supply. Similarly, cutting the required reserve ratio increases the level of deposits (i.e., money) consistent with a given level of reserves in the system. If the central bank chooses to target an interbank lending rate, as the Federal Reserve targets the federal funds rate in the United States, then it must add or drain reserves via open-market operations to maintain the target interest rate. If it raises (lowers) its target interest rate, it will have to drain (add) reserves in order to make reserves more (less) expensive in the interbank market. Thus, open-market operations and interest rate targeting are very closely related. The main distinction is whether the central bank chooses to target a level of reserves and let the market determine the interest rate or chooses to target the interest rate and let the market (i.e., banks) determine the level of reserves they desire to hold at that rate.

An increase in the money supply shifts the AD curve to the right so that each price level corresponds to a higher level of income and expenditure. There are various channels through which the additional expenditures may be induced. For example, the interest rate reduction required to induce investors to hold the additional money balances will encourage companies to invest more and households to borrow to purchase durable goods, such as cars. In addition, banks may facilitate greater expenditure by raising credit limits and loosening credit standards. Conversely, a reduction in the money supply shifts the AD curve to the left.

Exhibit 16 illustrates the short-run and long-run effect of expansionary monetary policy. Suppose the central bank expands the money supply in an attempt to stimulate demand when the economy is already in long-run equilibrium. The expansionary policy will shift the AD curve to the right, from AD_1 to AD_2. In the very short run, output will expand from Y_1 to Y_2 without an increase in the price level. After operating at higher-than-normal production rates for a few months or quarters, companies will begin to push for price increases and input prices will begin to rise as well. The aggregate supply curve will steepen, and prices will increase to P_3 while output declines to Y_3. As input prices become more flexible, the AS curve will steepen until, in the long run, it is vertical and output has returned to the long-run natural level, Y_1, with prices rising to P_4. Thus, expanding the money supply increases output in the short run, but in the long run it affects only the price level.

Exhibit 16 Short-Run and Long-Run Effects of Monetary Expansion



Exchange Rate Changes in the exchange rate affect the price of exports and imports and thus aggregate demand. For example, a lower euro relative to other currencies makes European exports cheaper in world markets and non-European products sold in Europe (European imports) more expensive. Therefore, a lower euro should cause European exports to increase and imports to decline, leading the AD curve to shift to the right. Conversely, a stronger euro reduces exports and raises imports, and the AD curve shifts to the left.

Growth in the Global Economy International trade is what links countries together and creates a global economy. Faster economic growth in non-domestic markets encourages people in other countries to buy more products from domestic producers and increases exports. For example, rapid GDP growth in ASEAN member countries has increased their demand for products from other nations. Japan has benefited from this rapid growth because it has exported more products to ASEAN countries. In terms of the AD and AS model, the AD curve for Japan has shifted to the right because of increased demand for Japanese products in ASEAN countries, resulting in higher exports. A decline in the growth rates of ASEAN members' economies would have a negative effect on the Japanese economy because exports would be lower. This change would cause the Japanese AD curve to shift to the left.

What happens to interest rates when the AD curve shifts? In the case of an increase in the money supply, the interest rate declines at each price level because the increase in income (Y) increases saving, and rates must decline to induce a corresponding increase in investment spending (I). In each of the other cases considered above, a rightward shift in the AD curve will increase the interest rate at each price level. With the real money supply held constant, the interest rate must rise as income increases. The increase in the interest rate reduces the demand for money at each level of expenditure/income and, therefore, allows expenditure/income to increase without an increase in the money supply. In terms of the quantity theory of money equation, this shift corresponds to a higher velocity of money, V.

Exhibit 17 summarizes the main factors that shift the AD curve. In each case, the impact of the factor is considered in isolation. In practice, however, various factors may be at work simultaneously and there may be interaction among them. This is especially true with regard to expectational factors—consumer and business confidence—which are likely to be influenced by other developments.

Exhibit 17 Impact of Factors Shifting Aggregate Demand

An Increase in the Following Factors	Shifts the AD Curve	Reason
Stock prices	Rightward: Increase in AD	Higher consumption
Housing prices	Rightward: Increase in AD	Higher consumption
Consumer confidence	Rightward: Increase in AD	Higher consumption
Business confidence	Rightward: Increase in AD	Higher investment
Capacity utilization	Rightward: Increase in AD	Higher investment
Government spending	Rightward: Increase in AD	Government spending a component of AD
Taxes	Leftward: Decrease in AD	Lower consumption and investment
Bank reserves	Rightward: Increase in AD	Lower interest rate, higher investment and possibly higher consumption
Exchange rate (foreign currency per unit domestic currency)	Leftward: Decrease in AD	Lower exports and higher imports
Global growth	Rightward: Increase in AD	Higher exports

EXAMPLE 7

Shifts in Aggregate Demand

Francois Ubert is a portfolio manager with EuroWorld, a French investment management firm. Ubert is considering increasing his clients' portfolio exposure to Brazilian equities. Before doing so, he asks you to prepare a report on the following recent economic events in Brazil and to summarize the effect of each event on the Brazilian economy and on Brazilian equity and fixed-income securities.

1 The Brazilian central bank reduced bank reserves, resulting in a lower money supply.

2 The capacity utilization rate in Brazil is currently estimated to be 86.4%, a 2.7% increase from the previous year.

3 Corporate profits reported by Brazilian companies increased by 30% over last year's levels, and corporations have revised their forecasts of future profitability upward.

4 The government recently announced that it plans to start construction on a number of hydroelectric projects to increase renewable energy sources.

5 Forecasts by private sector economists project that the European economy will enter a sharp slowdown and decline in the next year.

Solution to 1:

This monetary policy action is designed to reduce consumption and business investment spending. The reduction in real money balances will increase interest rates and discourage lending within the banking system. Higher interest rates and tighter credit will reduce both investment and consumption expenditures and shift the AD curve to the left. The prices of fixed-income securities will fall because of the rise in interest rates. The reduction in aggregate output should lower corporate profits, and it is likely that equity prices will also fall.

Solution to 2:

Capacity utilization is a key factor determining the level of investment spending. A current utilization rate of more than 86% and an increase from the previous year indicate a growing lack of spare capacity in the Brazilian economy. As a result, businesses will probably increase their level of capital spending. This change will increase AD and shift the AD curve to the right. Higher economic activity (income/output) will cause upward pressure on interest rates and may have a negative effect on fixed-income securities. Higher income/output should increase corporate profits and is likely to have a positive effect on equity securities.

Solution to 3:

Expected corporate profits are an important determinant of the level of investment spending. The large increase in expected profits will raise the level of investment spending and increase aggregate demand. This change will shift the AD curve to the right. The increase in corporate profits and the resulting increase in economic output should have a positive effect on equities. The increase in output will put upward pressure on interest rates and downward pressure on the prices of fixed-income securities.

Solution to 4:

Fiscal policy uses government spending to influence the level and growth rate of economic activity. The announcement indicates an increase in government spending, which is a direct component of AD. Therefore, higher spending on the projects will increase AD and shift the AD curve to the right. The increase in output and expenditure should be positive for equities. But it will be negative for existing fixed-income investments because higher interest rates will be required to induce investors to buy and hold the government debt issued to fund the new projects.

Solution to 5:

A sharp slowdown in Europe will decrease the demand for Brazilian exports by European households and businesses and shift the AD curve to the left. The resulting decline in income and downward pressure on prices will be positive for fixed-income securities but negative for equities.

3.3.2 *Shifts in the Short-Run Aggregate Supply Curve*

g explain the aggregate supply curve in the short run and long run

h explain causes of movements along and shifts in aggregate demand and supply curves

Factors that change the cost of production or expected profit margins will cause the SRAS curve to shift. These factors include changes in

- nominal wages,
- input prices, including the price of natural resources,
- expectations about future output prices and the overall price level,
- business taxes and subsidies, and
- the exchange rate.

In addition, factors that shift the long-run AS curve (discussed elsewhere) will also shift the SRAS curve by a corresponding amount because the SRAS and LRAS reflect the same underlying resources and technology. As the economy's resources and technology change, the full employment (or natural) level of output changes, and both the LRAS and SRAS shift accordingly.

Change in Nominal Wages Changes in nominal wages shift the short-run AS curve because wages are often the largest component of a company's costs. An increase in nominal wages raises production costs, resulting in a decrease in AS and a leftward shift in the SRAS curve. Lower wages shift the AS curve to the right. It is important to note that changes in nominal wages have no effect on the LRAS curve.

A better way to measure the impact of labor costs on the AS curve is to measure the change in unit labor cost. We define the change in unit labor cost as

$$\begin{aligned}\%\text{ Change in unit labor cost} = {} & \%\text{ Change in nominal wages} \\ & - \%\text{ Change in productivity}\end{aligned}$$

EXAMPLE 8

Unit Labor Cost and Short-Run Aggregate Supply

Suppose Finnish workers are paid €20 an hour and are able to produce 100 cell phones in an hour. The labor cost per cell phone is €0.20 (€20 divided by 100 units). If the wages per hour for Finnish workers rise by 10% from €20 to €22 and they are able to raise their productivity by 10%, what is the impact on unit labor cost and the short-run aggregate supply curve?

Solution:

The workers can now produce 110 cell phones per hour, and unit labor cost will not change (22/110 = 0.20). In this case, the SRAS curve will remain in its original position. If wages had increased by 20% instead of 10%, then unit labor cost would have increased and the SRAS would shift to the left. Conversely, if the wage increase were only 5%, then unit labor cost would have decreased and the SRAS would shift to the right.

Change in Input Prices The price of raw materials is an important component of cost for many businesses. Lower input prices reduce the cost of production, which, in turn, makes companies willing to produce more at any output price. This dynamic is reflected in a rightward shift of the SRAS curve. Conversely, higher input prices increase production costs, which, in turn, causes companies to reduce production at any output price. This dynamic shifts the SRAS curve to the left. During the 1970s, high oil prices caused the SRAS curve in most countries to shift to the left. In contrast, in the mid-1980s, declining oil prices lowered the cost of production and shifted the SRAS curve in most countries to the right. Oil prices currently have a smaller effect on the global economy than in the 1970s and 1980s because most countries have reduced their reliance on oil and improved their energy efficiency so that they now use less energy per unit of GDP.

Change in Expectations about Future Prices The impact of expected future prices on current output decisions is not as straightforward as it might seem. First, each company is primarily concerned about the price of its own output rather than the general price level. The latter may be more reflective of its costs. If it expects its own output price to rise (fall) relative to the general price level, then it may increase (decrease) production in response to the perceived change in its profit margin. As more and more companies become optimistic (pessimistic) about their ability to raise the relative price of their product, the SRAS will shift to the right (left). In the aggregate, of course, companies can neither raise nor lower their prices relative to the general price level. Hence, shifts in the SRAS driven by such price expectations are likely to be modest and temporary. Second, considering future prices introduces a temporal aspect into decision making. If the future price level is expected to be higher, companies may decide to produce more today in order to expand inventory available for future sale. But they will only do so if the cost of carrying inventory (financing, storage, and spoilage) is less than they expect to save on production costs by producing more today and less in the future. Conversely, they may cut current production and sell out of existing inventory if they expect future prices (and costs) to be lower.

The upshot is that expectations of higher (lower) future prices are likely to shift the SRAS curve to the right (left), but the effect may be modest and/or temporary.

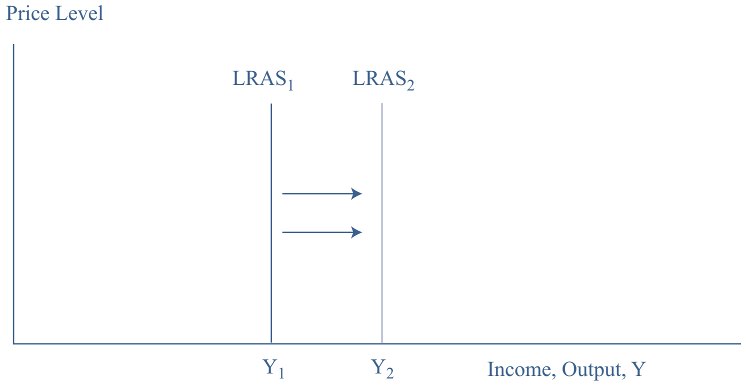
Change in Business Taxes and Subsidies Higher business taxes increase production costs per unit and shift the short-run AS curve to the left. Business subsidies are a payment from the government to the producer. Subsidies for businesses lower their production costs and shift the SRAS curve to the right.

Change in the Exchange Rate Many countries import raw materials, including energy and intermediate goods. As a result, changes in the exchange rate can affect the cost of production and, therefore, aggregate supply. A higher yen relative to the euro, for instance, would lower the cost of raw materials and intermediate goods imported to Japan from Europe. This, in turn, will lower the production costs of Japanese producers and shift the AS curve in Japan to the right. A lower yen would have the opposite effect.

3.3.3 *Shifts in the Long-Run Aggregate Supply Curve*

As discussed, the position of the LRAS curve is determined by the potential output of the economy. **Potential GDP** measures the productive capacity of the economy and is the level of real GDP that can be produced at full employment. Potential GDP is not a static concept but can increase each year at a steady rate as the economy's resource capacity grows. Therefore, any factor increasing the resource base of an economy causes the LRAS curve to shift as shown in Exhibit 18.

Exhibit 18 Shift in the Long-Run Aggregate Supply (LRAS) Curve



These factors include changes in

- supply of labor and quality of labor forces (human capital),
- supply of natural resources,
- supply of physical capital, and
- productivity and technology.

Supply of Labor The larger the supply of labor, the more output the economy can produce. The labor supply depends on growth in the population, the labor force participation rate (the percentage of the population working or looking for work), and net immigration. The determinants of the labor supply are discussed in more detail later in our coverage. Increases in the labor supply shift the LRAS curve to the right. Decreases shift the curve to the left.

Supply of Natural Resources Natural resources are essential inputs to the production process and include everything from available land to oil to water. Increased availability of natural resources shifts the LRAS curve to the right.

Supply of Physical Capital Investment in new property, plant, equipment, and software is an essential ingredient for growth. An increase in the stock of physical capital will increase the capacity of the economy to produce goods and services. Simply put, if workers are provided with more and better equipment to use, they should be able to produce more output than they could with the older equipment. Thus, strong growth in business investment, which increases the supply of physical capital, shifts the LRAS curve to the right.

Supply of Human Capital Another way to raise the productive capacity of a country is to increase human capital—the quality of the labor force—through training, skills development, and education. Improvement in the quality of the labor force shifts the LRAS curve to the right.

Labor Productivity and Technology Another important factor affecting the productive capacity of an economy is how efficient labor is in transforming inputs into final goods and services. **Productivity** measures the efficiency of labor and is the amount of output produced by workers during a given period—for example, output per hour worked. An increase in productivity decreases labor cost, improves profitability, and results in higher output. Two of the main drivers of labor productivity—physical capital per worker and the quality of the workforce—have been discussed already. The third key determinant of productivity is technology. Advances in technology shift the LRAS curve to the right.

EXAMPLE 9

Unit Labor Cost and Long-Run Aggregate Supply

Finnish workers are paid €20 per hour and are able to produce 100 cell phones in an hour. If workers develop a new technique for assembly and are able to produce 200 cell phones per hour, what is the effect on the long-run aggregate supply curve?

Solution:

Labor cost per unit will decline to €0.10 (20/200 = €0.10 per cell phone). As a result, profit per unit will rise and companies will have an incentive to increase production. Thus, the LRAS curve will shift to the right.

Exhibit 19 summarizes the factors shifting the AS curve. Rightward shifts in the SRAS or LRAS curves are defined as an increase in supply, while leftward shifts represent a decrease in supply.

Exhibit 19 Impact of Factors Shifting Aggregate Supply

An Increase in	Shifts SRAS	Shifts LRAS	Reason
Supply of labor	Rightward	Rightward	Increases resource base
Supply of natural resources	Rightward	Rightward	Increases resource base
Supply of human capital	Rightward	Rightward	Increases resource base
Supply of physical capital	Rightward	Rightward	Increases resource base
Productivity and technology	Rightward	Rightward	Improves efficiency of inputs
Nominal wages	Leftward	No effect	Increases labor cost
Input prices (e.g., energy)	Leftward	No effect	Increases cost of production
Expectation of future prices	Rightward	No effect	Anticipation of higher costs and/or perception of improved pricing power
Business taxes	Leftward	No effect	Increases cost of production
Subsidy	Rightward	No effect	Lowers cost of production
Exchange rate	Rightward	No effect	Lowers cost of production

As with our summary of factors that shift the AD curve, Exhibit 19 considers each of the factors affecting aggregate supply in isolation. In practice, various factors will be at work simultaneously, and there may be interaction among them. This is especially important with respect to interaction between factors listed as affecting only SRAS and those that also affect LRAS.

For example, consider an increase in the cost of natural resource inputs (e.g., energy). This change shifts the SRAS curve to the left, but according to Exhibit 19, it has no effect on LRAS. This presumes that the relative prices of the factors of production have not changed permanently. If a permanent change has occurred, companies will be forced to conserve on the now more expensive input and will be unable to produce as efficiently. The LRAS curve would, therefore, shift to the left, just as it would if the available supply of natural resources had declined relative to the supply of other inputs. Indeed, that is the most likely cause of a permanent change in relative input prices.

EXAMPLE 10

Shifts in Aggregate Supply

In this hypothetical scenario, John Donovan is a portfolio manager for a global mutual fund. Currently, his fund has 10% of its assets invested in Chinese equities. He is considering increasing the fund's allocation to the Chinese equity market. His decision will be based on an analysis of the following economic developments and their effect on the Chinese economy and equity market. What is the effect on SRAS and LRAS from the following factors?

1. Global oil prices, currently near their longer-run trend at US$75 a barrel, have increased from US$35 a barrel over the last three years because of strong demand from emerging markets.
2. The number of students studying engineering has dramatically increased at Chinese universities during the last decade.
3. Wages for China's workers are rising, leading some multinational companies to consider shifting their investments to Vietnam or Cambodia.
4. Data show that business investment as a share of GDP is more than 40% in China.
5. The People's Bank of China is likely to permit the yuan to appreciate by 10% during the next year.

Solution to 1:

Higher energy prices cause a decrease in short-run AS and shift the SRAS curve to the left. Because oil prices are back to their longer-run trend, the leftward shift in SRAS essentially reverses a previous shift that occurred when oil prices fell to US$35 a barrel, and it is likely that there will be no effect on the LRAS curve. Lower output and profit are likely to have a negative effect on Chinese equity prices.

Solution to 2:

More students studying engineering indicates an improvement in the quality of the labor force—an increase in human capital. As a result, AS increases and the AS curve shifts to the right. Both short-run and long-run curves are affected. Higher output and profits may be expected to have a positive effect on Chinese equity prices.

Solution to 3:

The increase in wages increases labor costs for businesses, causes short-run aggregate supply to decline, and shifts the SRAS curve to the left. Lower output and profit should have a negative effect on Chinese equity prices.

Solution to 4:

The high level of business investment indicates that the capital stock in China is growing at a fast rate. This growth means that workers have more capital to use, which increases their productivity. Thus, AS increases and the AS curve shifts to the right. Both short-run AS and long-run AS are affected. Higher output should have a positive effect on Chinese equity prices.

Solution to 5:

The probable appreciation of the yuan means that the cost of imported raw materials, such as iron ore, coal, and oil, will be lower for Chinese companies. As a result, short-run AS increases and the SRAS curve shifts to the right. The LRAS curve may also shift to the right if the appreciation of the yuan is permanent and global commodity prices do not fully adjust. Higher output and profit should have a positive effect on Chinese equity prices. Note that the stronger yuan will also reduce export demand and shift the AD curve to the left. The combined effect of the AD and AS shifts on output, profit, and equity prices is ambiguous.

The implications of the aforementioned factors for equity investment in China are ambiguous. If the long-run effects dominate, however, then the net effect should be positive. The positive factors—the high level of investment and the growing pool of engineering students—have a lasting effect on output and profit. The negative factors—higher wages and oil prices—should be temporary, because wages will realign with the price level and the increase in oil prices appears to offset a previous temporary decline. The reduction in raw material prices resulting from the stronger currency is positive for output, profit, and equities in the short run and perhaps in the long run as well.

3.4 Equilibrium GDP and Prices

i. describe how fluctuations in aggregate demand and aggregate supply cause short-run changes in the economy and the business cycle

j. distinguish among the following types of macroeconomic equilibria: long-run full employment, short-run recessionary gap, short-run inflationary gap, and short-run stagflation

k. explain how a short-run macroeconomic equilibrium may occur at a level above or below full employment

l. analyze the effect of combined changes in aggregate supply and demand on the economy

Now that we have discussed the components of the AD and AS model, we can combine them to determine the real level of GDP and the price level. Equilibrium occurs where the AD and AS curves intersect. At this point, the quantity of aggregate output demanded (or the level of aggregate expenditures) is equal to the quantity of aggregate output supplied. In Exhibit 20, equilibrium price and GDP occur at P_1 and Y_1. If the price level is above P_1, then the quantity of output supplied exceeds the amount demanded. This situation would result in unsold inventories and would require a reduction in production and in prices. If the price level is below P_1, then the quantity of aggregate output demanded exceeds the quantity of aggregate output supplied. This situation would result in a shortage of goods that would put upward pressure on prices.

It is important to understand that short-run macroeconomic equilibrium may occur at a level above or below full employment. We consider four possible types of macroeconomic equilibrium:

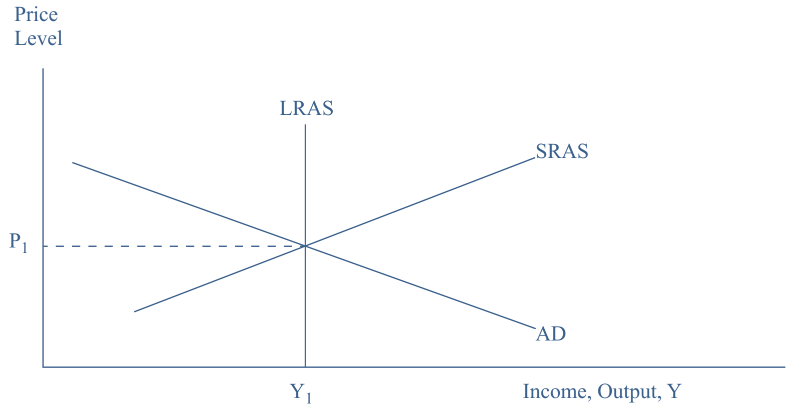
1. Long-run full employment
2. Short-run recessionary gap
3. Short-run inflationary gap
4. Short-run stagflation

From an investment perspective, the performance of asset classes and financial markets will differ in each case as the economy makes the adjustment toward the macroeconomic equilibrium. We look at these differences later in the reading.

3.4.1 *Long-Run Equilibrium*

Exhibit 20 shows the long-run full employment equilibrium for an economy. In this case, equilibrium occurs where the AD curve intersects the SRAS curve at a point on the LRAS curve. Because equilibrium occurs at a point on the LRAS curve, the economy is at potential real GDP. Both labor and capital are fully employed, and everyone who wants a job has one. *In the long run, equilibrium GDP is equal to potential GDP.*

Exhibit 20 Long-Run Macroeconomic Equilibrium

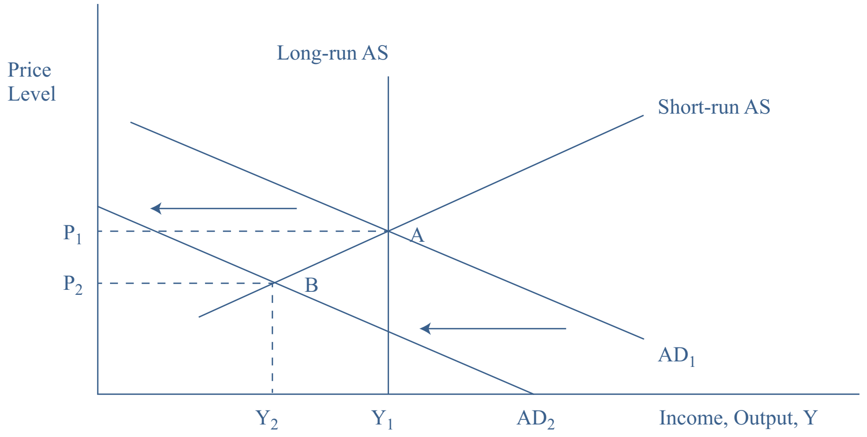


In practice, the level of potential GDP is difficult to measure with precision. Because of fluctuations arising from shifts in the AD and SRAS curves, the economy rarely operates at potential GDP. Thus, potential GDP is not observable from the data on actual GDP. In addition, potential GDP is determined by factors that are themselves difficult to measure. Thus, "bottom-up" estimates of the *level* of potential output are also quite imprecise. As we will cover subsequently, however, economists have confidence that the long-run *growth rate* of potential GDP can be estimated well enough to provide meaningful guidance for analysts and policymakers. Hence, in the short run, economists generally focus on factors that cause actual GDP to grow faster or slower than their estimate of the long-run growth rate of potential output. In addition, they focus on measures that indicate, albeit imprecisely, the extent to which the economy is operating above or below its productive capacity, such as unemployment and capacity utilization.

3.4.2 *Recessionary Gap*

Cyclical fluctuations in real GDP and prices are caused by shifts in both the AD and SRAS curves. A decline in AD or a leftward shift in the AD curve results in lower GDP and lower prices. Such declines in AD lead to economic contractions, and if such declines drive demand below the economy's potential GDP, the economy goes into a **recession** (defined as a period during which real GDP decreases for at least two consecutive quarters). In Exhibit 21, when aggregate demand falls, the equilibrium shifts from Point A to Point B. Real GDP contracts from Y_1 to Y_2, and the aggregate price level falls from P_1 to P_2. Because of the decline in demand, companies reduce their workforce and the unemployment rate rises. The economy is in recession, and the recessionary gap is measured as the difference between Y_2 and Y_1 or the amount by which equilibrium output is below potential GDP. Thus, a recessionary gap occurs when the AD curve intersects the short-run AS curve at a short-run equilibrium level of GDP below potential GDP. *Most importantly, in contrast to full employment, equilibrium GDP is below potential GDP.*

Exhibit 21 Recessionary Gap



Any of the factors discussed earlier could cause the shift in the AD curve. Tightening of monetary policy, higher taxes, more pessimistic consumers and businesses, and lower equity and housing prices all reduce AD and are all possible causes of a recession.

The question is, how does the economy return to full employment? There is considerable debate among economists about the answer to this question. Some economists argue that an automatic, self-correcting mechanism will push the economy back to its potential, without the need for government action. The idea is that because of the decline in prices and higher unemployment, workers will be willing to accept lower nominal wages. Workers will do this because each currency unit of wages now buys more goods and services because of their lower price. As a result, lower wages and input prices will shift the SRAS curve to the right (see Exhibit 19) and push the economy back to full employment and potential GDP.

The problem is that this price mechanism can take several years to work. As an alternative, government can use the tools of fiscal and monetary policy to shift the AD curve to the right (from Point B to Point A in Exhibit 21) and move the economy back to full employment. On the fiscal side, policymakers can reduce taxes or increase government spending. On the monetary side, the central bank can lower interest rates or increase the money supply. The problem, however, is that variable lags in the effectiveness of these policy measures imply that policy adjustments may end up reinforcing rather than counteracting underlying shifts in the economy.

Investment Implications of a Decrease in AD Aggregate demand and aggregate supply are theoretical measures that are very hard to measure directly. Most governments, however, publish statistics that provide an indication of the direction that aggregate demand and supply are moving over time. For example, statistics on consumer sentiment, factory orders for durable and nondurable goods, the value of unfilled orders, the number of new housing starts, the number of hours worked, and changes in inventories provide an indication of the direction of aggregate demand. If these statistics suggest that a recession is caused by a decline in AD, the following conditions are likely to occur:

- Corporate profits will decline.
- Commodity prices will decline.
- Interest rates will decline.
- Demand for credit will decline.

This situation suggests the following investment strategy:

- Reduce investments in **cyclical companies**, companies with sales and profits that regularly expand and contract with the business cycle or state of economy (for example, automobile and chemical companies), because their earnings are likely to decline the most in an economic slowdown.
- Reduce investments in commodities and/or commodity-oriented companies because the decline in commodity prices will slow revenue growth and reduce profit margins.
- Increase investments in **defensive companies**, companies with sales and profits that have little sensitivity to the business cycle or state of the economy (e.g., food and pharmaceutical companies), because they are likely to experience only modest earnings declines in an economic slowdown.
- Increase investments in investment-grade or government-issued fixed-income securities. The prices of these securities should increase as interest rates decline.
- Increase investments in long-maturity fixed-income securities because their prices will be more responsive to the decline in interest rates than the prices of shorter-maturity securities.
- Reduce investments in speculative equity securities and in fixed-income securities with low credit quality ratings.

As with most investment strategies, this strategy will be most successful if it is implemented before other market participants recognize the opportunities and asset prices adjust.

EXAMPLE 11

Using AD and AS: A Historical Example: 2007–2009

Many Asian economies were more adversely affected than the United States by the global recession that began in late 2007. In the first quarter of 2009, real GDP fell at an annualized rate of 16% in Japan and 11% in Singapore, compared with a 6% annualized decline in the United States. Using the data on exports as a share of GDP shown in Exhibit 22, explain how the following economic factors contributed to the recession in the Asian economies:

1. Collapse of house prices and home construction in the United States.
2. Oil prices rising from around US$30 a barrel in 2004 to nearly US$150 a barrel in 2008. (Note that most Asian economies rely on imports for almost all of their oil and energy needs. In contrast, the United States has a large domestic energy industry and imports only about half of its oil.)
3. The dramatic reduction in credit availability following the collapse or near collapse of major financial institutions in 2008.

Exhibit 22 Exports as a Share of GDP, 2007 and 2016

	2007		2016	
Economy	Exports as a Percentage of GDP	Percentage of Exports Going to United States	Exports as a Percentage of GDP	Percentage of Exports Going to United States
Hong Kong SAR	186	11.2	192	8.3
Singapore	166	11.5	175	6.5
Thailand	62	11.6	69	11.2
Germany	53	10.9	47	9
South Korea	47	7.1	44	12
Mexico	37	26.4	37	81.2
Canada	28	80.2	31	76.2
Chinese mainland	27	19	21	19
India	17	20.1	20	16
Japan	14	17	17	20.2
Kenya	12	—	16	6.7
United States	12	—	12	—
Ethiopia	11	6.7	9	9.9

Solution to 1:

The collapse in housing prices caused housing construction spending, a component of business investment, to decline in the United States. The decline in housing prices also caused a sharp fall in household wealth. As a result, consumption spending in the United States declined because of the wealth effect. The decline in both consumption and housing construction shifted the AD curve for the United States to the left, resulting in a US recession. The link to the Asian economies was through global trade because exports represented such a large share of the Asian economies' GDP (Exhibit 23). In turn, these economies exported a significant amount of goods and services to the United States. Thus, the recession in the United States and especially the decline in US consumption spending caused a sharp fall in exports among Asian economies. This decrease lowered their AD and shifted the AD curve to the left, resulting in a recessionary gap in these economies.

Solution to 2:

The rise in oil prices increased input cost and shifted the short-run AS curve to the left. Because the eastern Asian economies depend heavily on imported oil, their economies were more adversely affected than that of the United States.

Solution to 3:

The decline in housing prices caused financial institutions in the United States to suffer large losses on housing-related loans and securities. Several large lenders collapsed, and the US Treasury and the Federal Reserve had to intervene to prevent a wave of bankruptcies among large financial institutions. As a result of the crisis, it became difficult for households and businesses to obtain credit to finance their spending. This dynamic caused AD to fall and increased the severity of the recession in the United States, resulting in a significant decline in US imports and thus exports from the Asian economies. In addition, the financial crisis made it more difficult to obtain trade finance, further reducing exports from Asia.

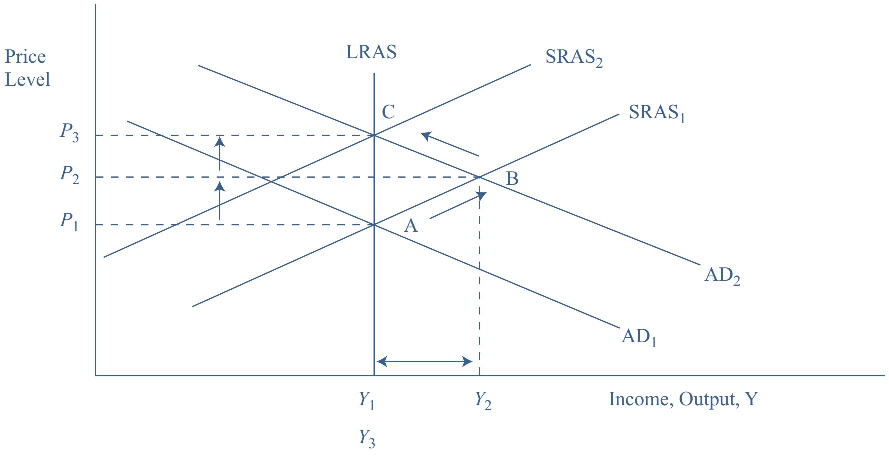
In summary, global investors need to be aware of the growing linkages among economies and the extent that one economy's growth depends on demand from within as well as from outside of that economy. Data on exports as a percentage of an economy's GDP provide an indication of this dependence. Although Japan is often viewed as an export-driven economy, Exhibit 23 shows that in 2018, exports were only 18% of its GDP. Similarly, the economy of India depends largely on domestic spending for growth because in 2018, exports accounted for only 20% of GDP.

3.4.3 *Inflationary Gap*

Increases in AD lead to economic expansions as real GDP and employment increase. If the expansion drives the economy beyond its production capacity, however, **inflation** will occur. The inflation rate is defined as the increase in the general price level from one period to the next. As summarized in Exhibit 17, higher government spending, lower taxes, a more optimistic outlook among consumers and businesses, a weaker domestic currency, rising equity and housing prices, and an increase in the money supply would each stimulate aggregate demand and shift the AD curve to the right. If aggregate supply does not increase to match the increase in AD, a rise in the overall level of prices will result.

As shown in Exhibit 23, an increase in AD will shift the equilibrium level of GDP from Point A to Point B. Real output increases from Y_1 to Y_2, and the aggregate price level rises from P_1 to P_2. As a result of the increase in aggregate demand, companies increase their production and hire more workers. The unemployment rate declines. Once an economy reaches its potential GDP, however, companies must pay higher wages and other input prices to further increase production. The economy now faces an inflationary gap, measured by the difference between Y_2 and Y_1 in Exhibit 23. *An inflationary gap occurs when the economy's short-run level of equilibrium GDP is above potential GDP, resulting in upward pressure on prices.*

Exhibit 23 Inflationary Gap



GDP cannot remain at Y_2 for long because the economy is overutilizing its resources—that is, extra shifts of workers are hired and plant and equipment are operating at their maximum capacity. Eventually, workers become tired and plants and equipment wear out. The increase in the general price level and input prices will set in motion the process of returning the economy back to potential GDP. Higher wages and input prices shift the SRAS curve to the left (from $SRAS_1$ to $SRAS_2$), moving the economy to Point C in Exhibit 23. Again, this self-correcting mechanism may work slowly.

A nation's government and/or its central bank can attempt to use the tools of fiscal and monetary policy to control inflation by shifting the AD curve to the left (AD_2 to AD_1 in Exhibit 23) so that the return to full employment occurs without the price increase. From a fiscal perspective, policymakers can raise taxes or cut government spending. From a monetary perspective, the central bank can reduce bank reserves, resulting in a decrease in the growth of the money supply and higher interest rates.

Investment Implications of an Increase in AD Resulting in an Inflationary Gap If economic statistics (consumer sentiment, factory orders for durable and nondurable goods, etc.) suggest that there is an expansion caused by an increase in AD, the following conditions are likely to occur:

- Corporate profits will rise.
- Commodity prices will increase.
- Interest rates will rise.
- Inflationary pressures will build.

This situation suggests the following investment strategy:

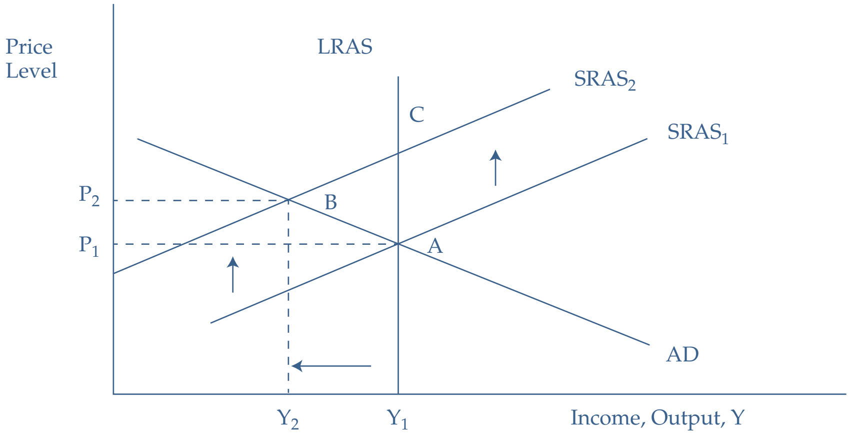
- Increase investment in cyclical companies because they are expected to have the largest increase in earnings.
- Reduce investments in defensive companies because they are expected to have only a modest increase in earnings.
- Increase investments in commodities and commodity-oriented equities because they will benefit from higher production and output.
- Reduce investments in fixed-income securities, especially longer-maturity securities, because they will decline in price as interest rates rise. Raise exposure to speculative fixed-income securities (junk bonds) because default risks decrease in an economic expansion.

3.4.4 *Stagflation: Both High Inflation and High Unemployment*

Structural fluctuations in real GDP are caused by fluctuations in SRAS. Declines in aggregate supply bring about **stagflation**—high unemployment and increased inflation. Increases in aggregate supply conversely give rise to high economic growth and low inflation.

Exhibit 24 shows the case of a decline in aggregate supply, perhaps caused by an unexpected increase in basic material and oil prices. The equilibrium level of GDP shifts from Point A to B. The economy experiences a recession as GDP falls from Y_1 to Y_2, but the price level, instead of falling, rises from P_1 to P_2. Over time, the reduction in output and employment should put downward pressure on wages and input prices and shift the SRAS curve back to the right, re-establishing full employment equilibrium at Point A. However, this mechanism may be painfully slow. Policymakers may use fiscal and monetary policy to shift the AD curve to the right, as previously discussed, but at the cost of a permanently higher price level at Point C.

Exhibit 24 Stagflation



The global economy experienced stagflation in the mid-1970s and early 1980s. Both unemployment and inflation soared. The problem was caused by a sharp decline in aggregate supply fueled by higher input prices, especially the price of oil. In 1973, the price of oil quadrupled. A steep global recession began in late 1973 and lasted through early 1975. The recession was unusual because prices rose rather than declined as would be expected in a typical demand-caused downturn. In 1979–1980, the price of oil doubled. Higher energy prices shifted the SRAS curve to the left, as shown in Exhibit 24, leading to a global recession in 1980–1982. In the United States, the contraction in output was reinforced by the Federal Reserve's decision to tighten monetary policy to fight the supply-induced inflation.

Investment Implications of a Shift in AS Labor and raw material costs, including energy prices, determine the direction of shifts in short-run aggregate supply: Higher costs for labor, raw materials, and energy lead to a decrease in aggregate supply, resulting in lower economic growth and higher prices. Conversely, lower labor costs, raw material prices, and energy prices lead to an increase in aggregate supply, resulting in higher economic growth and a lower aggregate price level. Productivity is also an important factor. Higher rates of productivity growth shift the AS to the right, resulting in higher output and lower unit input prices. Lower rates of productivity growth do the opposite and shift the AS curve to the left.

From an investment perspective, a decline in AS (leftward shift of the SRAS curve) suggests:

- reducing investment in fixed income because rising output prices (i.e., inflation) put upward pressure on nominal interest rates,
- reducing investment in most equity securities because profit margins are squeezed and output declines, and
- increasing investment in commodities or commodity-based companies because prices and profits are likely to rise.

On the other hand, an increase in AS (rightward shift of the SRAS curve) resulting from higher productivity growth or lower labor, raw material, and energy costs is favorable for most asset classes other than commodities.

3.4.5 *Conclusions on AD and AS*

The business cycle and the resulting fluctuations in real GDP are caused by shifts in the AD and AS curves. The effects of these shifts can be summarized as follows:

- An increase in AD raises real GDP, lowers the unemployment rate, and increases the aggregate level of prices.
- A decrease in AD lowers real GDP, increases the unemployment rate, and decreases the aggregate level of prices.
- An increase in AS raises real GDP, lowers the unemployment rate, and lowers the aggregate level of prices.
- A decrease in AS lowers real GDP, raises the unemployment rate, and raises the aggregate level of prices.

If both curves shift, the effect is a combination of the aforementioned individual effects. We look at four possible cases:

1. *Both AD and AS increase.* If both AD and AS increase, real GDP will increase but the effect on inflation is unclear unless we know the magnitude of the changes, because an increase in AD will increase the price level, whereas an increase in AS will decrease the price level. If AD increases more than AS, the price level will increase. If AS increases more than AD, however, the price level will decline.
2. *Both AD and AS decrease.* If both AD and AS decrease, real GDP and employment will decline but the effect on the price level is unclear unless we know the magnitude of the changes, because a decrease in AD decreases the price level, whereas a decrease in AS increases the price level. If AD decreases more than AS, the price level will fall. If AS decreases more than AD, the price level will rise.
3. *AD increases and AS decreases.* If AD increases and AS declines, the price level will rise but the effect on real GDP is unclear unless we know the magnitude of the changes, because an increase in AD increases real GDP, whereas a decrease in AS decreases real GDP. If AD increases more than AS declines, GDP will rise. If AS decreases more than AD increases, real GDP will fall.
4. *AD decreases and AS increases.* If AD decreases and AS increases, the price level will decline but the effect on real GDP is unclear unless we know the magnitudes of the changes, because a decrease in AD decreases real GDP, whereas an increase in AS increases real GDP. If AD decreases more than AS increases, real GDP will fall. If AS increases more than AD declines, real GDP will rise.

   Exhibit 25 summarizes these four cases.

Exhibit 25 Effect of Combined Changes in AS and AD

Change in AS	Change in AD	Effect on Real GDP	Effect on Aggregate Price Level
Increase	Increase	Increase	Indeterminate
Decrease	Decrease	Decrease	Indeterminate
Increase	Decrease	Indeterminate	Decrease
Decrease	Increase	Indeterminate	Increase

Whether the growth of the economy is demand- or supply-driven has an effect on asset prices. Demand-driven expansions are normally associated with rising interest rates and inflation, whereas contractions are associated with lower inflation and interest rates. Supply-driven expansions are associated with lower inflation and interest rates, whereas supply-driven contractions are associated with rising inflation and interest rates.

EXAMPLE 12

Investment Strategy Based on AD and AS Curves

An analyst is evaluating the possibility of investing in China, Italy, Mexico, or Brazil. What are the equity and fixed-income investment opportunities in these countries based on the following events?

1. The Chinese government announced a spending plan of US$1.2 trillion, or 13% of GDP. In addition, the central bank of China eased monetary policy, resulting in a surge of lending.
2. The Italian government announced a decline in labor productivity, and it expects this trend to continue into the future.
3. In response to rising inflationary pressure, the Mexican central bank tightened monetary policy, and the government announced tax increases and spending cuts to balance the budget.
4. A major discovery of oil off the coast of Brazil lowered oil prices, while the Brazilian government announced a major increase in spending on public infrastructure to stimulate the economy.

Solution to 1:

Stimulative fiscal and monetary policies should result in a demand-driven expansion. Investors should reduce investments in fixed-income securities and defensive companies and invest in cyclical companies and commodities. As a result, the prospects for growth-oriented equity investments look favorable in China.

Solution to 2:

A decline in labor productivity will result in a decline in AS; that is, the AS curve will shift to the left. This scenario is typically a poor investment environment. Investors should reduce investments in both fixed-income and equity securities and invest in commodities. Entry into Italian stocks and bonds does not look attractive.

Solution to 3:

The policy measures put in place by the Mexican government and central bank will cause a drop in AD and likely result in a recession. Investors should increase their investments in fixed-income securities because interest rates will most likely decline as the recession deepens. This scenario is a poor environment for equity securities.

Solution to 4:

In this situation, both the AD and AS curves will shift. The increase in spending on public infrastructure will shift the AD curve to the right, resulting in higher aggregate expenditures and prices. Lower oil prices will shift the AS curve to the right, resulting in higher GDP but lower prices. Thus, GDP will clearly increase, but the effect on prices and inflation is indeterminate. As a result, investors should increase their investment in equity securities; however, the effect on fixed-income securities is unclear.

EXAMPLE 13

Historical Example: Using AD and AS to Explain Japan's Economic Problem

Japan experienced sluggish growth in real GDP for nearly two decades following the bursting of an asset and investment bubble in the late 1980s. At the same time, Japan experienced deflation (declining prices) over the two-decade period. The reasons for this protracted period of stagnation continue to be debated among economists. Failure to recognize a change in the Japanese growth rate has hurt many investors, especially those taking a long-term perspective. From their peak in 1989, Japanese equity prices, as measured by the Nikkei index, fell by more than 60% before bottoming out in mid-1992. During the following two decades, the market was essentially flat despite considerable volatility.

The performance of the Japanese economy can be explained using the AD and AS model. The protracted slowdown of growth in Japan beginning in the early 1990s can be linked to the effect of the collapse of the equity and commercial real estate markets in the late 1980s and to excessive investment in capital goods (new factories and equipment) in the 1980s. These problems were compounded by persistent weakness in the banking sector, a profound lack of confidence among businesses and consumers, and negative demographics with slow growth in the working age population.

The sum of these developments caused a decline in both the AD and AS curves. Aggregate demand declined, shifting the AD curve to the left for the following reasons:

- The wealth effect resulting from the decline in equity and real estate prices sharply reduced consumption spending. Asset prices took more than two decades to recover.
- Excessive investment in capital goods caused a sharp decline in business investment during the period.
- Lack of confidence among businesses and consumers during the period.
- Problems in the banking sector made monetary policy ineffective because banks were unable to lend, which negatively affected both consumer and business spending.

AS declined for the following reasons:

- Marked slowing in private investment spending during the period reduced the capital stock. This dynamic also reduced potential GDP.
- Slow population growth limited the growth in the labor supply, which also reduced potential GDP.
- Higher energy prices slowed growth during the period because of Japan's heavy dependence on imported energy.

As would be expected, the declines in both AD and AS resulted in slow GDP growth. The fact that prices fell indicates that the AD curve shifted more than the AS curve.

ECONOMIC GROWTH AND SUSTAINABILITY

4

m describe sources, measurement, and sustainability of economic growth

n describe the production function approach to analyzing the sources of economic growth

o define and contrast input growth with growth of total factor productivity as components of economic growth

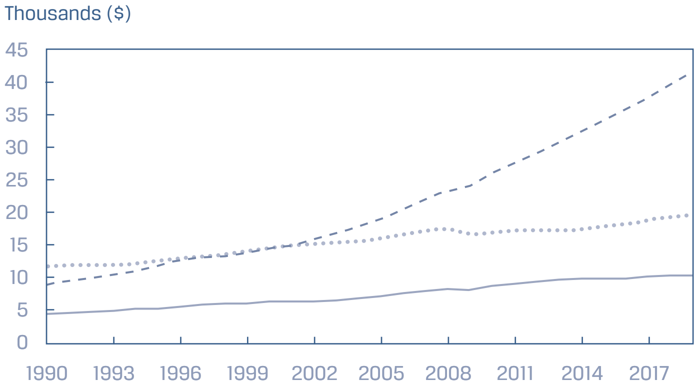
Understanding sources of economic growth is crucial for practitioners involved in various types of investment decision making. Economic growth is calculated as the annual percentage change in real GDP or the annual change in real per capita GDP:

- Growth in real GDP measures how rapidly the total economy is expanding.
- Per capita GDP, defined as real GDP divided by population, measures the standard of living in each country and the ability of the average person to buy goods and services.

Exhibit 26 illustrates growth in GDP in selected regions since 1990. It shows that although total GDP doubled in Latin America during the period, GDP per capita in the region increased by only about 50%, as a result of population growth.

Exhibit 26 Real GDP Growth and Per Capita GDP Growth for Selected Regions

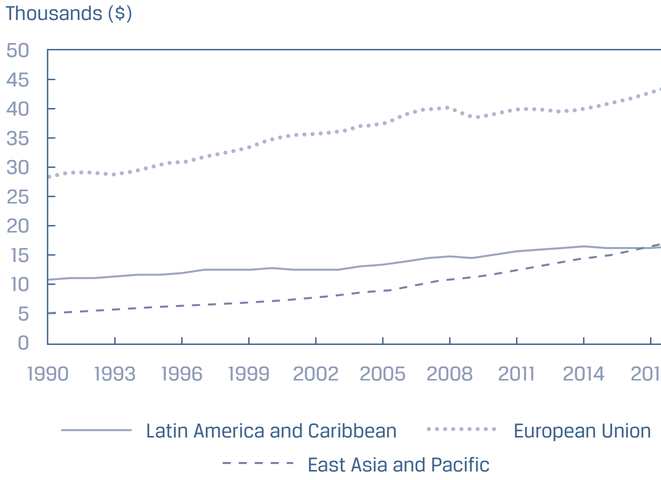
A. In PPP (constant 2017 US$ billion)



(continued)

Exhibit 26 (Continued)

B. GDP per Capita, PPP (constant 2017 US$)



Note: PPP is Purchasing Power Parity.
Source: World Bank data.

Economic growth is important because rapid growth in per capita real GDP can transform a poor nation into a wealthy one. Even small differences in the growth rate of per capita GDP, if sustained over time, have a large effect on an economy's standard of living. Nevertheless, there is a limit to how fast an economy can grow. Faster growth is not always better for an economy because there are costs associated with excess growth, such as higher inflation, potential environmental damage, and the lower consumption and higher savings needed to finance the growth.

These costs raise the issue of sustainable growth, which requires an understanding of the concept of potential GDP. Recall that potential GDP measures the economy's productive capacity and is the level of real GDP that an economy could produce if capital and labor are fully employed. In order to grow over time, an economy must add to its productive capacity. Thus, the **sustainable rate of economic growth** is measured by the rate of increase in the economy's productive capacity or potential GDP. It is important to note that economists cannot directly measure potential output. Instead, they estimate it using a variety of techniques that we will discuss.

For global investors, estimating the sustainable rate of economic growth for an economy is important in valuing a variety of assets. Growth in potential GDP matters for long-run equity market appreciation and for individual industries and company forecasts. Potential GDP can be used to gauge inflationary pressures, determine credit quality, and assess the likelihood of a change in central bank policy, all of which are relevant for fixed income investors. Economic growth in large economies or whole regions is also useful for forecasting demand for commodities.

4.1 The Production Function and Potential GDP

We focus on the simplest form of what is known as the neoclassical or Solow growth model, the framework used to understand and analyze the underlying sources of growth for an economy. The model shows that the economy's productive capacity and potential GDP increase for two reasons:

1. accumulation of such inputs as capital, labor, and raw materials used in production, and
2. discovery and application of new technologies that make the inputs in the production process more productive—that is, able to produce more goods and services for the same amount of input.

4.1.1 *The Production Function*

The model is based on a **production function** that provides the quantitative link between the levels of output that the economy can produce and the inputs used in the production process, given the state of technology. A two-factor production function with labor and capital as the inputs is expressed mathematically as

$$Y = A\boldsymbol{F}(L,K),$$

where Y denotes the level of aggregate output in the economy, L is the quantity of labor or number of workers in the economy, K is the capital stock or the equipment and structures used to produce goods and services, and A represents **total factor productivity** (TFP). TFP is a scale factor that captures the exogenous effect of technological change and other factors that raise output beyond the measured contribution of the capital and labor inputs. Like potential GDP, TFP is not directly observed in the economy but instead is estimated.

The production function shows that output in the economy depends on inputs and the level of technology. The economy's capacity to produce goods grows when these inputs increase and/or technology advances. The more technologically advanced an economy is, the more output it is able to produce from a given amount of inputs.

4.1.2 *The Model Assumptions*

The neoclassical model makes three assumptions about the production function that provide a link to microeconomics. First, it assumes that the production function has constant returns to scale. This means that if all the inputs in the production process are increased by the same percentage, then output will rise by that percentage. Thus, doubling all inputs would double output. Second, the model assumes that the production function exhibits **diminishing marginal productivity** with respect to any individual input. Finally, the model assumes no positive or negative externalities are associated with the use of the inputs. These assumptions play an important role in assessing the contribution of labor and capital to economic growth. Marginal productivity looks at the extra output produced from a one-unit increase in an input if the other inputs are unchanged. It applies to any input as long as the other inputs are held constant. For example, if we have a factory of a fixed size and we add more workers to the factory, the marginal productivity of labor measures how much additional output each additional worker will produce.

Diminishing marginal productivity means that at some point the extra output obtained from each additional unit of the input will decline. In the prior example, if we hire more workers at the existing factory (fixed capital input in this case), output will rise by a smaller and smaller amount with each additional worker.

In the case of capital, if we add more and more capital to a fixed number of workers, the amount of additional output contributed by each additional amount of capital will fall. Thus, if capital grows faster than labor, capital will become less productive, resulting in slower and slower growth. Diminishing marginal productivity of capital has two major implications for potential GDP and long-term growth:

1 Long-term sustainable growth cannot rely solely on **capital deepening investment** that increases the stock of capital relative to labor. More generally, increasing the supply of some input(s) relative to other inputs will lead to diminishing returns and cannot be the basis for sustainable growth.
2 Given that developing countries have relatively less capital, their productivity of capital is high. All else the same, the growth rates of developing countries should exceed those of developed countries. As a result, there should be a **convergence** of incomes between developed and developing countries over time.

Because of the assumption of diminishing returns to capital, the only way to sustain growth in potential GDP per capita in the long run is through growth in TFP. This results in an upward shift in the production function: The economy produces more goods and services using the same level of labor and capital inputs. In terms of the formal production function $Y = A\boldsymbol{F}(L,K)$, this dynamic is reflected by an increase in the parameter A.

4.1.3 *Growth Accounting Equation*

Using the production function, Robert Solow developed a model that explained the contribution of labor, capital, and TFP to economic growth. The growth accounting equation shows that the rate of growth of potential output equals growth in TFP plus the weighted average growth rate of labor and capital.

$$\text{Growth in potential GDP} = \text{Growth in TFP} + W_L\,(\text{Growth in labor}) + W_C\,(\text{Growth in capital})$$

where W_L and W_C are the relative shares of capital and labor in national income. The capital share is the sum of corporate profits, net interest income, net rental income, and depreciation divided by GDP. The labor share is employee compensation divided by GDP. For many developed countries, W_L and W_C are roughly 0.7 and 0.3, respectively.

The growth accounting equation highlights a key point: The contribution of labor and capital to long-term growth depends on their respective shares of national income. For the United States, because labor's share is higher, an increase in the growth rate of labor will have a significantly larger effect (roughly double) on potential GDP growth than will an equivalent increase in the growth rate of capital.

The growth accounting equation can be further modified to explain growth in per capita GDP. Because it measures the standard of living and purchasing power of the average person in an economy, per capita GDP is more relevant than the absolute level of GDP in comparing economic performance among countries. Transforming the growth accounting equation into per capita terms results in the following equation:

$$\text{Growth in per capita potential GDP} = \text{Growth in TFP} + W_C\,(\text{Growth in capital-to-labor ratio})$$

The capital-to-labor ratio measures the amount of capital available per worker and is weighted by the share of capital in national income. Because capital's share in national income in the US economy is 0.3, a 1% increase in the amount of capital available for each worker increases per capita output by only 0.3%.

EXAMPLE 14

Impact of Capital Investment in Laos

Annual GDP growth in Laos has averaged about 7% over the 10 years since 2009. The economy has benefitted from foreign direct investment in hydroelectric dams and mining projects. Using the neoclassical growth model, an emerging market analyst states that these capital inflows are unlikely to boost the long-term potential GDP growth rate of Laos.

Explain using the neoclassical model whether the analyst's statement is correct.

Solution:

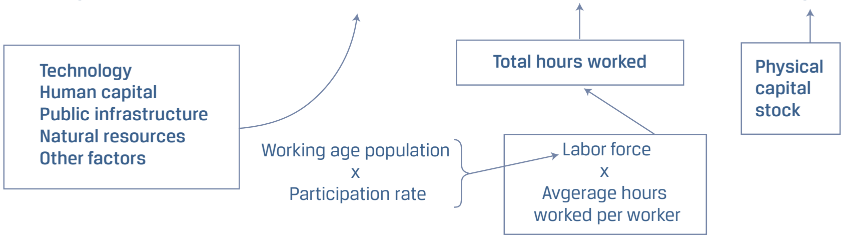
The capital inflows in the form of foreign direct investment are increasing capital spending in Laos and, through capital deepening, will raise the short-term GDP growth rate. Long-term potential GDP, however, depends on growth in TFP, the key driver of which is technical progress. Adding to capital through the foreign direct investment will be subject to diminishing returns. Thus, the analyst is correct because long-term potential GDP growth cannot rely on capital accumulation or capital deepening. To increase potential GDP, Laos must implement policies to boost the growth in TFP.

4.2 Sources of Economic Growth

The foregoing growth accounting equation focuses on the main determinants of growth—capital, labor, and TFP (the key driver being technology)—and omits a number of other sources of growth to simplify the analysis. For many countries, however, human capital, public infrastructure, natural resources, and the economic environment and institutions play an important role in explaining economic growth. In the standard neoclassical model discussed earlier, these inputs are measured as part of TFP growth along with technological changes. Using this model, the sources of growth for an economy that determine its capacity to supply goods and services are as shown in Exhibit 27. Note that the amount of labor, measured as total hours worked, is determined by the size of the average hours worked per worker multiplied by the labor force. Labor force itself is a product of working age population and the participation rate (the proportion of working age population choosing to work or seeking work).

Exhibit 27 Sources of Economic Growth

Growth in potential GDP = Growth in TFP + WL (Growth in labor) + WC (Growth in capital)



4.2.1 *Technology*

The most important factor affecting economic growth is technology, especially in developed countries. Technology refers to the process a company uses to transform inputs into outputs. Technological advances are discoveries that make it possible to produce more or higher-quality goods and services with the same resources or inputs. At the same time, technological progress results in the creation of new goods and services. Finally, technological progress improves how efficiently businesses are organized and managed.

Technological advances allow an economy to overcome the limits imposed by diminishing marginal returns. Thus, an economy will face limits to growth if it relies exclusively on expanding the inputs or factors of production. One of the key drivers of growth in developed countries is the information technology (IT) sector, whose growth has been driven by technological innovation that has caused the price of key technologies, such as semiconductors, to fall dramatically. The steep declines in prices have encouraged investment in IT at the expense of other assets. The sector has grown very fast and has made a significant contribution to economic growth, employment, and exports.

Countries can innovate through expenditures, both public and private, on research and development (R&D). Expenditures on R&D and the number of patents issued, although not directly measuring innovation, provide some useful insight into innovative performance. Countries can also acquire new technology through imitation or copying the technology developed elsewhere. The embodiment of technology in capital goods can also enable relatively poor countries to catch up to the technology leaders.

TFP is often used as a proxy for technological progress and organizational innovation. TFP is the amount by which output would rise because of improvements in the production process. It is not directly observed and is calculated as a residual, the difference between the growth rate of potential output and the weighted average growth rate of capital and labor. Specifically,

$$\text{TFP growth} = \text{Growth in potential GDP} - [W_L\ (\text{Growth in labor}) + W_C\ (\text{Growth in capital})]$$

The interpretation of the TFP as a pure technology measure is incorrect. Given the measurement and estimation difficulties, TFP will measure not only technological change but also the effect of other inputs into the production process such as human capital, public infrastructure, and natural resources. In addition to the other inputs, TFP measures the effect of externalities and spillover effects, omitted inputs, organizational efficiencies, and institutional and governance factors. Nevertheless, it is a useful indicator of the underlying technological forces.

4.2.2 *Labor Supply*

Growth in the number of people available for work (quantity of workforce) is an important source of economic growth and partially accounts for the superior growth performance of the US economy versus the European and Japanese economies. Most developing countries, such as China, India, and Mexico, have a large potential labor supply. We can measure the potential size of the labor input as the total number of hours available for work, which is given by

$$\text{Total hours worked} = \text{Labor force} \times \text{Average hours worked per worker}$$

The **labor force** is defined as the portion of the working age population (over the age of 16) that is employed or available for work but not working (unemployed). The contribution of labor to overall output is also affected by changes in the average hours worked per worker. The average number of hours worked is highly sensitive to the business cycle. The long-term trend, however, has been toward a shorter work week in the advanced countries. This development is the result of legislation, collective bargaining agreements, and the growth of part-time and temporary work.

4.2.3 *Human Capital*

In addition to the quantity of labor (the "*L*" in the earlier mentioned production function), the quality of the labor force is important. Human capital reflects the accumulated knowledge and skill that workers acquire from education, training, and life experience. It measures the quality of the workforce, and we treat it as part of TFP. In general, better-educated and skilled workers will be more productive and more adaptable to changes in technology.

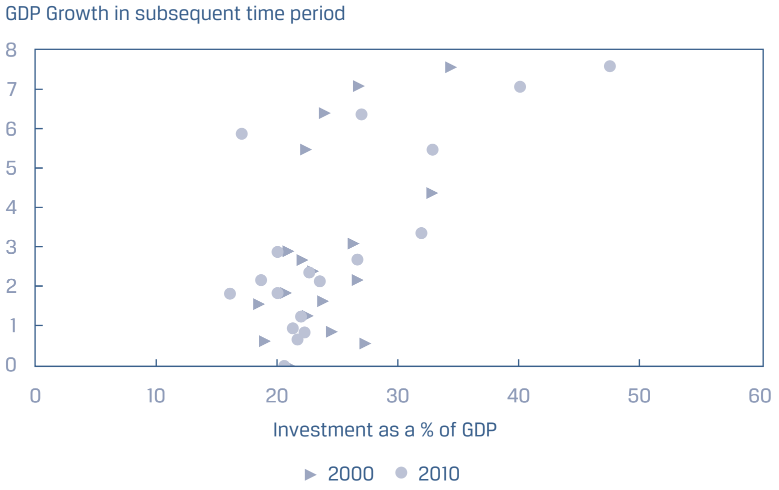
An economy's human capital is increased through investment in education and on-the-job training. Like physical capital, investment in education is costly. Studies show, however, that education offers a significant return—that is, people with more education earn higher wages. Moreover, education may also have a spillover or externality effect: Increasing the educational level of one person not only raises that person's output but also the output of those around her. The spillover effect operates through the link between education and advances in technology. Education not only improves the quality of the labor force but also encourages growth through innovation. Investment in health is also a major contributor to human capital, especially in developing countries.

4.2.4 *Physical Capital Stock*

The physical **capital stock** (accumulated amount of buildings, machinery, and equipment used to produce goods and services) increases from year to year as long as net investment (gross investment less depreciation of capital) is positive. Thus, countries with a higher rate of investment should have a growing physical capital stock and a higher rate of GDP growth.

Exhibit 28 shows the level of business investment as a share of GDP across a selection of 18 developed and developing economies. The exhibit shows significant variation across countries. As is evident in Exhibit 28, the correlation between investment (as a percentage of GDP) and economic growth in the subsequent period (19 years after 2000 and 9 years after 2010) is high. Economies that devote a large share of GDP to investment, such as China, India, and South Korea (numerical data not shown), have high growth rates. Ireland, Europe's fastest-growing economy from 2010–2018, has among the highest investment-to-GDP ratio in Europe. Economies that devote a smaller share of GDP to investment, such as Brazil and Mexico, have slower growth rates. The data helps explain why the Chinese economy has expanded so rapidly, achieving an annual GDP growth rate of nearly 10% over the last two decades. Investment spending in China on new factories, equipment, and infrastructure as a percentage of GDP is the highest in the world.

Exhibit 28 Business Investment As a Percentage of GDP and GDP Growth in the Subsequent Period



Notes: The term "investment" is represented by non-residential gross fixed capital formation as a share of GDP used. GDP growth is the average annual real GDP growth in the decade following the year of the investment as a percentage of GDP data.
Sources: GDP: OECD National Accounts Statistics (database), April 2019. Gross fixed capital: World Development Indicator, ne.gdi.totl.zs

4.2.5 *Natural Resources*

Raw materials are an essential input to growth and include everything from available land to oil to water. Historically, consumption of raw materials has increased as economies have grown. There are two categories of natural resources:

1 **Renewable resources** are those that can be replenished, such as a forest. For example, if a tree is cut, a seedling can be planted and a new forest harvested in the future.

2 **Non-renewable resources** are finite resources that are depleted once they are consumed. Oil and coal are examples.

Natural resources account for some of the differences in growth among countries. Today, such countries as Brazil and Australia, as well as those in the Middle East, have relatively high per capita incomes because of their resource base. Countries in the Middle East have large pools of oil. Brazil has an abundance of land suitable for large-scale agricultural production, making it a major exporter of coffee, soybeans, and beef.

Although natural resources are an important factor in growth, they are not necessary for a country to achieve a high level of income provided it can acquire the requisite inputs through trade. Countries in eastern Asia, such as Japan and South Korea, have in the past experienced rapid economic growth but own few natural resources. It is also important to note that having plentiful natural resources may hurt an economy's growth, a topic that will be explored at a later stage.

4.2.6 *Public Infrastructure*

Roads, water systems, mass transportation, airports, and utilities are all examples of public infrastructure or public capital. Even if the infrastructure assets are privately owned or operated, the economic impact will be the same. Infrastructure assets have few substitutes and generate significant economies of scale, so they have the characteristics of a natural monopoly. A key feature of public capital is that they create **externalities**. Externalities are spillover effects of production and consumption activities onto others who are not directly involved in a particular transaction, activity, or decision. In the case of public infrastructure, the externalities complement the production of private sector goods and services. The full benefit of public infrastructure investment may extend beyond its direct expenditure because it boosts the productivity of private capital.

4.2.7 *Other Factors Driving Growth*

Researchers have focused on the positive externalities associated with research and development and public education. Research and development efforts by one firm spill over and affect the stock of knowledge available to all firms, raising potential GDP growth. Thus, external or social benefits arise from increased spending on research and development that go beyond the benefit for the individual firm. The key point for economic growth is that there may be constant or increasing returns to the inputs, and thus the economy is no longer constrained by diminishing marginal productivity.

Externalities also have a negative effect on growth, with pollution being the primary example. Air and water quality in advanced countries have improved significantly over the last few decades, and there is a strong negative correlation between per capita GDP and pollution. But these success stories largely reflect the local economic effects of economic growth. The environmental problems we face today are global in nature and affect the entire planet. The burning of fossil fuels releases carbon dioxide into the atmosphere, causing a greenhouse effect that raises the earth's overall temperature. Climate change is closely linked to economic growth, because carbon dioxide emissions rise with economic growth. These emissions impose a cost on the global economy in terms of economic activity, food production, health, and habitability.

Without government action, individuals and firms may have no incentive to reduce these negative externalities. The more global the pollution problem, the less any single country benefits from reducing its emissions. Moreover, nations face an important trade-off on emissions: Reducing emissions today may result in lower short-term growth, but not reducing emissions today will negatively affect long-term sustainable GDP growth. Policy measures that create incentives to reduce the carbon intensity of output are the potential solution.

In addition to the aforementioned factors, a country's economic environment can play an important role in influencing economic growth. Lack of appropriate institutions and a poor legal and political environment restrains growth, especially in the developing countries. Factors such as internal competitive structure; poorly developed financial markets; a country's openness to trade; and its political stability, property rights, and rule of law can influence innovative activity and economic growth.

EXAMPLE 15

Sources of Growth for Westerland

Westerland is an advanced economy with a high capital-to-labor ratio. Working-age population growth has been close to zero for the last decade. During the same period, annual GDP growth has slowed to about 1%. More than 70% of Westerland's electricity is produced by renewable energy resources. The nation has reduced carbon dioxide emissions by 25% over the last decade. Policymakers hope to raise Westerland's sustainable rate of growth or its potential GDP.

Explain how the following factors are a potential source of growth for Westerland.

1. Tax reductions are proposed on business investment and R&D.

2 Labor market incentives are planned to create flexible work schedules and develop policies for maternity/parental leave and childcare.

3 Westerland plans to further reduce its carbon dioxide emissions, but global carbon dioxide emissions are expected to rise significantly as global GDP growth accelerates.

Solution to 1:

Because Westerland is an advanced economy operating at a high level of capital per worker, diminishing returns to capital are likely to be significant. If this is the case, additions to capital will have little effect on growth and are not a significant source of growth. In contrast, incentives encouraging increased R&D expenditures by increasing the growth rate of TFP and technological change are a potential source of growth.

Solution to 2:

Westerland is facing a demographic challenge because slow population growth will limit its potential growth rate. To offset this issue, the country can encourage immigration and/or increase its workforce participation rate. The objective of creating flexible work schedules and developing policies for parental leave and childcare is to raise the labor force participation rate (note that Working age population × Participation rate × Average hours worked gives L, the amount of labor). In the short run, the labor market incentives will increase the growth rate in the labor supply and thus are a potential source of growth. After the initial response to these incentives, however, the labor force participation rate will level off. As a result, the policies will have no long-term effect on the labor input and will not increase sustainable growth.

Solution to 3:

Westerland has successfully reduced its carbon dioxide emissions and plans further reduction, probably at the cost of slower GDP growth. Nevertheless, it still faces the negative effects of climate change despite its own effort to reduce emissions. This dynamic highlights climate change as a classic example of a negative externality that no single country can solve and requires global cooperation. This international burden sharing presents a stumbling block for success.

4.3 Measures of Sustainable Growth

Measuring how fast an economy can grow is an important exercise. Economists project potential GDP in order to forecast the economy's sustainable growth path. Potential GDP is an unobserved concept that is approximated using a number of alternative methods. Note that estimates of the economy's potential growth can change as new data become available. Being able to understand such changes is critical for financial analysts, because long-term forecasts for cash flows that companies generate are dependent on the sustainable rate of economic growth.

4.3.1 *Labor Productivity*

One approach to estimating potential GDP uses the productivity of the labor force, which is generally reliable data. **Labor productivity** consists of the quantity of goods and services (real GDP) that a worker can produce in one hour of work. Our standard of living improves if we produce more goods and services for each hour of work. Labor productivity is calculated as real GDP for a given year divided by the total number of hours worked in that year, counting all workers. We use total hours, rather than the number of workers, to adjust for the fact that not everyone works the same number of hours.

Labor productivity = Real GDP/Aggregate hours

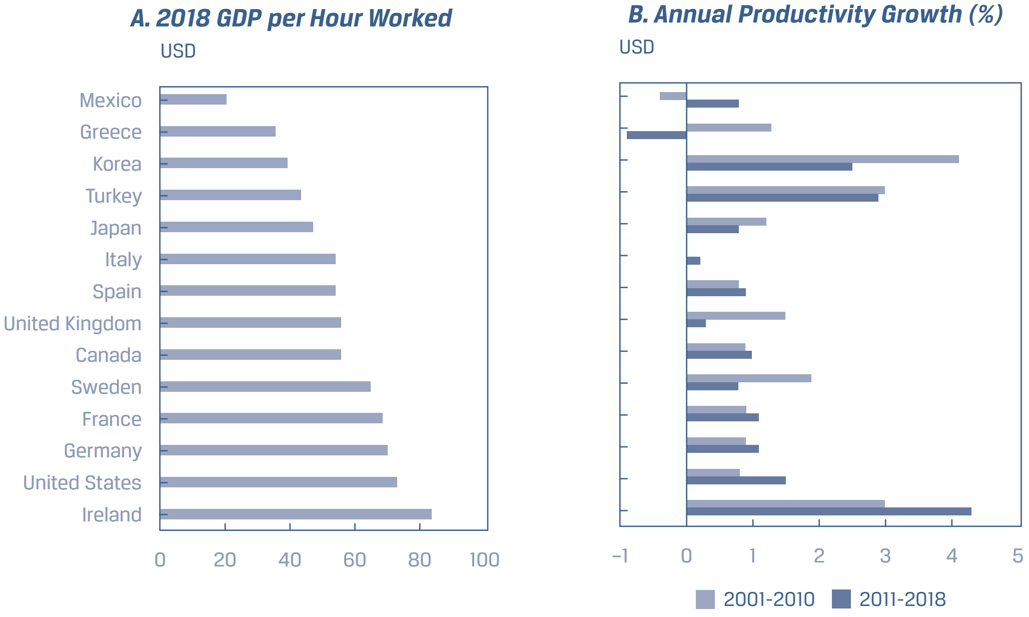
Therefore, we need to understand the forces that make labor more productive. Productivity is determined by the factors that we examined earlier: education and skill of workers (human capital), investments in physical and public capital, natural resources, improvements in technology, and other factors. An increase in any of these factors will increase the productivity of the labor force. The factors determining labor productivity can be derived from the production functions under the assumption of constant returns to scale, where a doubling of inputs causes output to double as well. Dividing the production function by L, we obtain the following:

$$Y/L = A\boldsymbol{F}(1,K/L),$$

where Y/L is output per worker, which is a measure of labor productivity. The equation states that labor productivity depends on physical capital per worker (K/L) and total factor productivity, which largely measures technological change (A). TFP is a scale factor that does not depend on the mix of inputs. Changes in TFP are measured as a residual, capturing growth that cannot be attributed to the labor supply and physical capital inputs. On the other hand, as shown in this equation, output per worker depends on both the general level of productivity (reflected in TFP) and the mix of inputs. Increases in either TFP or the capital-to-labor ratio boost output per worker. Because both output and labor input can be observed, labor productivity can be measured directly.

Labor productivity is a key concept for measuring the health and prosperity of an economy and its sustainable rate of growth. An analyst examining the growth prospects for an economy needs to focus on the labor productivity data for that country. Growth of labor productivity over time largely explains the differences in the living standards among countries. Labor productivity growth also helps analysts estimate the long-term sustainable growth rates among countries. The distinction between the level and growth rate of productivity is important to understand. Exhibit 29 shows that many countries have relatively high levels of productivity, even though productivity growth during the last decade or two has not been significant (e.g., Italy, the United Kingdom, Spain). Ireland, however, entered this century with a lower level of productivity and had a lower starting point compared with the other countries. Its substantial productivity growth in the last two decades has elevated the country to the top of this particular list.

Exhibit 29 Labor Productivity: Level vs. Growth Rate in Select Countries



Source: OECD Productivity Statistics (database), April 2019

4.3.2 *Level of Labor Productivity*

The higher the level of labor productivity, the more goods and services the economy can produce with the same number of workers. The level of labor productivity depends on the accumulated stock of human and physical capital and is much higher in the developed countries. For example, India has a population of about 1.3 billion people, compared with more than 83 million people in Germany (United Nations, World Population Prospects 2019). Because of its much larger population, India has significantly more workers than Germany; however, the German economy, as measured by real GDP, is larger. As shown in Exhibit 29, Germany has among the highest level of productivity in the world, producing more than US$70 of GDP per hour worked. Similarly, workers in France, the United States, and Ireland have high levels of productivity. In comparison, Mexican workers produce only US$20.70 worth of GDP per hour worked. Thus, German workers are more than three times more productive as Mexican workers.

4.3.3 *Growth Rate of Labor Productivity*

The growth rate of labor productivity is the percentage increase in productivity over a year. It is among the economic statistics that economists and financial analysts watch most closely. In contrast to the level of productivity, the growth rate of productivity is typically higher in developing countries where human and physical capital is scarce but growing rapidly.

If productivity growth is rapid, it means the same number of workers can produce more and more goods and services. In this case, companies can afford to pay higher future wages and still make a profit. Thus, high rates of productivity growth will translate into rising profits. Rising profits, if not already anticipated by the market, will support higher stock prices.

In contrast, persistently low productivity growth suggests the economy is in bad shape. Without productivity gains, businesses have to either cut wages or boost prices in order to increase profit margins. Low rates of productivity growth should be associated with slow growth in profits and flat or declining stock prices.

EXAMPLE 16

Prospects for Equity Returns in Mexico

John Todd, CFA, manages a global mutual fund with nearly 30% of its assets invested in Europe. Because of the low population growth rate, he is concerned about the long-term outlook for the European economies. With potentially slower economic growth in Europe, the environment for equities may be less attractive. Therefore, Todd is considering reallocating some of the assets from Europe to Mexico. Data shows that the level of business investment has been around 24% of GDP, while that of China is more than 40% and that of European countries is close to 20%. The level of productivity for Europe as a whole is more than $60 per hour worked (as of 2018). Data also shows that labor productivity since 2001 in Mexico is growing at about 0.2% annual rate, below that of Germany, France, and Spain. Do you think that investment opportunities are favorable in Mexico? According to the OECD, the Mexican population increased by 1.1% in 2018, compared with a 0.2% increase in the European Union population (27 countries).

Solution:

Other than the higher population growth rate, the potential sources of growth for Mexico are not favorable. The level of business investment in Mexico is quite low, especially compared with China, and not much higher than that of many of the advanced economies in Europe. The level of labor productivity in Mexico is well below that in most European countries. This is not surprising given that the amount of capital per worker in Mexico is much lower than that in Europe.

What is surprising and of concern is the low rate of labor productivity growth in Mexico. This means that the rightward shift in the aggregate supply curve is greater for the European countries than for Mexico, despite the more favorable demographic trend in the country. In addition, it implies that there is more potential for expanding profit margins in Europe than in Mexico. Thus, the analysis of potential growth does not suggest a favorable outlook for equity returns in Mexico. In this simplified example, in the absence of more favorable considerations—for example, compelling equity valuations—Todd should decide not to reallocate assets from Europe to Mexico.

4.4 Measuring Sustainable Growth

Labor productivity data can be used to estimate the rate of sustainable growth of the economy. A useful way to describe potential GDP is as a combination of aggregate hours worked and the productivity of those workers:

$$\text{Potential GDP} = \text{Aggregate hours worked} \times \text{Labor productivity}$$

Transforming the above equation into growth rates, we obtain the following:

$$\begin{aligned}\text{Potential growth rate} = {} & \text{Long-term growth rate of aggregate hours worked} + \\ & \text{Long-term labor productivity growth rate}\end{aligned}$$

Thus, potential growth is a combination of the long-term growth rate of the aggregate hours worked and the long-term growth rate of labor productivity. Therefore, if aggregate hours worked are growing at 1% per year and productivity per worker is rising at 2% per year, then potential GDP (adjusted for inflation) is rising at 3% per year.

EXAMPLE 17

Estimating the Rate of Growth in Potential GDP

Exhibit 30 provides data on the growth rate in aggregate hours worked and productivity growth for Canada, Germany, Japan, and the United States. Estimate the growth rate of potential GDP for each country by averaging the growth rates for these variables since 2001. Also, describe the role that the labor input plays in determining potential growth for each country.

Exhibit 30 Aggregate Hours Worked and Productivity: Average Annual Growth Rate

	Aggregate Hours Worked		Productivity	
	2011–2018	**2001–2010**	**2011–2018**	**2001–2010**
Canada	0.9%	1.4%	1.0%	0.9%
Germany	0.5	0.2	1.1	0.9
Japan	0.3	−0.2	0.8	1.2
United States	0.7	0.7	1.5	0.8

Solution:

Potential GDP is calculated as the sum of the trend growth rate in the aggregate hours worked (labor input) and the trend growth rate in labor productivity. The growth in the labor input depends on the population growth rate, changes in the labor force participation rate, and changes in hours worked per person. Estimating based on the average for the period from 2001–2018 gives the following data:

	Projected Growth in Aggregate Hours Worked	Projected Growth in Labor Productivity	Projected Growth in Potential GDP
Canada	1.2%	0.9%	2.1%
Germany	0.3	1.0	1.3
Japan	0.0	1.0	1.0
United States	0.7	1.1	1.8

Note: Rounding used throughout.

Most of the difference between the growth rates in potential GDP among these countries can be explained by the labor input. The most significant result is the difference in the growth rate in aggregate hours in Germany and Japan, in contrast to that in the United States and Canada. The results suggest that Japan's sluggish economic growth is likely to continue because of the lack of growth in the labor input.

EXAMPLE 18

Prospects for Fixed-Income Investments

As a fixed income analyst for a large Canadian bank, you are preparing the 2019–2020 forecast and have just received the latest GDP forecast from the OECD for Canada, Germany, Japan, and the United States. The forecast is given in Exhibit 31, along with the potential GDP growth estimates that the analyst has calculated.

Exhibit 31 Projected vs. Potential GDP Growth

	Projected Average Annual GDP Growth (2019–2020)	Projected Growth in Potential GDP
Canada	4.0%	2.1%
Germany	1.5	1.3
Japan	0.0	1.0
United States	3.5	1.8

To evaluate the future prospects for fixed-income investments, analysts must estimate the future rate of inflation and assess the possibility of changes in monetary policy by the central bank. An important indicator for both of these factors is the degree of slack in the economy, which can be measured by comparing the growth rates of actual GDP and potential GDP.

Based on the information in Exhibit 31, evaluate the prospects for fixed-income investments in each country.

Solution:

In comparing the OECD forecast for GDP growth with the estimated growth rate in potential GDP, there are two cases to consider:

1. If actual GDP is growing at a faster rate than potential GDP, it signals growing inflationary pressures, and an increased likelihood that the central bank will raise interest rates.
2. If actual GDP is growing at a slower rate than potential GDP, it signals growing resource slack, less inflationary pressures, and an increased likelihood that the central bank will reduce rates or leave them unchanged.

Projected and potential GDP for the aforementioned countries can be compared referring to Exhibit 31.

The data suggest that inflationary pressure will grow in the United States and Canada and that both the Federal Reserve and the Bank of Canada will eventually raise interest rates. Thus, the environment for bond investing is not favorable in the United States and Canada, because bond prices are likely to decline.

With Germany growing at close to its potential rate of GDP growth, the rate of inflation should neither rise nor fall. Monetary policy is set by the European Central Bank (ECB), but data on the German economy play a big role in the ECB's decision. Based on the data in Exhibit 31, no change in ECB policy is likely. For bond investors, little change in bond prices is likely in Germany, so investors need to focus on the interest (coupon) income received from the bond.

Finally, growing resource slack in Japan will put downward pressure on inflation and may force the Bank of Japan to keep rates low. Bond prices should rise in this environment.

SUMMARY

- GDP is the market value of all final goods and services produced within a country during a given period.
- GDP can be valued by looking at either the total amount spent on goods and services produced in the economy or the income generated in producing those goods and services.
- GDP counts only final purchases of newly produced goods and services during the current period. Transfer payments and capital gains are excluded from GDP.
- Intermediate goods are excluded from GDP in order to avoid double counting.
- GDP can be measured either from the value of final output or by summing the value added at each stage of the production and distribution process. The sum of the value added by each stage is equal to the final selling price of the good.
- Nominal GDP is the value of production using the prices of the current year. Real GDP measures production using the constant prices of a base year. The GDP deflator equals the ratio of nominal GDP to real GDP.
- Households earn income in exchange for providing—directly or indirectly through ownership of businesses—the factors of production (labor, capital, and natural resources including land). From this income, they consume, save, and pay net taxes.
- Businesses produce most of the economy's output/income and invest to maintain and expand productive capacity. Companies retain some earnings but pay out most of their revenue as income to the household sector and as taxes to the government.
- The government sector collects taxes from households and businesses and purchases goods and services, for both consumption and investment, from the private business sector.
- International trade consists of exports and imports. The difference between the two is net exports. If net exports are positive (negative), then the country spends less (more) than it earns. Net exports are balanced by accumulation of either claims on the rest of the world (net exports > 0) or obligations to the rest of the world (net exports < 0).
- Capital markets provide a link between saving and investment in the economy.
- From the expenditure side, GDP includes personal consumption (C), gross private domestic investment (I), government spending (G), and net exports ($X - M$).

- The major categories of expenditure are often broken down into subcategories. Gross private domestic investment includes both investment in fixed assets (plant and equipment) and the change in inventories. In some countries, government spending on investment is separated from other government spending.
- National income is the income received by all factors of production used in the generation of final output. It equals GDP minus the **capital consumption allowance** (depreciation) and a statistical discrepancy.
- Personal income reflects pre-tax income received by households. It equals national income plus transfers minus undistributed corporate profits, corporate income taxes, and indirect business taxes.
- Personal disposable income equals personal income minus personal taxes.
- Private saving must equal investment plus the fiscal and trade deficits. That is, $S = I + (G - T) + (X - M)$.
- Consumption spending is a function of disposable income. The marginal propensity to consume represents the fraction of an additional unit of disposable income that is spent.
- Investment spending depends on the average interest rate and the level of aggregate income. Government purchases and tax policy are often considered to be exogenous variables determined outside the macroeconomic model. Actual taxes collected depend on income and are, therefore, endogenous—that is, determined within the model.
- Aggregate demand and aggregate supply determine the level of real GDP and the price level.
- The downward slope of the aggregate demand curve arises as the result of three effects: the wealth effect, the interest rate effect, and the real exchange rate effect. The curve is drawn assuming a constant money supply.
- The aggregate demand curve will shift if there is a change in a factor, other than price, that affects aggregate demand. These factors include household wealth, consumer and business expectations, capacity utilization, monetary policy, fiscal policy, exchange rates, and other nations' GDP.
- The aggregate supply curve is the relationship between the quantity of real GDP supplied and the price level, keeping all other factors constant. Movements along the supply curve reflect the effects of price on supply.
- The short-run aggregate supply curve is upward sloping because higher prices result in higher profits and induce businesses to produce more and laborers to work more. In the short run, some prices are sticky, implying that some prices do not adjust to changes in demand.
- In the long run, all prices are assumed to be flexible. The long-run aggregate supply curve is vertical because input costs adjust to changes in output prices, leaving the optimal level of output unchanged. The position of the curve is determined by the economy's level of potential GDP.
- The level of potential output, also called the full employment or natural level of output, is unobservable and difficult to measure precisely. This concept represents an efficient and unconstrained level of production at which companies have enough spare capacity to avoid bottlenecks and there is a balance between the pool of unemployed workers and the pool of job openings.
- The long-run aggregate supply curve will shift because of changes in labor supply, supply of physical and human capital, and productivity/technology.

- The short-run supply curve will shift because of changes in potential GDP, nominal wages, input prices, expectations about future prices, business taxes and subsidies, and the exchange rate.
- Short-term fluctuations in GDP are caused by shifts in aggregate demand and aggregate supply.
- When the level of GDP in the economy is below potential GDP, such a recessionary situation exerts downward pressure on the aggregate price level.
- When the level of GDP is above potential GDP, such an overheated situation puts upward pressure on the aggregate price level.
- Stagflation, a combination of high inflation and weak economic growth, is caused by a decline in short-run aggregate supply.
- Growth in real GDP measures how rapidly the total economy is expanding. Per capita GDP, defined as real GDP divided by population, reflects a country's standard of living. Real GDP growth rates and levels of per capita GDP vary widely among countries.
- The sources of economic growth include the supply of labor, the supply of physical and human capital, raw materials, and technological knowledge.
- Output can be described in terms of a production function. For example, $Y = A\boldsymbol{F}(L,K)$, where L is the quantity of labor, K is the capital stock, and A represents total factor productivity (primarily technology). The function $\boldsymbol{F}(\cdot)$ is assumed to exhibit constant returns to scale but diminishing marginal productivity for each input individually.
- Total factor productivity is a scale factor that reflects the portion of output growth that is not accounted for by changes in the capital and labor inputs. TFP is mainly a reflection of technological change.
- Based on a two-factor production function, Potential GDP growth = Growth in TFP + W_L (Growth in labor) + W_C (Growth in capital), where W_L and W_C $(= 1 - W_L)$ are the shares of labor and capital in GDP.
- Diminishing marginal productivity implies that
  - increasing the supply of some input(s) relative to other inputs will lead to diminishing returns and cannot be the basis for sustainable growth. In particular, long-term sustainable growth cannot rely solely on capital deepening (i.e., on increasing the stock of capital relative to labor).
  - given the relative scarcity and hence high productivity of capital in developing countries, the growth rate of developing countries should exceed that of developed countries.
- The sustainable rate of economic growth is measured by the rate of increase in the economy's productive capacity or potential GDP.
- The labor supply is determined by both population growth (including immigration) and the labor force participation rate. The capital stock in a country increases with investment. Correlation between long-run economic growth and the rate of investment is high.
- In addition to labor, capital, and technology, human capital—essentially, the quality of the labor force—and natural resources are important determinants of output and growth as is the state of public infrastructure, institutional, legal and political environment.
- Technological advances are discoveries that make it possible to produce more and/or higher-quality goods and services with the same resources or inputs. Technology is the main factor affecting economic growth in developed countries.

- Externalities and spillover effects are also recognized to play an important role in growth. Positive externalities associated with research and development and public education. Negative externalities such as pollution have a negative effect on growth.
- Climate change is closely linked to economic growth as carbon dioxide emissions rise with economic growth. These emissions impose a cost on the global economy in terms of economic activity, food production, health and habitability.
- The sustainable rate of growth in an economy is determined by the growth rate of the labor supply plus the growth rate of labor productivity.

PRACTICE PROBLEMS

1 Which of the following statements is the *most* appropriate description of gross domestic product (GDP)?

A The total income earned by all households, firms, and the government whose value can be verified

B The total amount spent on all final goods and services produced within the economy during a given period

C The total market value of resalable and final goods and services produced within the economy during a given period

2 The component *least likely* to be included in a measurement of gross domestic product (GDP) is:

A the value of owner occupied rent.

B the annual salary of a local police officer.

C environmental damage caused by production.

3 Which of the following conditions is *least likely* to increase a country's GDP?

A An increase in net exports

B Increased investment in capital goods

C Increased government transfer payments

4 Which of the following would be included in Canadian GDP for a given year? The market value of:

A wine grown in Canada by US citizens.

B electronics made in Japan and sold in Canada.

C movies produced outside Canada by Canadian filmmakers.

5 Suppose a painting is produced and sold in 2018 for £5,000. The expenses involved in producing the painting amounted to £2,000. According to the sum-of-value-added method of calculating GDP, the value added by the final step of creating the painting was:

A £2,000.

B £3,000.

C £5,000.

6 A GDP deflator less than 1 indicates that an economy has experienced:

A inflation.

B deflation.

C stagflation.

7 The *most* accurate description of nominal GDP is:

A a measure of total expenditures at current prices.

B the value of goods and services at constant prices.

C a measure to compare one nation's economy to another.

8 From the beginning to the ending years of a decade, the annual value of final goods and services for country *X* increased from €100 billion to €300 billion. During that period, the GDP deflator increased from 111 to 200. Over the decade, real GDP for country *X* increased by approximately:

A 50%.

© 2020 CFA Institute. All rights reserved.

B 67%.

C 200%.

9 If the GDP deflator values for Year 1 and Year 3 were 190 and 212.8, respectively, which of the following *best* describes the annual growth rate of the overall price level?

A 5.8%.

B 6%.

C 12%.

10 The numerator of the GDP price deflator reflects:

A the value of base year output at current prices.

B the value of current year output at current prices.

C the value of current year output at base year prices.

11 Consider the following data for a hypothetical country:

Account name	Amount ($ trillions)
Consumption	15.0
Capital consumption allowance	1.5
Government spending	3.8
Imports	1.7
Gross private domestic investment	4.0
Exports	1.5

Based only on the data given, the gross domestic product and national income are respectively *closest* to:

A 21.1 and 20.6.

B 22.6 and 21.1.

C 22.8 and 20.8.

12 In calculating personal income for a given year, which of the following would *not* be subtracted from national income?

A Indirect business taxes

B Undistributed corporate profits

C Unincorporated business net income

13 Equality between aggregate expenditure and aggregate output implies that the government's fiscal deficit must equal:

A Private saving – Investment – Net exports.

B Private saving – Investment + Net exports.

C Investment – Private saving + Net exports.

14 Because of a sharp decline in real estate values, the household sector has increased the fraction of disposable income that it saves. If output and investment spending remain unchanged, which of the following is *most likely*?

A A decrease in the government deficit

B A decrease in net exports and increased capital inflow

C An increase in net exports and increased capital outflow

15 In explaining the downward slope of the aggregate demand curve, the interest rate effect suggests that a higher price level will:

A lead to lower interest rates, which will lead to higher levels of consumption and investment.

B lead to higher interest rates, which will lead to lower levels of consumption and investment.

C not affect interest rates and therefore will lead to a higher level of aggregate demand.

16 One of the reasons aggregate demand curve is downward sloping is because a lower price level means that the real exchange rate:

A depreciates, making domestic goods cheaper in other countries and imports less competitive, resulting in a higher level of net exports.

B appreciates, making domestic goods more expensive in other countries and imports more competitive, resulting in a higher level of net exports.

C appreciates, making the country's exports and imports less competitive and leading to lower net exports.

17 The full employment, or natural, level of output is *best* described as:

A the maximum level obtainable with existing resources.

B the level at which all available workers have jobs consistent with their skills.

C a level with a modest, stable pool of unemployed workers transitioning to new jobs.

18 Which of the following *best* describes the aggregate supply curve in the short run (one to two years)? The short-run aggregate supply curve is:

A flat, because output is more flexible than prices in the short run.

B vertical, because wages and other input prices fully adjust to the price level.

C upward sloping, because input prices do not fully adjust to the price level in the short run.

19 If wages were automatically adjusted for changes in the price level, the short-run aggregate supply curve would *most likely* be:

A flatter.

B steeper.

C unchanged.

20 The *least likely* cause of a decrease in aggregate demand is:

A higher taxes.

B a weak domestic currency.

C a fall in capacity utilization.

21 Which of the following is *most likely* to cause the long-run aggregate supply curve to shift to the left?

A Higher nominal wages

B A decline in productivity

C An increase in corporate taxes

22 Increased household wealth will *most likely* cause an increase in:

A household saving.

B investment expenditures.

C consumption expenditures.

23 The *most likely* outcome when both aggregate supply and aggregate demand increase is:

A a rise in inflation.

B higher employment.

C an increase in nominal GDP.

24 Which of the following is *least likely* to be caused by a shift in aggregate demand?

A Stagflation

B A recessionary gap

C An inflationary gap

25 Following a sharp increase in the price of energy, the overall price level is *most likely* to rise in the short run:

A and remain elevated indefinitely unless the central bank tightens.

B but remain unchanged in the long run unless the money supply is increased.

C and continue to rise until all prices have increased by the same proportion.

26 Among developed economies, which of the following sources of economic growth is *most likely* to explain superior growth performance?

A Technology

B Capital stock

C Labor supply

27 Which of the following can be measured directly?

A Potential GDP

B Labor productivity

C Total factor productivity

28 The sustainable growth rate is *best* estimated as:

A the weighted average of capital and labor growth rates.

B growth in the labor force plus growth of labor productivity.

C growth in total factor productivity plus growth in the capital-to-labor ratio.

29 In the neoclassical or Solow growth model, an increase in total factor productivity reflects an increase in:

A returns to scale.

B output for given inputs.

C the sustainable growth rate.

The following information relates to Questions 30–31

An economic forecasting firm has estimated the following equation from historical data based on the neoclassical growth model:

$$\text{Potential output growth} = 1.5 + 0.72 \times \text{Growth of labor} + 0.28 \times \text{Growth of capital}$$

30 The intercept (1.5) in this equation is *best* interpreted as:

A the long-run sustainable growth rate.

B the growth rate of total factor productivity.

C above-trend historical growth that is unlikely to be sustained.

31 The coefficient on the growth rate of labor (0.72) in this equation is *best* interpreted as:

A the labor force participation rate.

B the marginal productivity of labor.

C the share of income earned by labor.

---

32 Convergence of incomes over time between emerging market countries and developed countries is *most likely* the result of:

A total factor productivity.

B diminishing marginal productivity of capital.

C the exhaustion of non-renewable resources.

SOLUTIONS

1 B is correct. GDP is the total amount spent on all final goods and services produced within the economy during a specific period.

2 C is correct. Byproducts of production processes that have no explicit market value are not included in GDP.

3 C is correct. Government transfer payments, such as unemployment compensation or welfare benefits, are excluded from GDP.

4 A is correct. Canadian GDP is the total market value of all final goods and services produced during a given period within Canada. The wine was produced in Canada and counts toward Canadian GDP.

5 B is correct. The value added by the artist is £5,000 – £2,000 = £3,000.

6 B is correct. The GDP deflator = Nominal GDP/Real GDP. To obtain a ratio less than 1, real GDP must exceed nominal GDP, which indicates that prices have decreased and, accordingly, deflation has occurred.

7 A is correct. Nominal GDP is defined as the value of goods and services measured at current prices. Expenditure is used synonymously with the value of goods and services because aggregate expenditures must equal aggregate output of an economy.

8 B is correct. Real GDP in the first year was €100 billion/1.11 = €90 billion, and in the last year it was €300 billion/2.00 = €150 billion. Thus, (€150 – €90)/€90 = 0.67, or 67%.

9 A is correct: $(212.8/190)^{1/2} - 1 = 0.0583$, or 5.8%.

10 B is correct.

$$\text{GDP deflator} = \frac{\text{Value of current year output at current year prices}}{\text{Value of current year output at base year prices}} \times 100$$

11 B is correct. GDP = Consumption + Gross private domestic investment + Government spending + (Exports – Imports) = 15 + 4 + 3.8 + (1.5 – 1.7) = 22.6. National income = GDP – CCA = 22.6 – 1.5 = 21.1

12 C is correct. Unincorporated business net income, also known as proprietor's income, is included in personal income.

13 A is correct. The fundamental relationship among saving, investment, the fiscal balance, and the trade balance is $S = I + (G - T) + (X - M)$. This form of the relationship shows that private saving must fund investment expenditures, the government fiscal balance, and net exports (= net capital outflows). Rearranging gives $G - T = (S - I) - (X - M)$. The government's fiscal deficit $(G - T)$ must equal the private sector's saving/investment balance $(S - I)$ minus net exports.

14 C is correct. The fundamental relationship among saving, investment, the fiscal balance, and the trade balance is $S = I + (G - T) + (X - M)$. Given the levels of output and investment spending, an increase in saving (reduction in consumption) must be offset by either an increase in the fiscal deficit or an increase in net exports. Increasing the fiscal deficit is not one of the choices, so an increase in net exports and corresponding increase in net capital outflows (increased lending internationally and/or increased international purchases of assets) is the correct response.

15 B is correct. Assuming a fixed supply of money, a higher price level will lead to a higher price of money. Because the price of money is the interest rate, as the price level increases, the interest rate increases. Higher interest rates will lead to lower consumption and investment.

16 A is correct. A lower price level results in a weaker real exchange rate, making domestic goods cheaper to people in other countries and imports less competitive, resulting in a higher level of net exports.

17 C is correct. At the full employment, or natural, level of output, the economy is operating at an efficient and unconstrained level of production. Companies have enough spare capacity to avoid bottlenecks, and there is a modest, stable pool of unemployed workers (job seekers equal job vacancies) looking for and transitioning into new jobs.

18 C is correct. Because of long-term contracts and other rigidities, wages and other input costs do not fully adjust to changes in the price level in the short run. Given input prices, firms respond to output price changes by expanding or contracting output to maximize profit. Hence, the SRAS is upward sloping.

19 B is correct. The slope of the short-run aggregate supply curve reflects the extent to which wages and other input costs adjust to the overall price level. Automatic adjustment of wages would mitigate the impact of price changes on profitability. Hence, firms would not adjust output as much in response to changing output prices—the SRAS curve would be steeper.

20 B is correct. A weak domestic currency will result in an increase in aggregate demand at each price level—a rightward shift in the AD curve. A weaker currency will cause a country's exports to be cheaper in global markets. Conversely, imports will be more expensive for domestic buyers. Hence, the net exports component of aggregate demand will increase.

21 B is correct. Productivity measures the efficiency of labor and is the amount of output produced by workers during a given period. A decline in productivity implies decreased efficiency. A decline in productivity increases labor costs, decreases profitability, and results in lower output at each output price level—a leftward shift in both the short-run and long-run aggregate supply curves.

22 C is correct. The wealth effect explains the impact of increases or decreases in household wealth on economic activity. Household wealth includes financial and real assets. As asset values increase, consumers save less and spend more out of current income because they will still be able to meet their wealth accumulation goals. Therefore, an increase in household wealth results in a rightward shift in the aggregate demand curve.

23 B is correct. Higher aggregate demand and higher aggregate supply raise real GDP and lower unemployment, meaning employment levels increase.

24 A is correct. Stagflation occurs when output is declining and prices are rising. This dynamic most likely results from a decline in aggregate supply—a leftward shift of the SRAS curve. Depending on the source of the shift, the LRAS may shift too.

25 B is correct. An increase in energy prices will shift the short-run aggregate supply curve (SRAS) to the left, reducing output and increasing prices. If the aggregate demand curve does not change—in particular, if the central bank does not expand the money supply—slack in the economy will put downward pressure on in input prices, shifting the SRAS back to its original position. In the long run, the price level will be unchanged.

26 A is correct. Technology is the most important factor affecting economic growth for developed countries. Technological advances are very important because they allow an economy to overcome the limits imposed by diminishing marginal returns.

27 B is correct. Labor productivity can be directly measured as output/hour.

28 B is correct. Output growth is equal to the growth rate of the labor force plus the growth rate of labor productivity—that is, output per worker. Unlike total factor productivity, output per worker is observable, so this measure is the most practical way to approach estimation of sustainable growth.

29 B is correct. Total factor productivity is a scale factor primarily reflecting technology. An increase in TFP means that output increases for any level of factor inputs.

30 B is correct. The estimated equation is the standard Solow growth accounting equation. The intercept is the growth rate of total factor productivity.

31 C is correct. In the standard Solow growth accounting equation, the coefficient on each factor's growth rate is its share of income.

32 B is correct. Diminishing marginal productivity of capital means that as a country accumulates more capital per worker, the incremental boost to output declines. Thus, all else equal, economies grow more slowly as they become more capital intensive. Given the relative scarcity and hence high marginal productivity of capital in developing countries, these economies tend to grow more rapidly than developed countries. This dynamic leads to convergence in income levels over time.

Understanding Business Cycles

by Michele Gambera, PhD, CFA, Milton Ezrati, and Bolong Cao, PhD, CFA

Michele Gambera, PhD, CFA, is with UBS Asset Management and the University of Illinois at Urbana-Champaign (USA). Milton Ezrati (USA). Bolong Cao, PhD, CFA, is at Ohio University (USA).

LEARNING OUTCOMES

Mastery	*The candidate should be able to:*
☐	**a.** describe the business cycle and its phases;
☐	**b.** describe credit cycles;
☐	**c.** describe how resource use, consumer and business activity, housing sector activity, and external trade sector activity vary as an economy moves through the business cycle;
☐	**d.** describe theories of the business cycle;
☐	**e.** interpret a set of economic indicators, and describe their uses and limitations;
☐	**f.** describe types of unemployment, and compare measures of unemployment;
☐	**g.** explain inflation, hyperinflation, disinflation, and deflation;
☐	**h.** explain the construction of indexes used to measure inflation;
☐	**i.** compare inflation measures, including their uses and limitations;
☐	**j.** contrast cost-push and demand-pull inflation.

INTRODUCTION

1

A typical economy’s output of goods and services fluctuates around its longer-term path. We now turn our attention to those recurring, cyclical fluctuations in economic output. Some of the factors that influence short-term changes in the economy—such as changes in population, technology, and capital—are the same as those that affect long-term sustainable economic growth. But forces that cause shifts in aggregate

© 2021 CFA Institute. All rights reserved.

demand and aggregate supply curves—such as expectations, political developments, natural disasters, and fiscal and monetary policy decisions—influence economies particularly in the short run.

We first describe a typical business cycle and its phases. While each cycle is different, analysts and investors need to be familiar with the typical cycle phases and what they mean for the expectations and decisions of businesses and households that influence the performance of sectors and companies. These behaviors also impact financial conditions and risk appetite, thus impacting the setting of expectations and choices of portfolio exposures to different investment sectors or styles.

In the sections that follow, we describe credit cycles, introduce several theories of business cycles, and explain how different economic schools of thought interpret the business cycle and their recommendations with respect to it. We also discuss variables that demonstrate predictable relationships with the economy, focusing on those whose movements have value in predicting the future course of the economy. We then proceed to explain measures and features of unemployment and inflation.

2

OVERVIEW OF THE BUSINESS CYCLE

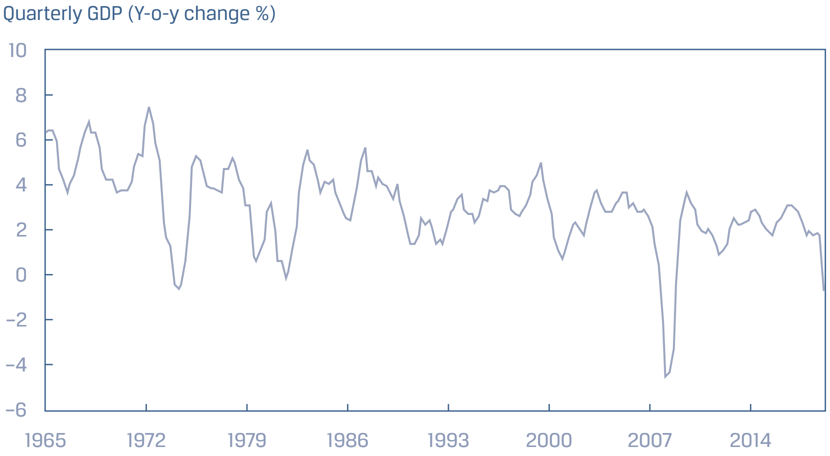
a describe the business cycle and its phases

Business cycles are recurrent expansions and contractions in economic activity affecting broad segments of the economy. Burns and Mitchell (1946) define the business cycle as follows:

> Business cycles are a type of fluctuation found in the aggregate economic activity of nations that organize their work mainly in business enterprises: a cycle consists of expansions occurring at about the same time in many economic activities, followed by similarly general recessions, contractions, and revivals which merge into the expansion phase of the next cycle; this sequence of events is recurrent but not periodic; in duration, business cycles vary from more than one year to 10 or 12 years.

This definition is rich with important insights. First, business cycles are typical of economies that rely mainly on business enterprises—therefore, not agrarian societies or centrally planned economies. Second, a cycle has an expected sequence of phases, alternating between expansion and contraction, or upswings and downturns. Third, such phases occur at about the same time throughout the economy. Finally, cycles are recurrent; they happen again and again over time but not in a periodic way; they do not all have the exact same intensity and duration. Exhibit 1 provides an illustration of the pattern of economic growth rate in developed markets.

Exhibit 1 Fluctuations of Growth in OECD Countries over Time



Note: The Organisation for Economic Co-Operation and Development (OECD) includes more than 30 large countries.
Source: OECD.Stat (htttps://stats.oecd.org/) YoY change in quarterly GDP in OECD countries.

Burns' and Mitchell's definition remains helpful. History never repeats itself in quite the same way, but it certainly does offer patterns that can be used when analyzing the present and forecasting the future. Business cycle analysis is a wide-ranging topic with conflicting perspectives held by industry participants.

2.1 Phases of the Business Cycle

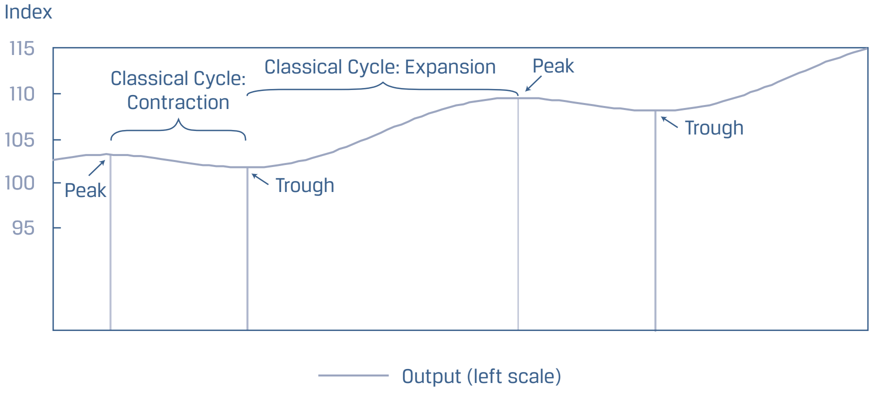
Business cycles are recurring sequences of alternating upswings and downturns. There are various ways to break the business cycle into phases. The most obvious is to divide it into two primary segments: the expansion, or the upswing, and the contraction, or the downturn, with two key turning points, or peaks and troughs (see Exhibits 2 and 3). These two periods are fairly easy to identify in retrospect. Subdividing the cycle more finely, however, becomes ambiguous, even in retrospect, because it requires identifying more nuanced changes, such as acceleration or deceleration of growth without a change in its direction. It is thus useful to divide the cycle into several phases distinguished through both economic and financial market characteristics. Our focus is on economic characteristics of the different phases, but we will highlight their implication for the behavior of different segments of the financial markets along the way.

The timing of these periods will depend on the type of cycle. Before moving on to the description of the four distinct phases to which we will refer in the subsequent sections, we first explain the different cycle concepts that analysts should be aware of given the range of different opinions, interpretations, and descriptions that practitioners use.

2.1.1 *Types of Cycles*

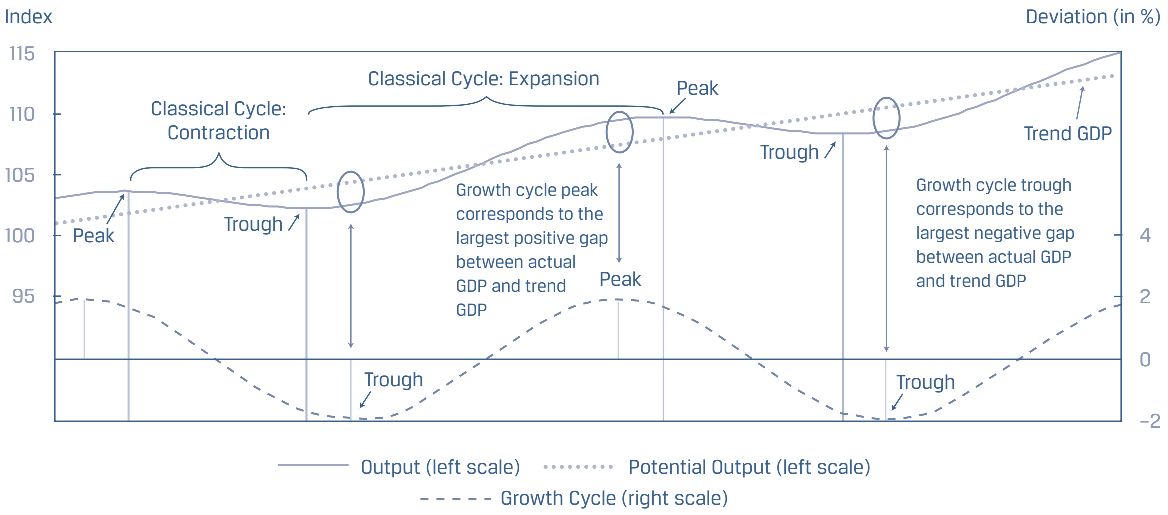
- **Classical cycle** refers to fluctuations in the level of economic activity (e.g., measured by GDP in volume terms). The contraction phases between peaks and troughs are often short, while expansion phases are much longer. Exhibit 2 shows the classical cycle of economic activity. In practice, the classical cycle is not used extensively by academics and practitioners because it does not easily allow the breakdown of movements in GDP between short-term fluctuations and long-run trends. In addition, an absolute decline in activity between peaks and troughs does not occur frequently.

Exhibit 2 Classical Cycle



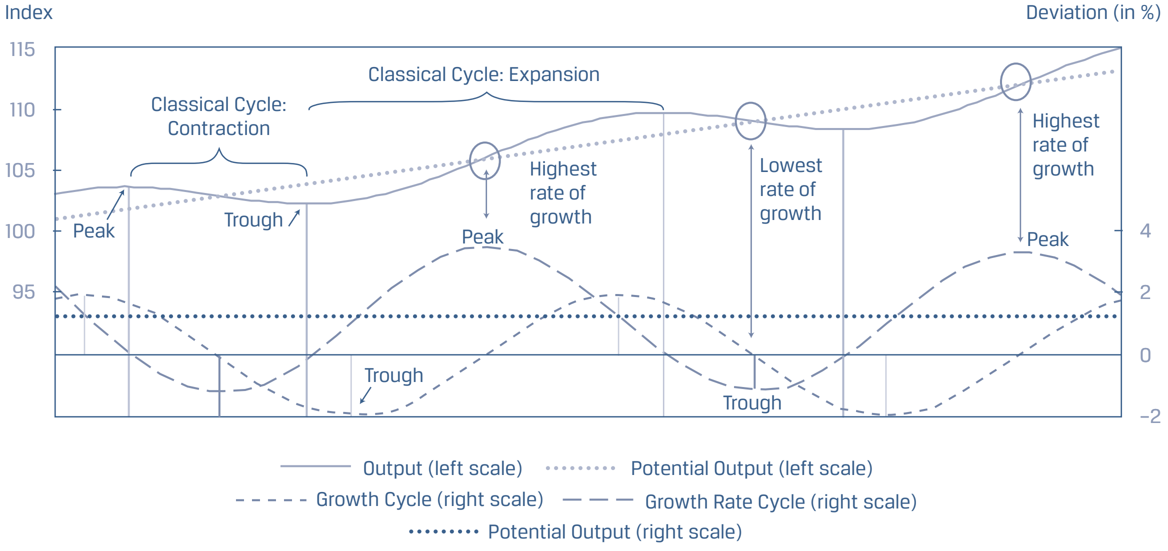
- **Growth cycle** refers to fluctuations in economic activity around the long-term potential or trend growth level. The focus is on how much actual economic activity is below or above trend growth in economic activity. The dashed "wave" in the lower part of Exhibit 3 captures the fluctuation of actual activity from trend growth activity. Exhibit 3 shows "gaps" between actual and trend output. The growth cycle definition comes closest to how mainstream economists think: It dissects overall economic activity into a part driven by long-run trends and a part reflecting short-run fluctuations. Compared to the classical view of business cycles, peaks are generally reached earlier and troughs later in time. The time periods below and above trend growth are of similar length.

Exhibit 3 Classical and Growth Cycles



- **Growth rate cycle** refers to fluctuations in the growth rate of economic activity (e.g., GDP growth rate). Peaks and troughs are mostly recognized earlier than when using the other two definitions (see Exhibit 4). An advantage is that there is not necessarily a need to first estimate a long-run growth path. Nevertheless, economists often refer to economic growth being above or below potential growth rate, reflecting upswings or downturns.

Exhibit 4 Classical, Growth, and Growth Rate Cycles



Notes: The vertical lines indicate troughs and peaks when using either the classical, growth, or growth rate cycle definition of a business cycle. The growth cycle reflects the percentage deviation of output relative to its trend. The growth rates in the growth rate cycle are calculated as annualized month-over-month growth rates.

2.1.2 *Practical Issues*

In practice, the definitions of a business cycle are used interchangeably, which often causes confusion with regard to how one labels the phases and their timing. The classical cycle definition is rarely used. In line with how most economists and practitioners view the cycle, we will generally be using the growth cycle concept in which business cycles can be thought of as fluctuations around potential output (the trend in potential output is shown as the upward sloping dotted line in Exhibit 3).

2.1.3 *Four Phases of the Cycle*

The overall business cycle can be split into four phases:

> **Recovery**: The economy is going through the "trough" of the cycle, where actual output is at its lowest level relative to potential output. Economic activity, including consumer and business spending, is below potential but is starting to increase, closing the negative output gap.
>
> **Expansion**: The recovery gathers pace, output increases, and the rate of growth is above average. Actual output rises above potential output, and the economy enters the so-called "boom" phase. Consumers increase spending, and companies increase production, employment, and investment. Prices and interest rates may start increasing. As the expansion continues, the economy may start to experience shortages in factors of production. Overinvestment in productive capacity may lead companies to reduce further investment spending.
>
> **Slowdown**: Output of the economy reaches its highest level relative to potential output (largest positive output gap). The growth rate begins to slow relative to potential output growth, and the positive output gap begins to narrow. Consumers remain optimistic about the economy, but companies may rely on overtime rather than using new hires to meet demand. Inflation slows at some point, and price levels may decrease.
>
> **Contraction**: Actual economic output falls below potential economic output. Consumer and business confidence declines. Companies reduce costs by eliminating overtime and reducing employment. The economy may experience declines in absolute economic activity, a recession, or if the fall in activity is particularly large, a depression. If the decline is moderate, this phase tends to be shorter than the expansion phase.

Exhibit 5 provides a summary of the key characteristics of each phase and describes how several important economic variables evolve through the course of a business cycle.

Exhibit 5 Business Cycle Phase Characteristics

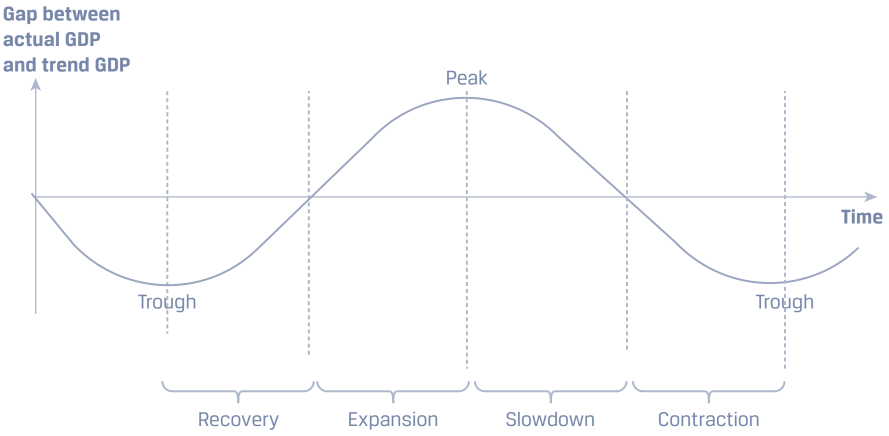


Exhibit 5 (Continued)

Phase	Recovery	Expansion	Slowdown	Contraction
Description	Economy going through a trough. Negative output gap starts to narrow.	Economy enjoying an upswing. Positive output gap opens.	Economy going through a peak. Positive output gap starts to narrow.	Economy weakens and may go into a recession. Negative output gap opens.
Activity levels – consumers and businesses	Activity levels are below potential but start to increase.	Activity measures show above-average growth rates.	Activity measures are above average but decelerating. Moving to below-average rates of growth.	Activity measures are below potential. Growth is lower than normal.
Employment	Layoffs slow. Businesses rely on overtime before moving to hiring. Unemployment remains higher than average.	Businesses move from using overtime and temporary employees to hiring. Unemployment rate stabilizes and starts falling.	Business continue hiring but at a slower pace. Unemployment rate continues to fall but at decreasing rates.	Businesses first cut hours, eliminate overtime, and freeze hiring, followed by outright layoffs. Unemployment rate starts to rise.
Inflation	Inflation remains moderate.	Inflation picks up modestly.	Inflation further accelerates.	Inflation decelerates but with a lag.

2.2 Leads and Lags in Business and Consumer Decision Making

The behavior of businesses and households is key to the cycle and frequently incorporates leads and lags relative to what are established as turning points. For example, at the beginning of an expansion phase, companies may want to fully use their existing workforce and wait to hire new employees until they are sure that the economy is indeed growing. However, gradually all economic variables are going to revert toward their normal range of values (e.g., GDP growth will be close to potential, or average, growth).

2.3 Market Conditions and Investor Behavior

Many economic variables and sectors of the economy have distinctive cyclical patterns. Knowledge of these patterns can offer insight into likely cyclical directions overall, or it can be particularly applicable to an investment strategy that requires more specific rather than general cyclical insights for investment success.

Recovery phase When asset markets expect the end of a recession and the beginning of an expansion phase, risky assets will be repriced upward. When an expansion is expected, the markets will start incorporating higher profit expectations into the prices of corporate bonds and stocks. Typically, equity markets will hit a trough about three to six months before the economy bottoms and well before the economic indicators turn up. Indeed, as we will see later, the equity market is classified as a leading indicator of the economy.

Expansion phase When an economy's expansion is well-established, a later part of an expansion, referred to as a "**boom**," often follows. The boom is an expansionary phase characterized by economic growth "testing the limits" of the economy, strong confidence, profit, and credit growth. For example, companies may expand so much that they have difficulty finding qualified workers and will compete with other prospective employers by raising wages and continuing to expand capacity, relying on strong cash flows and borrowing. The government and/or central bank may step in if it is concerned about the economy overheating.

Slowdown phase During the boom, the riskiest assets will often have substantial price increases. Safe assets, such as government bonds that were more highly prized during recession, may have lower prices and thus higher yields. In addition, investors may fear higher inflation, which also contributes to higher nominal yields.

Contraction phase During contraction, investors place relatively high values on such safer assets as government securities and shares of companies with steady (or growing) positive cash flows, such as utilities and producers of staple goods. Such preferences reflect the fact that the marginal utility of a safe income stream increases in periods when employment is insecure or declining.

EXAMPLE 1

When Do Recessions Begin and End?

A simple and commonly referred to rule is the following: A recession has started when a country or region experiences two consecutive quarters of negative real GDP growth. Real GDP growth is a measure of the "real" or "inflation-adjusted" growth of the overall economy. This rule can be misleading because it does not indicate a recession if real GDP growth is negative in one quarter, slightly positive the next quarter, and again negative in the next quarter. Many analysts question this result. This issue is why some countries have statistical and economic committees that apply the principles stated by Burns and Mitchell to several macroeconomic variables—not just real GDP growth—as a basis to identify business cycle peaks and troughs. The National Bureau of Economic Research (NBER) is an organization that dates business cycles in the United States. Interestingly, the economists and statisticians on NBER's Business Cycle Dating Committee analyze numerous time series of data focusing on employment, industrial production, and sales. Because the data are available with a delay (preliminary data releases can be revised even several years after the period they refer to), it also means that the Committee's determinations may take place well after the business cycle turning points have occurred. As we will see later in the reading, there are practical indicators that may help economists understand in advance if a cyclical turning point is about to happen.

1 Which of the following rules is *most likely* to be used to determine whether the economy is in a recession?
   - A The central bank has run out of foreign reserves.
   - B Real GDP has two consecutive quarters of negative growth.
   - C Economic activity experiences a significant decline in two business sectors.

2 Suppose you are interested in forecasting earnings growth for a company active in a country where no official business cycle dating committee (such as the NBER) exists. The variables you are *most likely* to consider to identify peaks and troughs of a country's business cycle are:
   - A inflation, interest rates, and unemployment.
   - B stock market values and money supply.
   - C unemployment, GDP growth, industrial production, and inflation.

Solution to 1:

B is correct. GDP is a measure of economic activity for the whole economy. Changes in foreign reserves or a limited number of sectors may not have a material impact on the whole economy.

Solution to 2:

C is correct. Unemployment, GDP growth, industrial production, and inflation are measures of economic activity. The discount rate, the monetary base, and stock market indexes are not direct measures of economic activities. The first two are determined by monetary policy, which react to economic activities, whereas the stock market indexes tend to be forward looking or leading indicators of the economy.

CREDIT CYCLES AND THEIR RELATIONSHIP TO BUSINESS CYCLES

3

b describe credit cycles

Whereas business cycles mostly use GDP as a measure of economic activity, a literature has emerged in which cyclical developments of financial variables are analyzed separately. This is most commonly done in terms of credit and property prices. Credit cycles describe the changing availability—and pricing—of credit. They describe growth in private sector credit (availability and usage of loans), which is essential for business investments and household purchases of real estate. They are therefore connected to real economic activity captured by business cycles that describe fluctuations in real GDP.

When the economy is strong or improving, the willingness of lenders to extend credit, and on favorable terms, is high. Conversely, when the economy is weak or weakening, lenders pull back, or "tighten" credit, by making it less available and more expensive. This frequently contributes to the decline of such asset values as real estate, causing further economic weakness and higher defaults. This is because of the importance of credit in the financing of construction and the purchase of property. Credit cycles are a subset of a wider family of so-called financial cycles, a topic that goes beyond the scope of our coverage.

3.1 Applications of Credit Cycles

Financial factors were for a long time not prominent on the radar screens of macroeconomists. Monetary and financial phenomena were largely seen as a veil that could be ignored when trying to understand the economy. But loose private sector credit is considered to have contributed to a number of financial crises, such as the Latam crisis of the 1980s; the Mexican, Brazilian, and Russian crises of the 1990s; the Asian crisis of 1997–1998; and the global financial crisis of 2008–2009. Loose credit conditions often lead to asset price and real estate bubbles that burst when capital market outflows and drawdowns occur mostly due to weaker fundamentals.

It is recognized that in a world with financial frictions, business cycles can be amplified, with deeper recessions and more extensive expansions because of changes in access to external financing. In line with this, it is found that the duration and magnitude of recessions and recoveries are often shaped by linkages between business and credit cycles (Claessens, Kose, and, Terrones 2012). In particular, recessions accompanied by financial disruption episodes (notably, house and equity price busts), tend to be longer and deeper. Recoveries combined with rapid growth in credit, risk-taking, and house prices tend to be stronger.

However, whereas financial variables tend to co-vary closely with each other and can often help explain the size of an economic expansion or contraction, they are not always synchronized with the traditional business cycle. Credit cycles tend to be longer, deeper, and sharper than business cycles. Although the length of a business cycle varies from peak to trough, the average length of a credit cycle is mostly found to be longer than that of the business cycle. Exhibit 6 illustrates how credit cycles can be visualized.

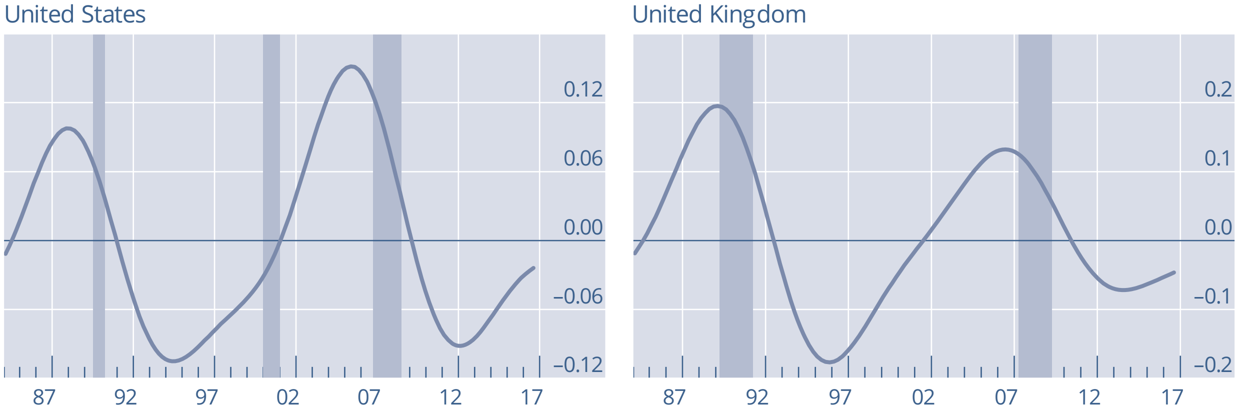
VISUALIZING FINANCIAL CYCLES

In an October 2019 Working Paper titled "Predicting Recessions: Financial Cycle versus Term Spread," the Bank for International Settlements (BIS) provided a visual presentation of credit cycles, which is reproduced in Exhibit 6. It shows that such cycles tend to boom before recessions.

Exhibit 6

Financial cycles tend to boom ahead of recessions[1]

Graph 1



The shaded areas represent recessions.

[1] Financial cycles are measured by the composite financial cycle proxy calculated from frequency-based (bandpass) filters capturing medium-term cycles in real credit, the credit-to-GDP ratio and real house prices.

Source: BIS Material (available on the BIS website free of charge: www.bis.org).

Notes: Credit cycles are measured by a (composite) proxy calculated from variables that include credit-to-GDP ratio and real house prices. The axis on the right shows the year-on-year change in the proxy.

3.2 Consequences for Policy

Investors pay attention to the stage in the credit cycle because (1) it helps them understand developments in the housing and construction markets; (2) it helps them assess the extent of business cycle expansions as well as contractions, particularly the severity of a recession if it coincides with the contraction phase of the credit cycle; and (3) it helps them better anticipate policy makers' actions. Whereas monetary and fiscal policy traditionally concentrate on reducing the volatility of business cycles, macro-prudential stabilization policies that aim to dampen financial booms have gained importance. This is further stressed by findings that strong peaks in credit cycles are closely associated with subsequent systemic banking crises (Schüler, Hiebert, and Peltonen 2017).

EXAMPLE 2

A senior portfolio manager at Carnara Asset Management explains her analysis of business cycles to a junior analyst. She makes two statements:

Statement I	Business cycles measure activity by GDP, whereas credit cycles combine a range of financial variables, such as the amount of and pricing of credit.
Statement II	Credit cycles and business cycles are unrelated and serve different purposes.

A Only Statement I is true.

B Only Statement II is true

C Both statements are true

Solution:

A is correct. Only Statement I is true. Statement II is not true because researchers have found linkages between financial and business cycles that help explain the magnitude of business cycle expansions and contractions depending on the state of the credit cycle.

BUSINESS CYCLE FLUCTUATIONS FROM A FIRM'S PERSPECTIVE

4

c describe how resource use, consumer and business activity, housing sector activity, and external trade sector activity vary as an economy moves through the business cycle

This section provides a broad overview of how the use of resources needed to produce goods and services typically evolves during a business cycle. We start by focusing on circumstances of firms and explore some of the links between fluctuations in inventory, employment, and investment in physical capital with economic fluctuations.

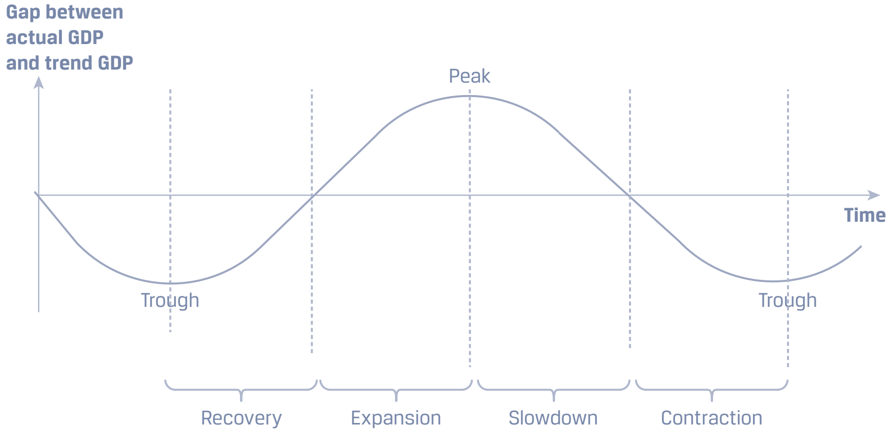
4.1 The Workforce and Company Costs

The pattern of hiring and employment is shown in Exhibit 7. When the economy enters contraction, companies reduce costs and eliminate overtime. They may try to retain workers rather than reducing employment only to increase it later. Finding and training new workers is costly, and it may be more cost efficient to keep workers on the payroll even if they are not fully utilized. Companies may also benefit from an implicit bond of loyalty between a company and its workers, boosting productivity in the process. In prolonged contractions, companies will start reducing costs more aggressively—terminating consultants, advertising campaigns, and workers beyond the strict minimum. Capacity utilization will be low, and few companies will invest in new equipment. Companies will try to liquidate their inventories of unsold products. In addition, banks will be reluctant to lend because bankruptcy risks are perceived to be higher, adding to the weakness in the economy.

Decreases in aggregate demand are likely to depress wages or wage growth as well as prices of inputs and capital goods. After a while, all of these input prices will be relatively low. In addition, interest rates may be cut to try to revive the economy.

As prices and interest rates decrease, consumers and companies may begin to purchase more and aggregate demand may begin to rise. This stage is the turning point of the business cycle: Aggregate demand starts to increase and economic activity increases.

Exhibit 7 Business Cycle Phases—Levels of Employment



Phase	Recovery	Expansion	Slowdown	Contraction
Description of activity levels	Economy starts at trough and output below potential. Activity picks up, and gap starts to close.	Economy enjoying an upswing, with activity measures showing above-average growth rates.	Economy at peak. Activity above average but decelerating. The economy may experience shortages of factors of production as demand may exceed supply.	Economy goes into a contraction, (recession, if severe). Activity measures are below potential. Growth is lower than normal.
Employment	Layoffs slow. Businesses rely on overtime before moving to hiring. Unemployment remains higher than average.	Businesses move from using overtime and temporary employees to hiring. Unemployment rate stabilizes and starts falling.	Businesses continue hiring but at a slower pace. Unemployment rate continues to fall but at slowly decreasing rates.	Businesses first cut hours, eliminate overtime, and freeze hiring, followed by outright layoffs. Unemployment rate starts to rise.

Levels of employment lag the cycle

4.2 Fluctuations in Capital Spending

Capital spending—spending on tangible goods, such as property, plant, and equipment—typically fluctuates with the business cycle. Because business profits and cash flows are sensitive to changes in economic activity, capital spending is also highly sensitive to changes in economic activity. In fact, investment is one of the most procyclical and volatile components of GDP. Companies' spending decisions are driven by business conditions, expectations, and levels of capacity utilization, all of which fluctuate over the cycle. With regard to efficiency, firms will run "lean production" to generate maximum output with the fewest number of workers at the end of contractions. Exhibit 8 provides a description of capital spending over the cycle. Note that new orders statistics include orders that will be delivered over several years. For example, it is common for airlines to order 40 airplanes to be delivered over five years. Where relevant, analysts use "core" orders that exclude defense and aircrafts for a better understanding of the economy's trend.

Exhibit 8 Capital Spending during the Economic Cycle

Phase of the Cycle	Recovery	Expansion	Slowdown	Contraction
Business conditions and expectations	Excess capacity during trough, low utilization, little need for capacity expansion. Interest rates tend to be low—supporting investment.	Companies enjoy favorable conditions. Capacity utilization increases from low levels. Over time, productive capacity may begin to limit ability to respond to demand. Growth in earnings and cash flow gives businesses the financial ability to increase investment spending.	Business conditions at peak, with healthy cash flow. Interest rates tend to be higher—aimed at reducing overheating and encouraging investment slowdown.	Companies experience fall in demand, profits, and cash flows.
Capital spending	Low but increasing as companies start to enjoy better conditions. Capex focus on efficiency rather than capacity. Upturn most pronounced in orders for light producer equipment. Typically, the orders initially reinstated are for equipment with a high rate of obsolescence, such as software, systems, and technological hardware.	Customer orders and capacity utilization increase. Companies start to focus on capacity expansion. The composition of the economy's capacity may not be optimal for the current structure of demand, necessitating spending on new types of equipment. Orders precede actual shipments, so orders for capital equipment are a widely watched indicator of the future direction of capital spending.	New orders intended to increase capacity may be an early indicator of the late stage of the expansion phase. Companies continue to place new orders as they operate at or near capacity.	New orders halted, and some existing orders canceled (no need to expand). Initial cutbacks may be sharp and exaggerate the economy's downturn. As the general cyclical bust matures, cutbacks in spending on heavy equipment further intensify the contraction. Maintenance scaled back.
Examples	Software, systems, and hardware (high rates of obsolescence) orders placed or reinstated first.	Heavy and complex equipment, warehouses, and factories. A company may need warehouse space in locations different from where existing facilities are.	Fiber-optic overinvestment in late 1990s that peaked with the "technology, media, telecoms bubble."	Technology and light equipment with short lead times get cut first. Cuts in construction and heavy equipment follow.

EXAMPLE 3

Capital Spending

1 Levels of capacity utilization are one of the factors that determine companies' aggregate need for additional capital expenditure. Which of the following is another factor that impacts the capital expenditure decision?

   A The rate of unemployment.

   B The composition of the economy's capacity in relation to how it can satisfy demand.

   C The ability to re-instate orders canceled during the contraction stage.

2 Orders for technology and light equipment decline before construction orders in a contraction because:

   A businesses are uncertain about cyclical directions.

   B they are easier to cancel than large construction contracts.

   C businesses value light equipment less than structures and heavy machinery.

Solution to 1:

B is correct. The composition of the current productive capacity may not be optimal of the current structure of demand. C is incorrect because the ability to re-instate canceled orders is a matter that is relevant once the decision to increase capital expenditure is made.

Solution to 2:

B is correct. Because it usually takes much longer time to plan and complete large construction projects than for equipment orders, construction projects may be less influenced by business cycles.

4.3 Fluctuations in Inventory Levels

The aggregate size of inventories is small relative to the size of the economy, but their accumulation and cutbacks by businesses can occur with substantial speed and frequency. Changing inventories reflect differences between the growth (or decline) in sales and the growth (or decline) in production. A key indicator in this area is the inventory–sales ratio that measures the inventories available for sale to the level of sales. Analysts pay attention to inventories to gauge the position of the economy in the cycle. Exhibit 9 shows how production, sales, and inventories typically move through the phases of a cycle.

Exhibit 9 Inventories throughout the Cycle

Phase of the Cycle	Recovery	Expansion	Slowdown	Contraction
Sales and production	Sales decline slows. Sales subsequently recover. Production upturn follows but lags behind sales growth. Over time, production approaches normal levels as excess inventories from the downturn are cleared.	Sales increase. Production rises fast to keep up with sales growth and to replenish inventories of finished products. This increases the demand for intermediate products. "Inventory rebuilding or restocking stage."	Sales slow faster than production; inventories increase. Economic slowdown leads to production cutbacks and order cancellations.	Businesses produce at rates below the sales volumes necessary to dispose of unwanted inventories.
Inventory–sales ratio	Begins to fall as sales recovery outpaces production.	Ratio stable.	Ratio increases. Signals weakening economy.	Ratio begins to fall back to normal.

EXAMPLE 4

Inventory Fluctuation

1 Although a small part of the overall economy, changes in inventories can influence economic growth measures significantly because they:

- **A** reflect general business sentiment.
- **B** tend to move forcefully up or down.
- **C** determine the availability of goods for sale.

2 Inventories tend to rise when:

- **A** inventory–sales ratios are low.
- **B** inventory–sales ratios are high.
- **C** economic activity begins to rebound.

3 Inventories will often fall early in a recovery because:

- **A** businesses need profit.
- **B** sales outstrip production.
- **C** businesses ramp up production because of increased economic activity.

Solution to 1:

B is correct. Inventory levels can fluctuate dramatically over the business cycle.

Solution to 2:

A is correct. When the economy starts to recover, sales of inventories can outpace production, which results in low inventory–sales ratios. Companies then need to accumulate more inventories to restore the ratio to normal level. C is incorrect because in the early stages of a recovery, inventories are likely to fall as sales increase faster than production.

Solution to 3:

B is correct. The companies are slow to increase production in the early recovery phase because they first want to confirm the recession is over. Increasing output also takes time after the downsizing during the recession.

5 CONSUMER BEHAVIOR

Households represent the largest single sector of most economies. As a result, patterns of household consumption determine overall economic direction more than any other sector. For this reason, the patterns of household consumption are important to a range of practitioners, not just to analysts focusing on companies serving consumers.

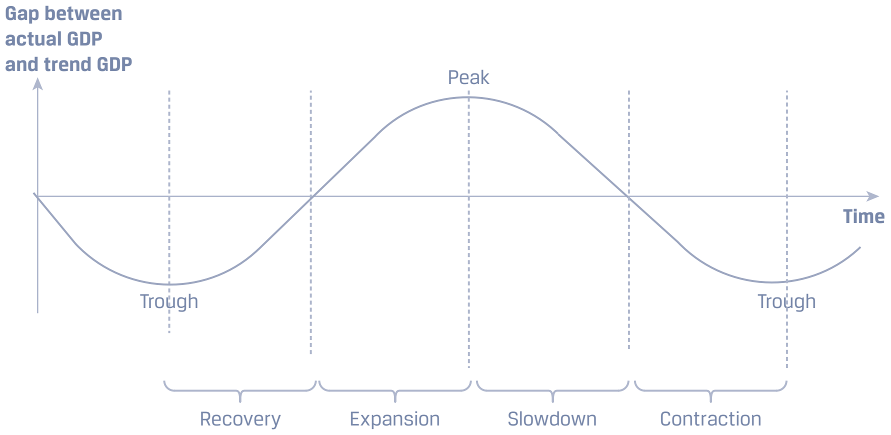
5.1 Consumer Confidence

Consumer confidence plays a significant role in spending decisions and reflects expectations of future incomes and employment prospects. Beyond direct observations of consumer spending and its mix, practitioners can also gauge future directions of spending by analyzing measures of consumer confidence or sentiment to ascertain how aggressive consumers may be in their spending. Usually, such information is in the form of surveys intended to provide practitioners with a general guide to trends.

5.2 Measures of Consumption

Two primary measures of household consumption are retail sales (physical as well as online) and broad-based indicators of consumer spending that also include purchases outside purely retail establishments, such as utilities and household services. Some additional measures make finer distinctions, such as tracking spending, both real and nominal, of a specific group of consumer products. Exhibit 10 shows how consumer spending changes through the economic cycle, and it splits consumer spending into three parts: (1) durable goods, (2) non-durable goods, and (3) services. Spending on durables is the most cyclical part, while spending on non-durables is the least cyclical. Spending on services, which include both more and less cyclical sub-components, in aggregate fits between the durable and non-durable goods categories. It is also worth noting that consumer spending, including that on durables, while cyclical, is less cyclical than investment spending by firms.

Exhibit 10 Consumer Behavior



Phase of the Cycle	Recovery	Expansion	Slowdown	Contraction
Incomes, employment, and confidence	Unemployment remains above average. Layoffs slow. Businesses rely on overtime before moving to hiring. Consumer confidence starts improving.	Hiring restarts. Unemployment rate stabilizes and starts falling. Consumers experience rising incomes, healthy employment prospects, and greater confidence.	Businesses continue hiring but at a slower pace. Unemployment rate continues to fall. Incomes are still growing. Consumers remain confident.	Businesses first cut hours of overtime prior to freezing hiring and starting layoffs. Employment levels decline, and consumer confidence weakens.
Spending on consumer durables (autos, motorcycles, appliances, furniture)	Spending limited as households postpone spending.	Spending increases.	Spending above average.	Purchases postponed; spending decreasing.
Consumer non-durables (i.e., medicines, food, household products)	Spending shows little change through the cycle.			
Services (entertainment, outdoor eating, communications, personal services)	Spending below average.	Spending increases.	Spending above average.	Spending declines.

Analysts often compare trends in durable purchases with those in the other categories to understand the economy's progress through the cycle. Because durable goods purchases usually replace items with longer useful lives, households usually postpone such purchases during economic downturns. Therefore, a weakness in durables spending may be an early indication of general economic weakness, and an increase in such spending may signal a more general cyclical recovery.

5.3 Income Growth

Growth in income is normally a good indicator of consumption prospects, and, albeit not as timely as consumer surveys, household income figures are widely available in most countries. Especially relevant is after-tax income, known as disposable income. Some analysts chart consumer spending based on a concept termed permanent income. Permanent income excludes temporary income (windfall or sudden, unexpected) and unsustainable losses and gains and tries to capture the income flow on which households believe they can rely. The basic level of consumption reflects this notion of permanent income. However, spending on durables tends to rise and fall with disposable income, regardless of the source, not just permanent income.

5.4 Saving Rates

Consumer spending patterns frequently diverge from trends in income, no matter how income is measured. An analysis of the saving rates can assist practitioners in this regard. Changes in saving rates can capture consumers' intent to reduce spending out of current income. The saving rate may also reflect future income uncertainties perceived by consumers (precautionary savings). Therefore, a higher saving rate may indicate consumers' ability to spend despite possible lower income in the future. A rise in the saving rate, usually measured as a percentage of income, may indicate caution among households and signal economic weakening. At the same time, the greater the stock of savings in the household sector and the wider the gap between ongoing income and spending, the greater the capacity for households to increase their spending. So, although unusually high savings may at first say something negative about the cyclical outlook, they point longer-term to the potential for recovery.

EXAMPLE 5

Consumer Behavior

1 Durable goods have the most pronounced cyclical behavior because:
  - **A** they have a longer useful life.
  - **B** their purchase cannot be delayed.
  - **C** they are needed more than non-durable goods or services.

2 Permanent income provides a better guide to:
  - **A** saving rates.
  - **B** spending on services.
  - **C** spending on durable goods.

Solution to 1:

A is correct. Durable goods are usually big ticket items, the life span of which can be extended with repairs and without incurring high replacement costs. So, consumers tend to delay replacement when the economic outlook is not favorable.

Solution to 2:

B is correct. Households adjust consumption of discretionary goods and services based on the perceived permanent income level rather than temporary earning fluctuations. Saving rates and durable goods consumption are more related to the short-term uncertainties caused by recessions.

6 HOUSING SECTOR BEHAVIOR

Housing sector activity includes new and existing home sales and residential construction activity. It is a small part of the overall economy compared to consumer spending, but because housing activity experiences dramatic swings, it often counts more in overall economic movements than the sector's relatively small size might suggest. In many countries, such as the United States and the United Kingdom, changing property values are closely related to consumer wealth and confidence.

6.1 Available Statistics

Many economies offer statistics on a range of housing activities, including the inventory of unsold homes on the market and average or median price of homes (sometimes recorded by type of housing unit and sometimes as the price per square foot or square meter). The relationships in this area typically follow fairly regular cyclical patterns.

6.2 Sensitivity to Interest Rates and Relationship to Credit Cycle

Because many home buyers finance their purchase with a loan (called mortgage in some countries), the sector is especially sensitive to interest rates. Home buying and consequently construction activity expand in response to lower loan interest rates and contract in response to higher loan interest rates.

Beyond such interest rate effects, housing also follows its own internal cycle, seen as part of the credit cycle. When housing prices are low relative to average incomes, and especially when mortgage rates are also low, the cost of owning a house falls and demand for housing increases. Often indicators of the cost of owning a house are available to compare household incomes with the cost of supporting an average house, both its price and the expense of a typical mortgage. Commonly, housing prices and mortgage rates rise disproportionately as expansionary cycles mature, bringing on an increase in relative housing costs even as household incomes rise. The resulting slowdown of house sales can lead to a cyclical downturn first in buying and then, as the inventory of unsold houses builds, in actual construction activity.

These links, clear as they are, are far from mechanical. If housing prices have risen rapidly in the recent past, for instance, many people will buy to gain exposure to the expected further price gains even as the purchase in other respects becomes harder to rationalize. Such behavior can extend the cycle upward and may later result in a more severe correction. This result occurs because "late buying" activity invites overbuilding. The large inventory of unsold homes eventually puts downward pressure on real estate prices, catching late buyers, who have stretched their resources. This pattern occurred in many countries during the 2008–2009 global financial crisis.

6.3 The Role of Demographics

Cyclical behavior in housing occurs around the long0run growth trend in housing determined by demographics, such as family and household formation. Where data on family formation are unavailable, analysts can gauge the rate of family formation by assessing the age structure of the population, as household formation commonly occurs in the 25–40-year-old age group. Adjusted for older people who are vacating existing homes, such calculations serve as an indicator of underlying, longer-term, secular housing demand.

6.4 Impact on the Economic Cycle

Although such measures have little to do with business cycles, they do offer a gauge, along with affordability, of how quickly the housing market can correct excess and return to growth. As some faster-growing developing economies experience urbanization (people moving from the countryside to cities), they witness fast growth in demand for housing units. Such housing demand may quickly reverse any cyclical weakness in the economy, more so than in such economies as Italy or Japan where net new family formation is relatively slight.

EXAMPLE 6

Housing Sector Behavior

1 Housing is more sensitive than other sectors of the economy to:
- **A** interest rates.
- **B** permanent income.
- **C** government spending.

2 Apart from questions of affordability, house buying is affected by:
- **A** the rate of family formation.
- **B** expectation of housing price increases.
- **C** both the rate of family formation and expectation of housing price increases.

Solution to 1:

A is correct. Because real estate purchases are usually financed with mortgage loans, interest rate changes directly influence the monthly payment amounts.

Solution to 2:

C is correct. Family formation constitutes the actual need for housing, whereas buying on the expectation of housing price increases reflects the fact that real estate has investment value.

7 EXTERNAL TRADE SECTOR BEHAVIOR

The external trade sector varies tremendously in size and importance from one economy to another. In such places as Singapore or smaller open economies, such as Lithuania, where almost all inputs are imported and the bulk of the economy's output finds its way to the export market, trade (the sum of both exports and imports) easily exceeds its GDP. External conditions, especially the stage of the cycle in key export regions and in primary trading partners, play a crucial role. In other places, such as Brazil or the United States, external trade assumes a much smaller part of GDP. Since the 1970s, global trade has risen substantially, so the business cycles of the large economies in the world can be more easily transmitted to other economies.

7.1 Cyclical Fluctuations of Imports and Exports

Typically, imports rise, all else equal, with the pace of domestic GDP growth because rising domestic demand increases purchases of goods and services, by consumers and business, from abroad. Thus, imports respond to the domestic cycle. Exports are more dependent on cycles in the rest of the world. If these external cycles are strong, all else equal, exports will grow even if the domestic economy should experience a decline in growth. To understand the impact of exports, financial analysts need to understand the strength of the major trading partners of the economy under consideration. The net effect of trade may offset cyclical weakness and, depending on the importance of exports to the economy, could erase it altogether. For these reasons, such differences can mean the pattern of external trade balances is entirely different from the rest of the domestic economic cycle. Exhibit 11 provides a short summary.

Exhibit 11 External Trade

Phase of the Cycle (domestic economy)	Recovery	Expansion	Slowdown	Contraction
Exports	Driven by external demand			
Imports (*assuming exchange rate remains unchanged)	Imports below average, start to increase.	Imports increase.	Imports peak and start to decline.	Imports in decline to below-average levels.

7.2 The Role of the Exchange Rate

The currency exchange rate also has an independent effect that can move trade in directions strikingly different from the domestic economic cycle. When a nation's currency appreciates (the currency gains in strength relative to other currencies), foreign goods seem cheaper than domestic goods to the domestic population, prompting, all else equal, a relative rise in imports. At the same time, such currency appreciation makes that nation's exports more expensive in global markets and may reduce exports. Of course, currency depreciation has the opposite effect. Although currency moves may be volatile and on occasion extreme, they have a significant effect on trade and the balance of payments only when they cumulate in a single direction for some time. Moves from one month or quarter to the next, however great, have a minimal effect until they persist. Thus, cumulative currency movements that take place over a period of years will have an impact on trade flows that will persist even if the currency subsequently moves in the opposite direction for a temporary period.

7.3 Overall Effect on Exports and Imports

Financial analysts need to consider a wide range of variables, both in the domestic economy and abroad, to assess relative GDP growth rates and then factor in currency considerations to ascertain whether they reinforce or counteract other cyclical forces. Generally, GDP growth differentials in global economic growth rates between countries have the most immediate and straightforward effects: Domestic changes in economic activity raise or reduce imports, and foreign economic activity changes raise or reduce exports. Currency moves have a more complex and, despite the interim short-term currency moves, a more gradual effect.

EXAMPLE 7

External Trade

1 Imports most clearly respond to:
   - A the level of exports.
   - B domestic industrial policy.
   - C domestic GDP growth rate.

2 Exports generally respond to the:

A government expenditure
B global GDP growth rates.
C domestic GDP growth rates.

Solution to 1:

C is correct. As a part of aggregate demand, imports reflect the domestic needs for foreign goods, which vary together with domestic economic growth.

Solution to 2:

B is correct. Exports reflect the foreign demands on domestic output, which depend on the conditions of the global economy.

EXAMPLE 8 INVESTMENT IMPLICATIONS

A junior portfolio manager is reviewing portfolio holdings. He focuses on three specific companies that he was tasked with reviewing. He has just received an analysis of the stage of the business cycle from a team of the firm's economists. To set the context of his analysis, he needs to understand the behavior of the three companies as they have exposures to different parts of the economy. One is focused on consumer goods (electronics and small vehicles) sold on the local market; one is focused on equipment sold to domestic companies; and one makes household and personal care consumer products, which it sells both domestically and abroad.

Which of the these three companies' financial performance fluctuates with the business cycle of their domestic economy the *most*?

A Consumer goods company
B Business equipment company
C Producer of household and personal care products

Solution:

B is correct. Business investment fluctuates more than consumer spending and exports. A and C are incorrect because although consumer goods companies are impacted by the cycle, they are impacted less than companies exposed to business investment.

8 THEORETICAL CONSIDERATIONS

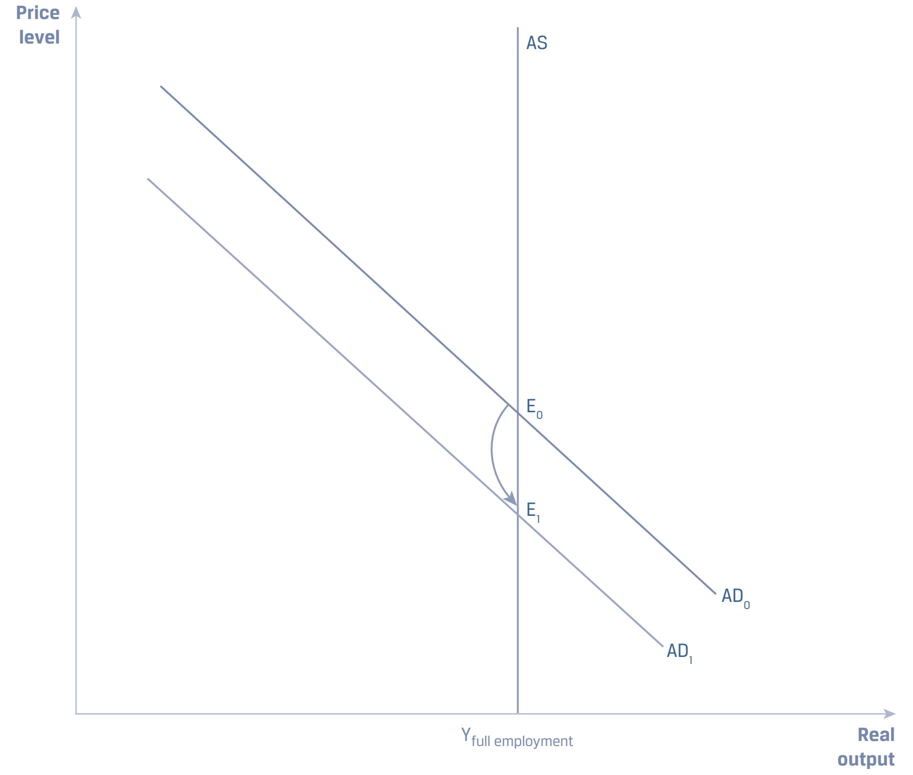
d describe theories of the business cycle

In this section we review the main theories that try to explain causes of business cycles and mechanisms through which the economy returns (or does not return) to the longer-term growth path.

8.1 Historical Context

Modern mainstream macroeconomists use the aggregate demand/aggregate supply (AD/AS) framework to synthesize the different schools of thought that have developed over the decades. In all of the key theories, movements in either of these curves create business cycles over time. Until the 1930s, the classical view has been that the aggregate supply curve is very steep (see Exhibit 12), prices and wages adjust quickly, and therefore recessions are mild and only short-lived. There was no need for government policy to intervene in the economy to try to smooth the business cycle as full employment level of output would be quickly restored. On the contrary, a policy of active demand management might, because of reaction lags that we will explore later, actually trigger business cycles rather than smooth them.

Exhibit 12 Classical Aggregate Supply Curve



The depth and severity of the Great Depression in the 1930s triggered the development of so-called Keynesian theories, in which fiscal policies play an important role in stabilizing the aggregate demand curve. Because prices and wages are seen as sticky and do not adjust, particularly on the way down (shown in Exhibit 13), the economy may experience a significant output gap without intervention.

Rising inflation in the late 1960s and the subsequent stagflation periods triggered by the oil price shocks in the 1970s were an incubator for another approach: monetarism. This school of thought highlights the importance of monetary policy and advocates stable money growth to keep the position of the aggregate demand curve stable, inflation under control, and reduce business cycle volatility.

Since the mid-1980s, we witnessed the emergence of micro-founded theories and the role of rational expectations that spurred the development of neoclassical (within which are Real Business Cycle, RBC, theorists) and new-Keynesian types of macroeconomic models to explain short-term fluctuations. Despite the “neo” and “new” in front of the classical and Keynesian theories, the fundamental differences remain the same: Classical-oriented economists have more faith in the working of the "invisible hand" (i.e., the proper functioning of markets), while Keynesian-oriented economists see rigidities and market failures as more prevalent and the government in a position to actively intervene.

We will now explain the two broad groups of theories through this "non-intervention" vs "intervention" lens and describe each in terms of a) the role of demand and supply shocks; b) the completeness of markets and thereby the stickiness of prices; c) the importance of asymmetric information problems; and d) the role of policy lags.

8.2 Neoclassical Economics

Neoclassical economists, but in particular the so-called Real Business Cycle (RBC) advocates, stress the importance of movements in the supply curve. Technological progress, natural disasters, changes in relative prices of key inputs, other supply-side constraints, or changes in firm expectations lead to changes in the position of the supply curve. RBC models of the business cycle conclude that expansions and contractions represent efficient operation of the economy in response to external real shocks; the level of economic activity at any time is consistent with maximizing expected utility. For that reason, the policy recommendation of RBC theorists, and neoclassical economists in general, is for governments *not* to intervene in the economy with discretionary fiscal and monetary policy. This is stressed even further by arguing that monetary and fiscal policy will affect the economy with substantial delay, referred to as "lags": There is a lag between when policy makers realize what is happening with the economy and when they develop a plan and implement it. Finally, it takes time for policy to actually have an impact on the economy. It is possible that any policy action will impact the economy too late, and instead of bringing output closer to the long-term path, it may amplify the next cycle.

In a more mainstream context, reducing economic volatility is translated into stressing the importance of expectation and information management. Removing asymmetric information problems should speed up price adjustments. If all participants in a market are well informed, market forces can work efficiently. Information problems, however, create inefficiencies. If a firm cannot distinguish between an increase in the relative price of the good it is offering and general inflation, it might make inefficient production decisions. If the price increase in the market arises due to an increase in demand, then the firm should increase production. However, if price increases merely reflect general inflation, the firm should not increase production. Removing such information problems reduces economic volatility. Similarly, fostering agents in the economy to form precise and well-anchored expectations about inflation, for example, can lead to self-fulfilling outcomes and stabilize the position of the supply curve.

Neoclassical economists would also argue that policies should not prevent Schumpeterian "creative destruction" from taking place. The term "creative destruction" describes the disruptive process of transformation that accompanies innovation, originally described by Joseph Schumpeter in the 1950s. When an inventor presents a new product or a new, better way to produce an existing good or service (e.g., radio frequency identification tracking of inventories), then the entrepreneur that introduces the new discovery will likely have bigger profits and may drive the existing producers out of business. Therefore, innovations can generate movements in the aggregate supply curve that policy makers should not try to correct.

8.3 The Austrian School

The so-called Austrian school, another "non-intervention" theory, shares many views of the neoclassical economists. In contrast to the neoclassical school, however, it focuses on the role of money, which they believe does more than facilitate the exchange of goods and services. Austrian economists argue that low interest rates and excessive credit growth during boom times result in over-investment in projects with low returns, causing failure and a move into recession. They argue that following a period of overinvestment, companies will realize that they have overinvested, resulting in a sudden drop in investment with a negative shock for aggregate demand. Because the Austrian school sees business cycles arising from government (and central bank) policies as the cause of overinvestment and subsequent failure, they suggest that policy makers should rarely intervene in the economy.

These classical views stress that markets are in general flexible and prices will easily adjust to changing situations. This makes the aggregate supply curve very steep, even in the short run (see Exhibit 12). Policy should be designed to allow markets to function and prices to adjust with flexibility.

8.4 Monetarism

For monetarists, other than maintaining steady growth of the money supply, government should play only a very limited role in the economy. They reject active management of aggregate demand. Fiscal and monetary policy should be clear and consistent over time so all economic agents can forecast government actions. In this way, the uncertainty of economic fluctuations would not be increased by any uncertainty about the timing and magnitude of economic policies and their lagged effects.

According to the monetarist school, business cycles may occur both because of exogenous shocks and because of government intervention. So, it is better to let aggregate demand and supply find their own equilibrium than to risk causing further economic fluctuations. In contrast to neoclassical economists, a key part of monetarist thought is that the money supply needs to continue to grow at a moderate rate. If it falls, as occurred in the 1930s, the economic downturn could be severe; whereas if money grows too fast, inflation will follow.

Monetarists also see business cycles largely stemming from movements in the aggregate demand curve. But their conclusions differ from Keynesian interventionism, which they reject, for three main reasons:

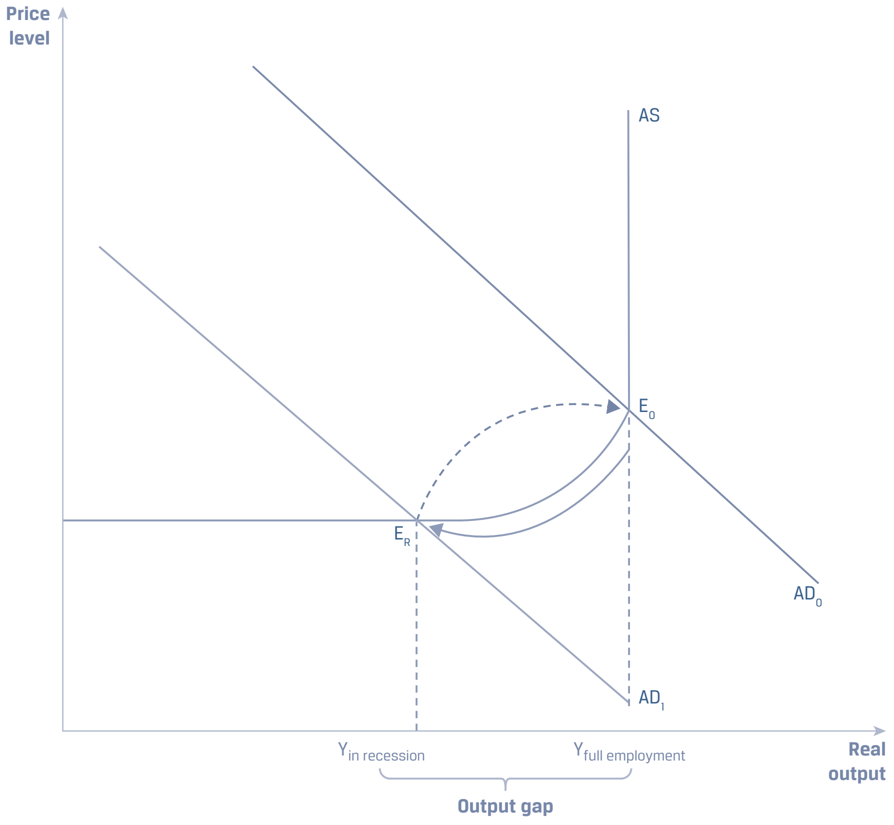
1. Unlike the monetarist model, the Keynesian model does not recognize the supreme importance of the money supply. If the money supply grows too fast, there will be an unsustainable boom, and if it grows too slowly, there will be a recession.
2. Monetarists consider the long-term costs of government intervention (e.g., growing government debt and a high cost of interest on this debt).
3. The timing of a government's economic policy responses is uncertain, and the stimulative effects of a fiscal expansion may take effect after the crisis was over, thus causing more harm than good.

8.5 Keynesianism

Keynesians see an active role for the government in managing aggregate demand. Keynesian-oriented theories give limited importance to the supply curve. Instead of thinking about it as being rather steep, these theories see prices being sticky in the short run, leading to a relatively flat AS curve (see the horizontal section of the AS curve in Exhibit 13). It is argued that nominal wages, as one of the most important prices in the economy, are generally rigid and not downward flexible; workers do not want to see their nominal compensation decrease. Movements in the AD curve, therefore, have large consequences on the overall output of the economy.

But even if workers agreed to accept lower salaries in times of recession, this situation might exacerbate the crisis. Lower wage expectations would hurt confidence, and workers would cut back on their spending—reducing aggregate demand, causing further weakening of confidence, and leading to contractions in demand for goods and services. These contractions would start with the more expensive items, such as durable goods, and move in a "domino effect" through the economy (the downward spiral of the aggregate demand curve continuously shifting left). Exhibit 13 shows how a decrease in aggregate demand (from AD_0 to AD_1) may result in an output gap and an equilibrium in recession (ER) from which it may take a long time to recover and restore full employment levels of output (at equilibrium E_0).

Exhibit 13 Keynesian AS/AD Framework



Furthermore, there could be circumstances in which lower interest rates would not reignite growth because business confidence or "animal spirit" (consumer's lack of confidence) was too low. Therefore, Keynesian economists advocate government intervention in the form of fiscal policy. While Keynes accepted the possibility that markets would reach the equilibrium envisioned by neoclassical economists over the long run, he famously quipped that "in the long run, we are all dead"—that is, the human suffering is excessive while waiting for all shocks to be absorbed and for the economy to return to equilibrium.

In Keynesians' opinion, when crises occur, the government should intervene to keep capital and labor employed by deliberately running a larger fiscal deficit. This intervention would limit the damage caused by major recessions. Although this concept continues to be a highly politically charged debate, many economists agree that government expenditure can limit the negative effect of major economic crises in the short term. The practical criticisms that are often expressed about Keynesian fiscal policy are:

1. Fiscal deficits mean higher government debt that needs to be serviced and repaid eventually.
2. Keynesian cyclical policies are focused on the short term. In the long run, the economy may come back and the presence of the expansionary policy may cause it to "overheat"—that is, to have unsustainably fast economic growth, which causes inflation and other problems. This result is because of the typical lags involved in expansionary policy taking effect on the economy.
